Wilmington, NC 28401

EXECUTIVE SUMMARY

This Environmental Assessment presents an evaluation of potential environmental, cultural, and anthropogenic effects associated with Carteret County's Post-Irene Renourishment Project (Project). The Project potentially includes sand placement in three discrete locations of Carteret County's Bogue Banks shoreline: (1) western Emerald Isle (EI) between transects 9 - 16; (2) eastern EI between survey transects 35 - 46; and (3) Pine Knoll Shores (PKS) between survey transects 61 - 70. The borrow source would be previously dredged sand from an operational Ocean Dredged Material Disposal Site (ODMDS) located on the Outer Continental Shelf (OCS) approximately three miles (mi) south of Beaufort Inlet, North Carolina (NC). The ODMDS is a functioning element of NC's federal deep-draft navigation project at the Port of Morehead City. Carteret County, as represented by the County's Shore Protection Office (SPO), proposes entering into a negotiated non-competitive lease agreement with the Bureau of Ocean Energy Management (BOEM) authorizing a maximum reclamation of up to one million cubic yards (cy) of previously dredged sand. The sand would be extracted by hopper dredge, transported, and placed via pipeline along approximately 7.1 mi of "Irene" affected oceanfront shoreline.

Following Hurricane Irene, the Federal Emergency Management Agency (FEMA) evaluated and confirmed sand losses as documented by Carteret County's monitoring and maintenance plan for their locally engineered beaches. The eligible sand volumes determined through the Bogue Banks Beach and Nearshore Mapping Program (BBBNMP) totals 1,344,123 cy. The sand volume estimated for this Project totals up to 1,000,000 cy (992,000 cy); including a base volume eligible for FEMA reimbursement in addition to supplemental sand desired by EI, PKS, and the County. The total proposed volume is based on federal, state, and local economic viability while facilitating FEMA participation. The recipient beaches and the ODMDS have been included in previous post storm renourishment events without significant natural or anthropogenic effects. Agency consultation has been initiated by BOEM and the United States Army Corps of Engineers South Atlantic Wilmington District with the National Marine Fisheries Service and the United States Fish and Wildlife Service. This Post-Irene EA has found that no significant long-term environmental effects are anticipated from implementing the Proposed Action Alternative, i.e., using OCS resources from the ODMDS, located approximately three mi offshore of Beaufort Inlet, NC. With implementation of the Proposed Avoidance and Minimization Measures (Section 8), the potential effects of the ODMDS dredging reclamation and beach placement would be localized and temporary.

1.0 INTRODUCTION

Hurricane Irene made landfall at Cape Lookout, North Carolina (NC) on 27 August 2011, approximately nine miles (mi) east of Bogue Banks (Figure 1). One of the storm's major impacts was oceanfront beach erosion within Carteret County's engineered beaches of Pine Knoll Shores (PKS), Indian Beach/Salter Path, and Emerald Isle (EI) (Figure 2). Incipient and primary dunes and other subaerial and subaqueous environments sustained erosion through the -12-foot (ft) North American Vertical Datum (NAVD) contour. The volumetric sand losses within the engineered beaches were quantified through the Bogue Banks Beach and Nearshore Mapping Program (BBBNMP) and confirmed by the Federal Emergency Management Agency (FEMA) following the federal government's declaration of Hurricane Irene as a federal disaster in Carteret County.

Renourishment triggers established for the publicly engineered beaches include: (1) sand losses of 50% or greater of initial construction volumes placed or (2) if average sand volumes from the top of dune to -12 ft NAVD88 fall below 225 cubic yards (cy)/ft (typical cross-sections are provided in Section 4.2). Criterion (1) was used by FEMA to assess Post-Irene sand volume losses. To fully utilize FEMA's settlement, the State, County, EI, and PKS are proposing to place up to one million (M) cy (992,000 cy) of the 1.34 M cy eligible for FEMA reimbursement. FEMA's participation covers a dredge plant's mobilization and demobilization (estimated at $4,000,000) plus approximately 300,000 cy of beach renourishment. In an effort to fully maximize FEMA's participation, the State; County; and local municipalities are supplementing volumes as local budgets allow. Maximum potential replacement volumes are delineated in Table 1.

Similar post hurricane FEMA renourishment projects have been implemented along reaches of EI and PKS. Hurricane Isabel occurred in 2003 with renourishment in 2004 and Hurricane Ophelia occurred in 2005 with renourishment in 2007. The County would target Post-Irene renourishment efforts to occur during the 2012 - 2013 winter dredging window.

Carteret County's Shore Protection Office (SPO) previously managed the development of the NEPA compliant *Environmental Impact Statement (EIS), Bogue Banks Restoration – Phase I and Phase II* [Coastal Science & Engineering (CSE) 2001 (Appendix A); CSE 2002 (Appendix B)]. Phases I and II of this project covered beach restoration projects along portions of EI and PKS. The United States Army Corps of Engineers (USACE) South Atlantic Wilmington District (SAW) prepared: (1) *Evaluation Report and Environmental Assessment/Finding of No Significant Impact for Morehead City Harbor Section 933 Carteret County, North Carolina,* (*August 2003*) (USACE 2003; Appendix C). The 2003 document addresses a two phase effort (2004 and 2007) by the USACE and SPO to beneficially use active maintenance and upland stockpiled dredge material for shoreline renourishment purposes. These shoreline protection actions took place within and adjacent to the proposed Project areas. In conjunction with the above efforts and as a result of shoreline losses from previously named storm events, Isabel and Ophelia, NEPA compliant documents were prepared supporting permits placing additional Ocean Dredged Material Disposal Site (ODMDS) material within and adjacent to the proposed Project areas (2004 and 2007). Subsequent to the EIS and the two USACE Environmental Assessments (EA), the SPO was issued sand placement authorizations in 2004 and 2007 for the FEMA Post-Isabel

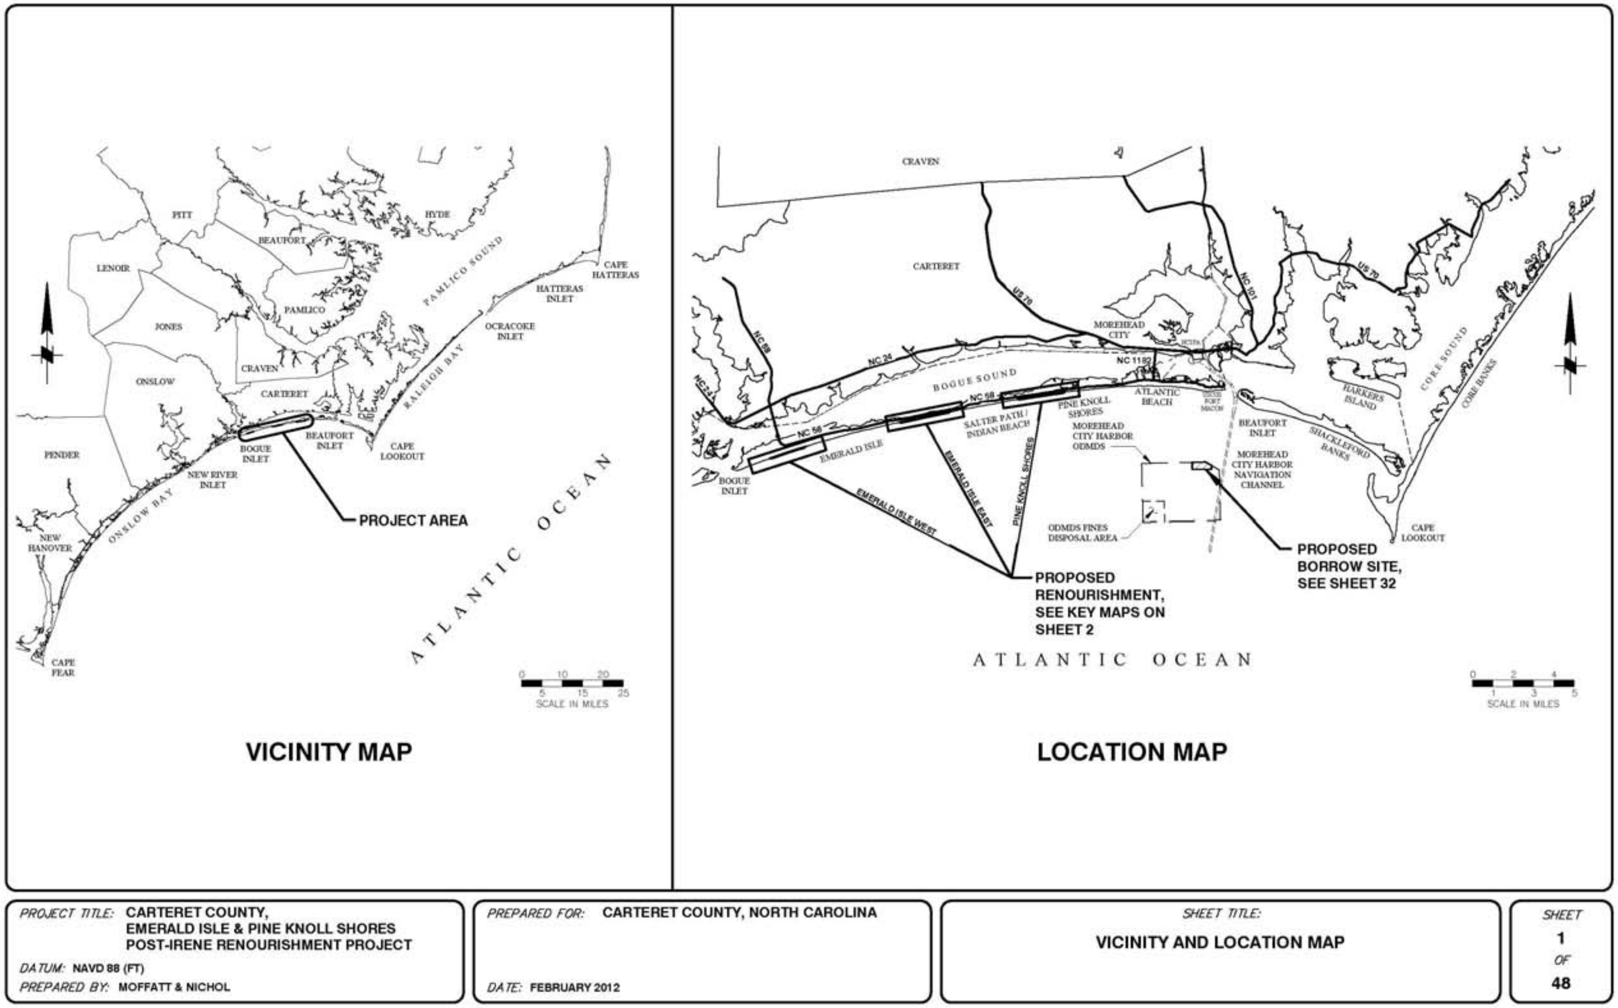

Figure 1. Vicinity and Location Map

Table 1. Maximum potential replacement volumes.

	Transect Survey Stations	FEMA (cy)	County (cy)	Municipality (cy)	Total (cy)
Emerald Isle	9-16, 35-46	157,000	259,000	259,000	675,000
PKS	61-70	113,000	102,000	102,000	317,000
Totals		**270,000**	**361,000**	**361,000**	**992,000**

Restoration and FEMA Post-Ophelia Restoration, respectively (USACE 2004a, 2007; Appendices D and E). These post-storm authorizations allowed the SPO to utilize ODMDS sands for beach renourishment within and adjacent to the proposed Project areas. Figure 3 and Table 2 describe past projects resulting in supplemental shoreline placements along all of Bogue Banks for the last 30 years.

This EA will assist the Bureau of Ocean Energy Management (BOEM) in determining if the Proposed Action Alternative would significantly affect the environmental, cultural, or anthropogenic resources within the proposed Project area (Figure 1). This EA incorporates by reference existing analyses and provides supplemental analysis of potential environmental effects resulting from the Proposed Project Alternative.

This EA is supplemented by:

- Essential Fish Habitat Assessment (EFH) compliant with the Magnuson-Stevens Fishery Conservation and Management Act (MSFCMA);
- Biological Assessment (BA) meeting specifications of the Endangered Species Act (ESA);
- concurrence from the NC State Historic Preservation Office (SHPO);
- NC Division of Coastal Management (NCDCM) Major Permit;
- NC Division of Water Quality (NCDWQ) 401 Water Quality Certification; and a
- Clean Water Act Section 404 authorization via General Permit 291 (Personal communication, David L. Timpy, USACE SAW, February 6, 2012).

This project meets BOEM's project criteria for accessing Outer Continental Shelf (OCS) sand resources because of local government sponsorship, local funding, and public accessibility. BOEM's negotiated non-competitive lease agreement would allow reclamation, transport, and placement of beach compatible sand along the recipient project shorelines.

1.1 Authorization

Public Law 103-426 enacted 31 October 1994 gave BOEM the authority to convey, on a noncompetitive basis, the rights to OCS sand, gravel, or shell resources for shore protection; beach or wetlands restoration projects; or for use in construction projects funded in whole or part or authorized by the federal government. In implementing this authority, BOEM may issue a negotiated non-competitive lease agreement for the use of OCS sand to a qualifying entity.

[1] Authors include USACE, CSE, and Coastal Planning & Engineering (CPE).
[2] Documentation includes EA/Finding of No Significant Impact (FONSI), EISs, and Dredged Material Management Plans (DMMP).

NEPA and Title 40 of the Code of Federal Regulations (CFR), Parts 1500-1508 (40 CFR 1500-1508) require federal agencies to consider the potential environmental consequences of proposed actions and alternatives. Executive Order (EO) 11514, Protection and Enhancement of Environmental Quality (amended by EO 11991), provides a policy directing the federal government to take leadership in protecting and enhancing the environment.

BOEM and the USACE are cooperating agencies having jurisdiction over different project facets and locations. OCS resources (beyond three mi) fall under BOEM's jurisdiction, as found in the OCS Land Act. Beach nourishment permitting is a federal action requiring review through the Rivers and Harbors Act Section 10 and the Clean Water Act Section 404. These federal permitting actions, including BOEM issuance of a negotiated non-competitive lease for OCS sand use and the USACE's Section 404 authorization, trigger the preparation of this EA. This EA will be used by BOEM and the USACE for evaluation of potential project effects, guidance in developing a permit decision, and consideration of a negotiated non-competitive lease agreement.

2.0 PROJECT HISTORY

The project area beaches have received supplemental sand under three previous renourishment projects as well as previous post-hurricane events. As listed in Tables 3 and 4, over 8M cy of material have been placed on EI and PKS since 1984.

The target reaches were first nourished in 2002 - 2005 during Phases I, II, and III of the BBBRP, which placed approximately 4.3 M cy of sand on an approximate 16.7 mi section of EI, Indian Beach, and PKS. Sand sources for the BBBRP included two nearshore ocean borrow sites off EI and Indian Beach; and sand beneficially used from the realignment of Bogue Inlet. The project area beaches received additional sand in 2004 during the Post-Isabel Sand Replacement Project, which placed 156,000 cy of sand from the ODMDS within EI. Project area beaches were last renourished in 2007 during the Post-Ophelia Sand Replacement Project, which placed approximately 1M cy sand from the ODMDS on approximately 10.4 mi of beach. Two Section 933 projects were also completed (2004 & 2007) along the recipient beaches and the adjacent reach of Indian Beach/Salter Path with total nourishment volumes approaching 0.7M cy and 0.5M cy, respectively. The Carteret County SPO is currently developing a Master Beach Nourishment Plan (MBNP) and Programmatic Environmental Impact Statement (PEIS) that will provide for long-term maintenance of the entire Bogue Banks.

Existing information for the proposed project reaches is contained within the NCDCM Major Permit #124-01 and USACE Permit #200000362 (Appendices D and E). These permits outline the original formulation and data sources for the Bogue Banks renourishment projects (Phases 1 and 2 accomplished between December 2001 and April 2003) and previous FEMA projects. Since the last 2007 FEMA placement, the project area has continued to lose sand at an accelerated pace and the protection trigger of 225 cy/ft above -12' NAVD may be reached within the next year or two without the proposed project. A recent beach survey in 2010 indicated that the profile volume above -12 feet NAVD along portions of the target beaches had fallen to 48 percent of the baseline volume. The Post-Irene survey has shown that some portions of these reaches are now down to 35 percent of the original engineered volumes (Moffatt and Nichol 2010). Given the overall health of the beach along Bogue Banks, the project team anticipates this could be the last individual project required until the Bogue Banks MBNP is implemented (barring another major storm event).

3.0 PURPOSE AND NEED

The Project's purpose is to restore sand volumes and elevations providing future storm protection and reducing future potential storm damage to the subaerial beach, protective berm, adjacent infrastructure, and coastal structures along the approximate seven miles of Project shoreline. Since the last shore protection effort in 2007 and with the recent sand volume losses resulting from Hurricane Irene; erosion has been exacerbated, detrimentally affecting the shorelines of EI and PKS.

The SPO's proposed Project would provide:

- existing public and private infrastructure improved storm protection,
- minimization of potential structural storm damage,
- improved continued public access and use,
- further support of NC and Bogue Banks' tourism industry, and
- restoration of pre-storm shoreline sand volumes for continued natural resource usage.

While providing the above, the proposed Project would retain compliance with FEMA's criteria for publicly engineered and managed beaches and fulfill NC's static line exception stipulations. The static vegetation line is defined by the NCDCM in Section .0300 - Ocean Hazard Areas 15A NCAC 7H .0305: A static vegetation line shall be established in coordination with the NCDCM using on-ground observation and survey or aerial imagery for all areas of oceanfront that undergo a large-scale beach fill project. Once a static vegetation line is established, and after the onset of project construction, this line shall be used as the reference point for measuring oceanfront setbacks in all locations where it is landward of the vegetation line.

The purpose of this BOEM proposed action is to respond to an OCS sand use request under the authority granted to the United States Department of the Interior (USDOI) by the Outer Continental Shelf Lands Act (OCSLA). The proposed action is necessary because the Secretary of the Interior delegates the authority granted in the OCSLA to BOEM for authorizing the use of OCS sand resources for the purpose of shore protection and beach restoration.

The proposed project is located in an area affected by Hurricane Irene with higher erosion losses compared to adjacent shorelines. The sand volumes per linear foot are quickly approaching the minimum volume historically targeted by the SPO as a nominally accepted healthy shoreline (225 cy/ft). FEMA representatives agreed that, based on a site visit on 8 November 2011, some portions of the project areas have experienced sand volume losses beyond the 50% locally placed for managing an engineered beach. Initially, efforts were made to coordinate beneficial use of USACE dredged material removed during annual maintenance (2012) from the Port of Morehead City's federal deep-draft navigation project. This proposed option was unavailable to the USACE as the SPO's proposed project area is beyond the USACE's authorized disposal area. The USACE validated the decision based upon the fact that the Proposed Action Alternative was beyond the area of inlet influence; thereby removing the material from the coastal system as affected by the USACE's channel maintenance efforts. As indicated above, the SPO is also managing the development of a MBNP encompassing the entirety of Bogue Banks (approximately 26 mi). The MBNP's tasks and ensuing schedules plus resulting effects of Hurricane Irene resulted in a timeline risk potentially jeopardizing the Project's immediate needs; a risk that Carteret County, the SPO, and the Towns of EI and PKS are uncomfortable taking. As such, the SPO is initiating the proposed Project as a response to Hurricane Irene and as an interim step toward the MBNP. The proposed Project will expedite a course of action addressing the Project area's imminent needs and leveraging FEMA participation towards maximizing proposed sand volumes.

4.0 ALTERNATIVE EVALUATION

4.1 Alternative to the Proposed Action (No Action)

The following was considered as an alternative to the proposed action: Do Not Authorize Use of OCS Sands. Under this alternative, BOEM would not authorize a negotiated non-competitive lease agreement for use of OCS material. Project proponents, the SPO, and the Towns of EI and PKS, could either:

Option (a) Re-evaluate the project, choosing another alternative borrow location or offshore sand source to restore the three reaches, or
Option (b) Locate onshore sources of comparable sand quantity and quality.

Option (a) would not minimize overall environmental effects because of the imminent need to protect the shorelines associated with the Project by either constructing new or augmenting existing protection mechanisms for the beaches. Carteret County has previously considered a range of non-structural alternatives to beach fill (USACE 2004a). Beach fill using an offshore borrow area was chosen as the preferred alternative. In addition, the ODMDS borrow material includes highly compatible sand based on recent investigations (Alpine 2012). Option (b) is not considered to be viable, as upland sources of needed quality and quantity are limited in the Project vicinity.

The No Action alternative would not meet the Project's purpose and need and; therefore, was not carried forward for further evaluation.

4.2 Borrow from the ODMDS (Proposed Action)

The Carteret County SPO proposes to renourish approximately 7.1 mi of oceanfront shoreline (within the Towns of EI and PKS) that was affected by Hurricane Irene (Figure 2). As determined through the BBBNMP, 1,344,123 cy of sand were eroded from the top of the dune out to -12 ft NAVD and were considered eligible for FEMA reimbursement as the engineered beach volume losses. The sand volume estimated for this proposed Project totals up to approximately 1,000,000 cy (992,000 cy); including a base volume approved by FEMA for reimbursement; in addition to supplemental sand volumes desired by the Towns of EI, PKS, and the County. The total proposed volume is based on federal, state, and local economic viability while facilitating FEMA participation. Based on previous post-storm renourishment events involving the recipient beaches and ODMDS, the fill material would consist of beach-quality sand. The material to be dredged from the ODMDS was confirmed by recent sediment analyses (Figures 4 and 5) (Appendix F). Specific sediment characteristics are discussed in further detail in Section 4.2.

The Morehead City ODMDS is a United States Environmental Protection Agency (USEPA) designated ocean dredged material disposal site. The site is utilized by the USACE as a disposal area for material dredged during maintenance of the Morehead City Harbor navigation channels. Disposal is limited to dredged materials that have been evaluated and approved in accordance with USEPA Ocean Dumping Regulations and Criteria. The ODMDS occupies an area of approximately eight square nautical miles (nm) offshore of eastern Bogue Banks. The

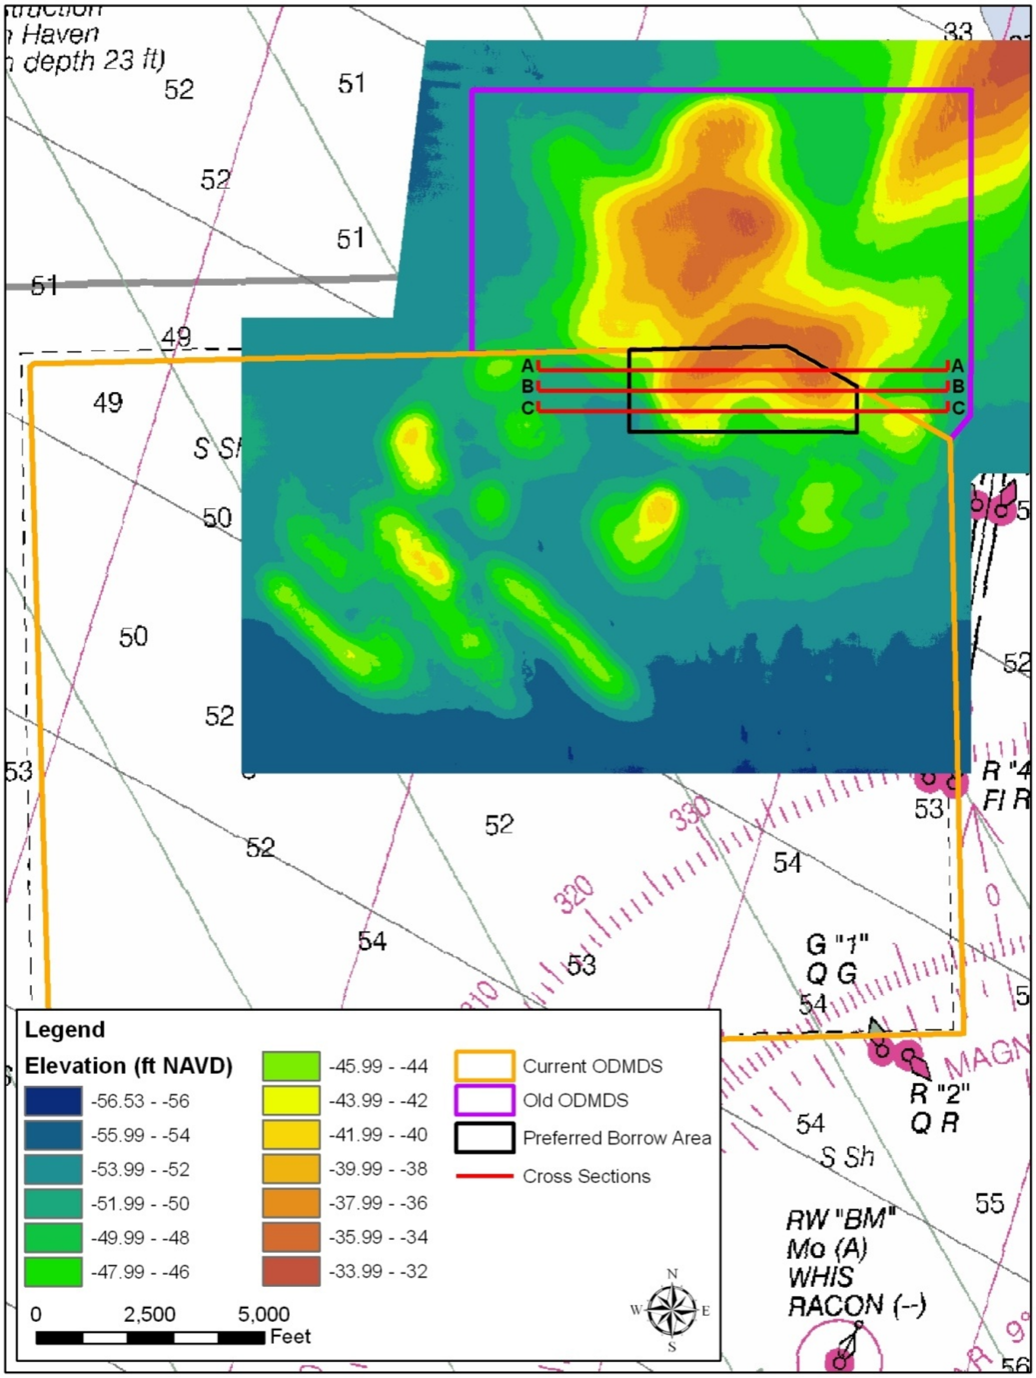

Figure 4. Borrow Area Site Plan

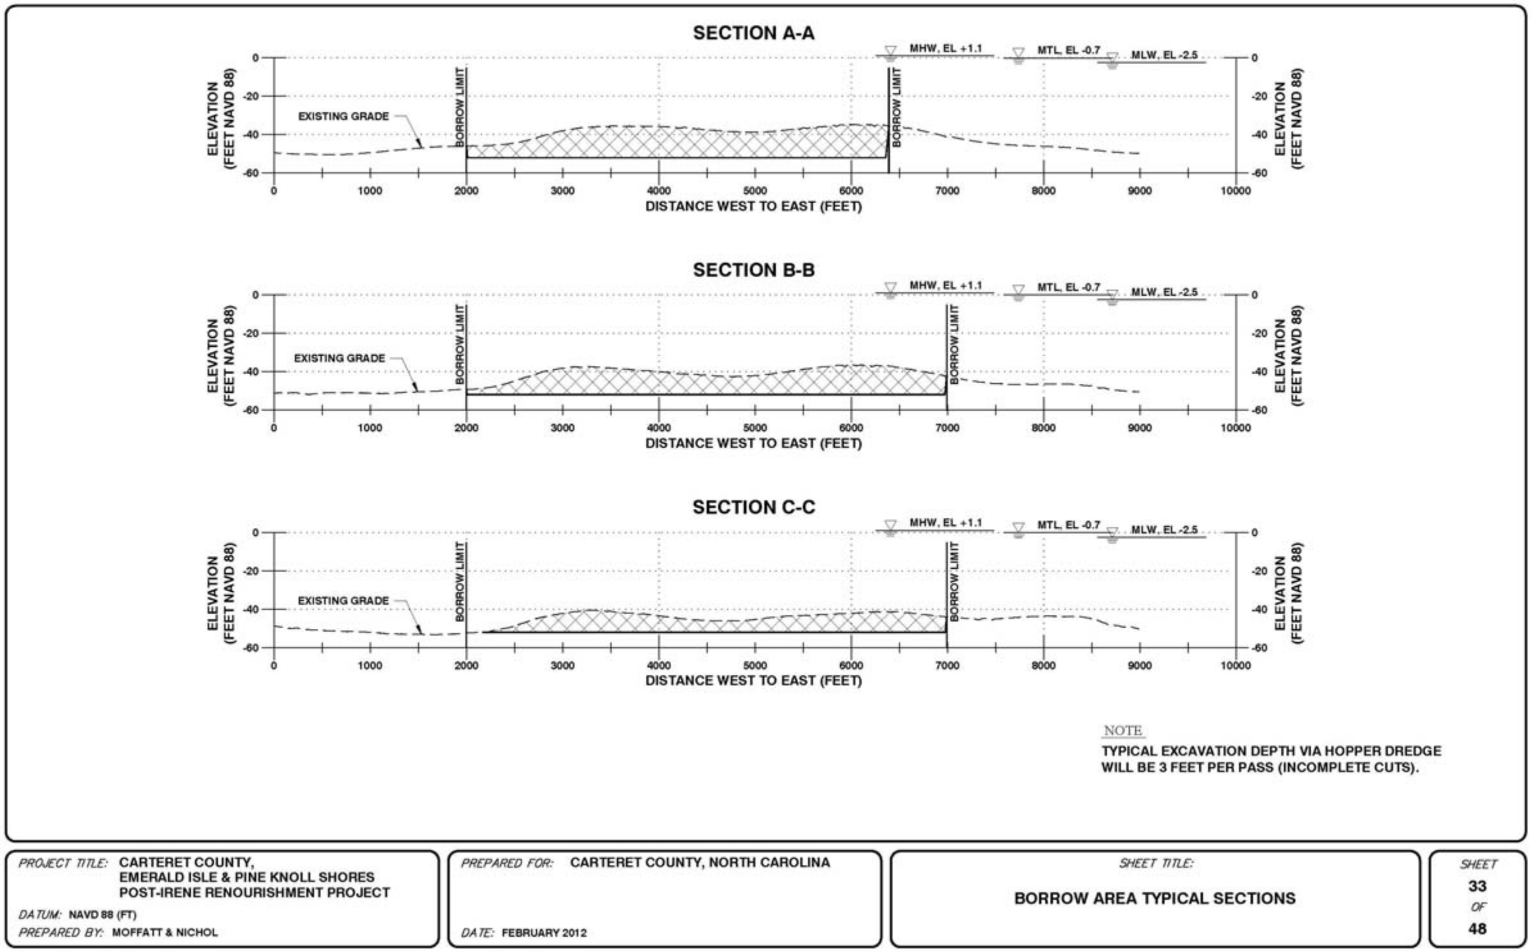

Figure 5. Borrow Area Typical Sections

inner boundary of the ODMDS is just over three nm from shore, and the outer boundary is approximately 11 nm from shore. Depths range from approximately -31 to -55 ft mean low water (MLW). Sand from the ODMDS has been used during previous renourishment projects on Bogue Banks, including the 2004 Post-Isabel and the 2007 Post-Ophelia sand replenishment projects that placed sand on or adjacent to the proposed Project beaches.

The proposed Project includes sand placement of up to 1M cy along 7.1 mi in three discrete oceanfront shoreline locations of Bogue Banks shoreline: (1) western EI between survey transects 9-16 (approximately 265,000 cy along 2 mi); (2) eastern EI between survey transects 35-46 (approximately 410,000 cy along 2.6 mi); and (3) PKS between survey transects 61-70 (approximately 317,000 cy along 2.5 mi) (Figure 2, 6 – 11). The western boundary of the Project is approximately two miles east of Bogue Inlet, and the eastern boundary of the Project is approximately eight miles west of Beaufort Inlet (Figure 1).

4.2.1 Methods of Construction

The proposed Project would involve use of a hopper dredge to excavate sand from the ODMDS. Hopper dredges are self-propelled vessels that employ a trailing suction draghead to remove sediment from the seafloor. The draghead is equipped with various types of steel cutting teeth or blades and/or high pressure water nozzles that dislodge thin layers (approximately two to five feet deep) of sediment from the seafloor. A mixture of loose sediment and water is pumped through a suction pipe into a hopper onboard the dredge. Sediment settles in the hopper and excess water is discharged via an overflow system (i.e., scuppers). Once fully loaded, the hopper dredge would travel from the ODMDS to a nearshore pump-out station along the target beach. As specifically described by Hales (1995) the proposed methodology includes removing dredged material from the hopper dredge, where the dredge moors to an anchored floating structure, buoy, or multiple buoy berths. An underwater pipeline, situated in approximately 30 ft of water, then extends from the buoy to shore. A hose is connected from the buoy to the hopper-dredge discharge manifold. The dredge then mixes the dredged material with water to form a slurry and pumps the slurry from its discharge manifold through the floating hose to the anchored floating buoy and on through the underwater pipeline toward shore where it would be pumped onto the recipient beach (Hales 1995). The dredge would then return to the ODMDS and the cycle of dredging and discharging would be repeated. Equipment refueling would occur as needed at the Port of Morehead City. The position of the nearshore pump-out station and discharge pipeline would shift incrementally as construction progresses along the beach. Potential effects as they related to construction methodology are described in Section 6.0.

Placement and grading activities on the beach would involve the use of bulldozers to redistribute and grade the beach fill material to the proposed beach profile. Bulldozers would access the beach via existing public access points. Bulldozer operations would be restricted to areas seaward of the existing dune toe. Dunes and vegetation would be avoided and protected during construction. Dredging and grading would occur around the clock, thus requiring nighttime lighting on the beach and onboard the dredge. All construction activities would take place within the 16 November through 31 March hopper dredging environmental window. Based on previous renourishment projects, the project team expects the dredge will excavate and discharge 10,000 to 15,000 cy of sediment per 24-hour period. Sand placement and grading will progress along the beach at a rate of 400 to 700 linear ft per 24-

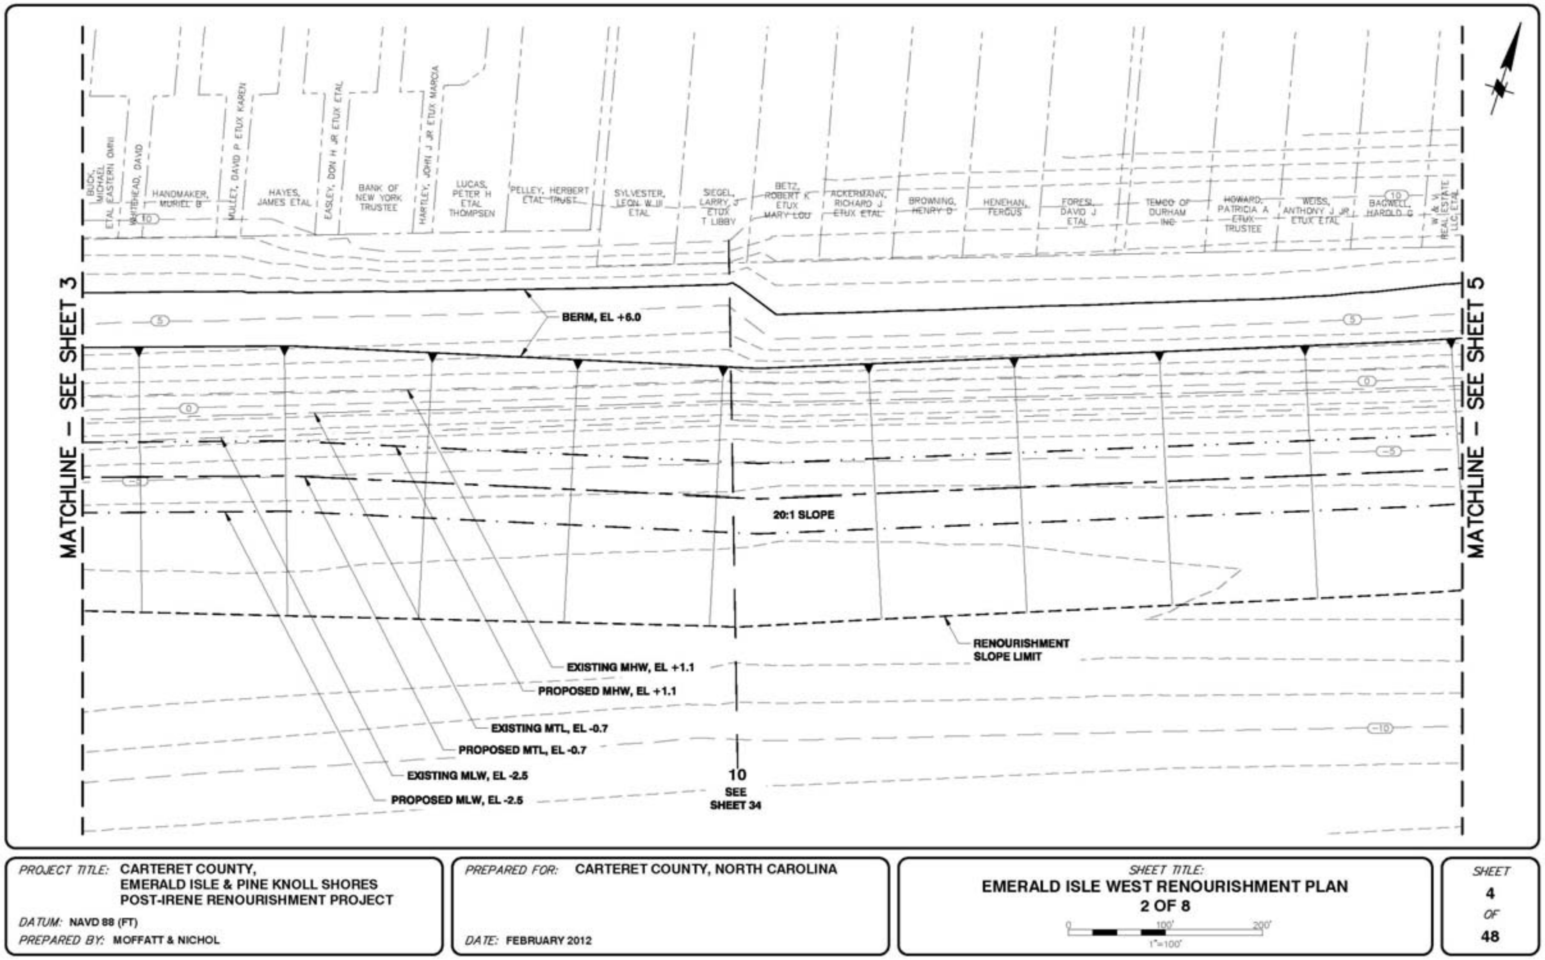

Figure 6. Emerald Isle West Renourishment Plan (Typical)

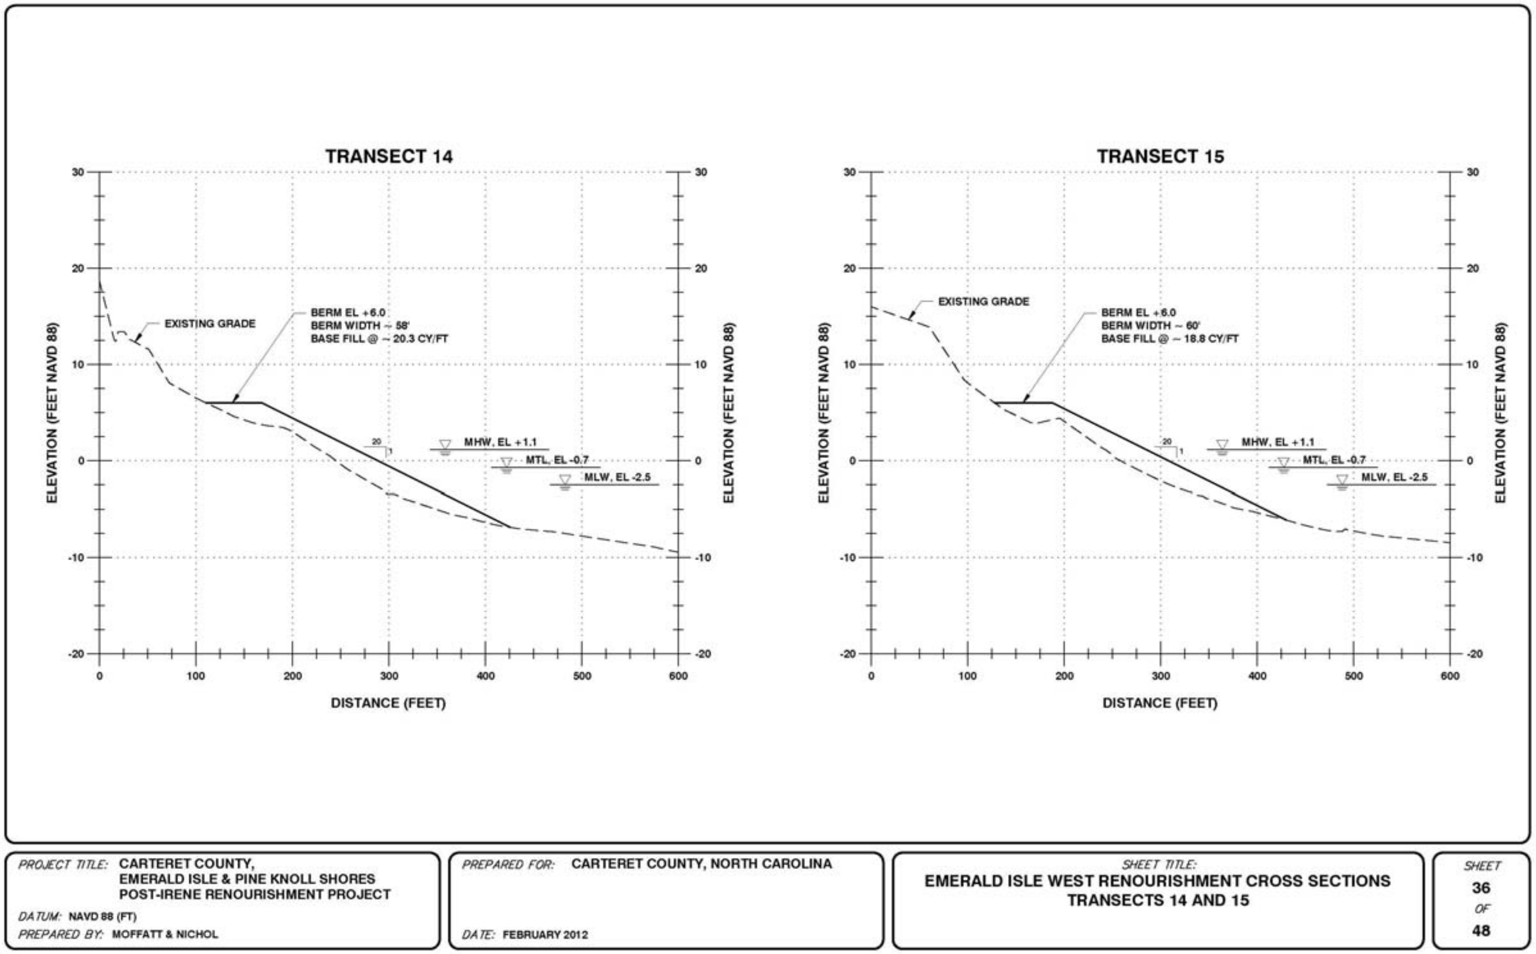

Figure 7. Emerald Isle West Fill Template (Typical)

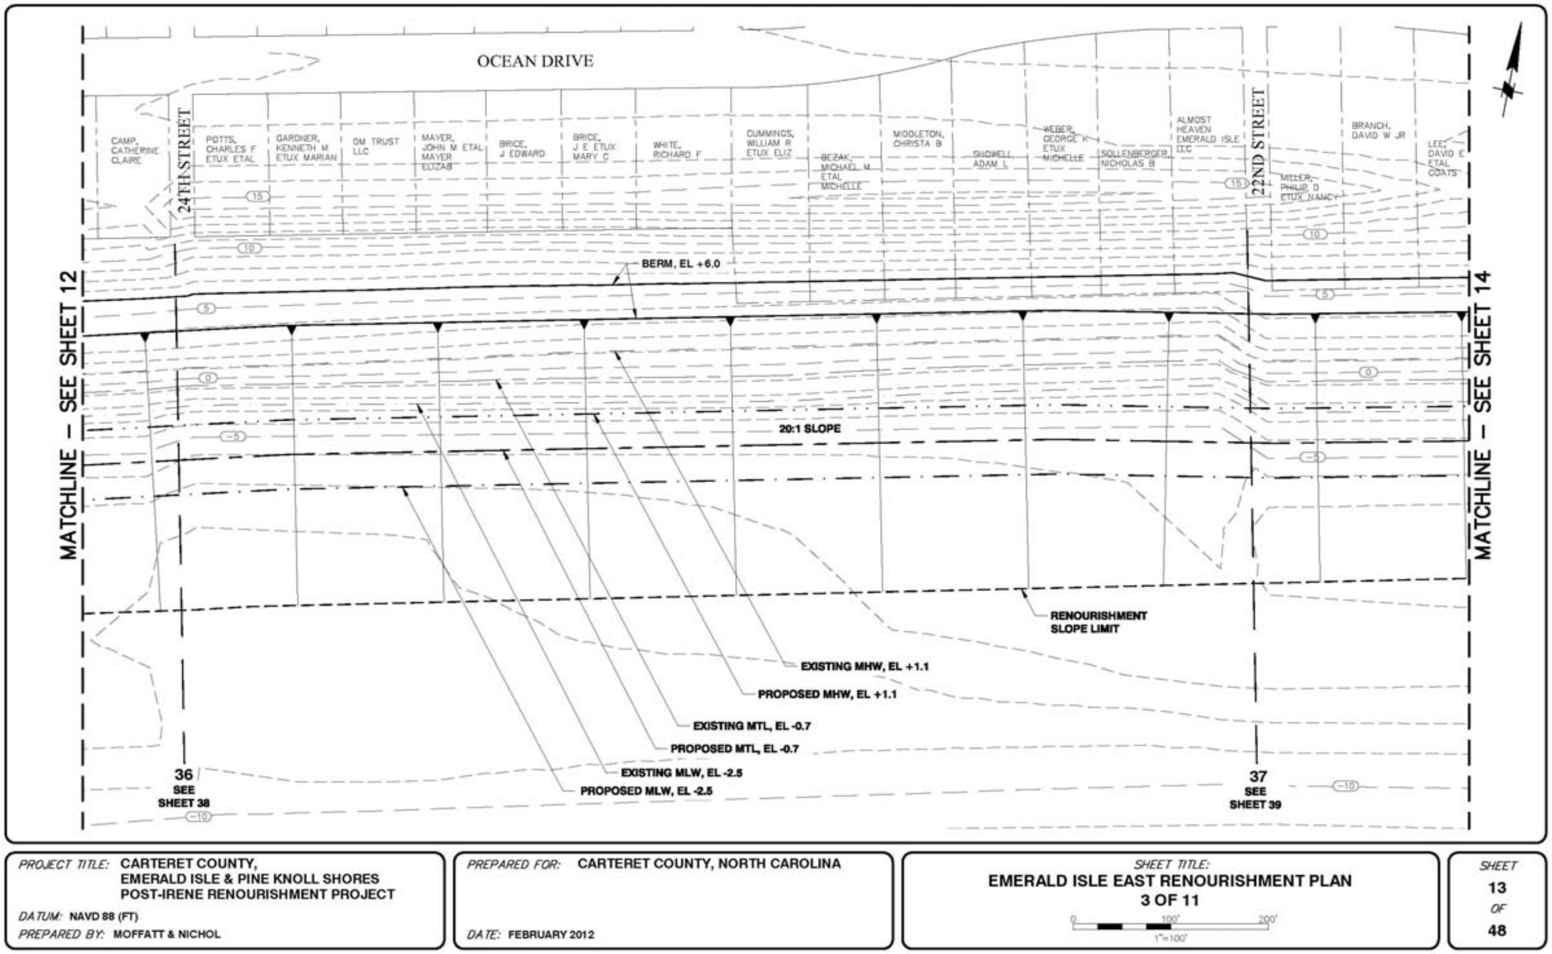

Figure 8. Emerald Island East Renourishment Plan (Typical)

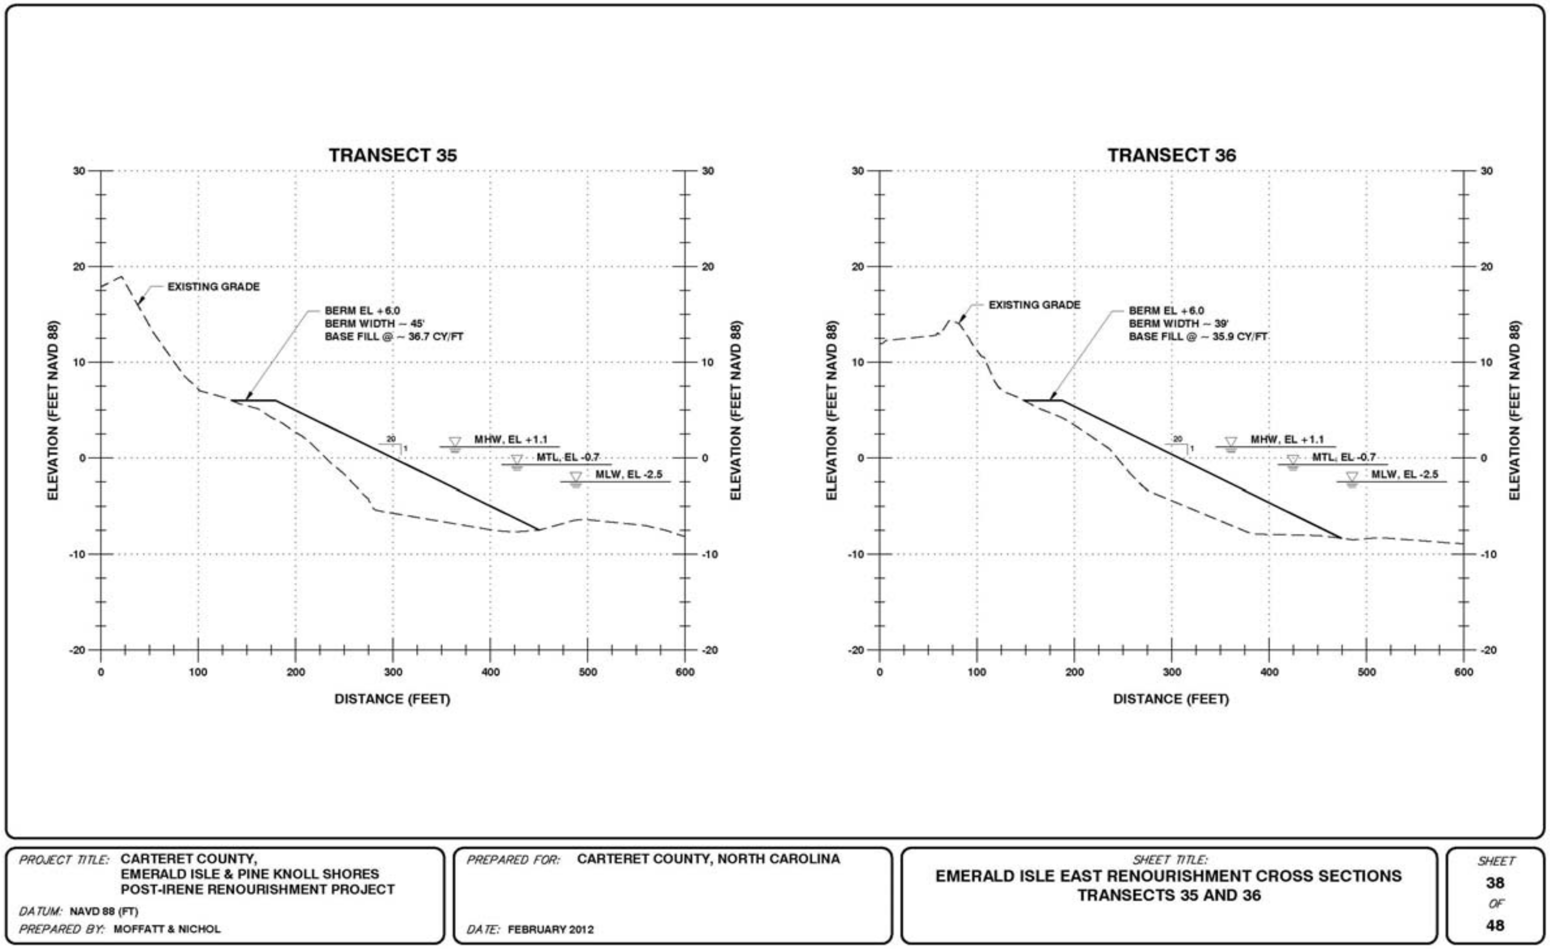

Figure 9. Emerald Isle East Fill Template (Typical)

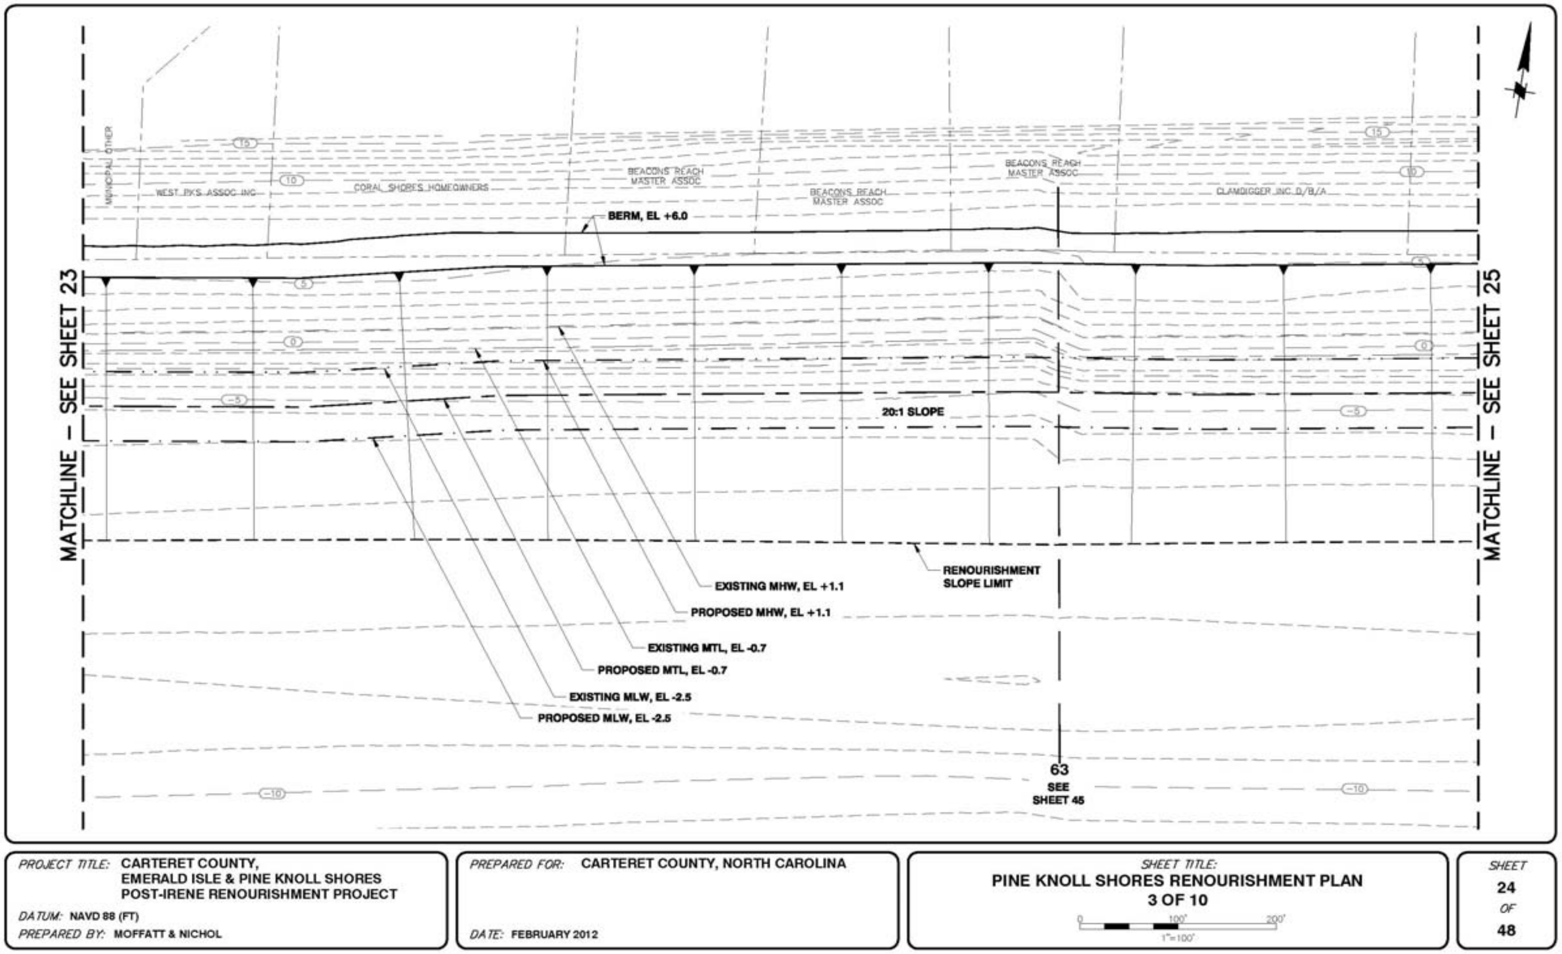

Figure 10. Pine Knoll Shores Renourishment Plan (Typical)

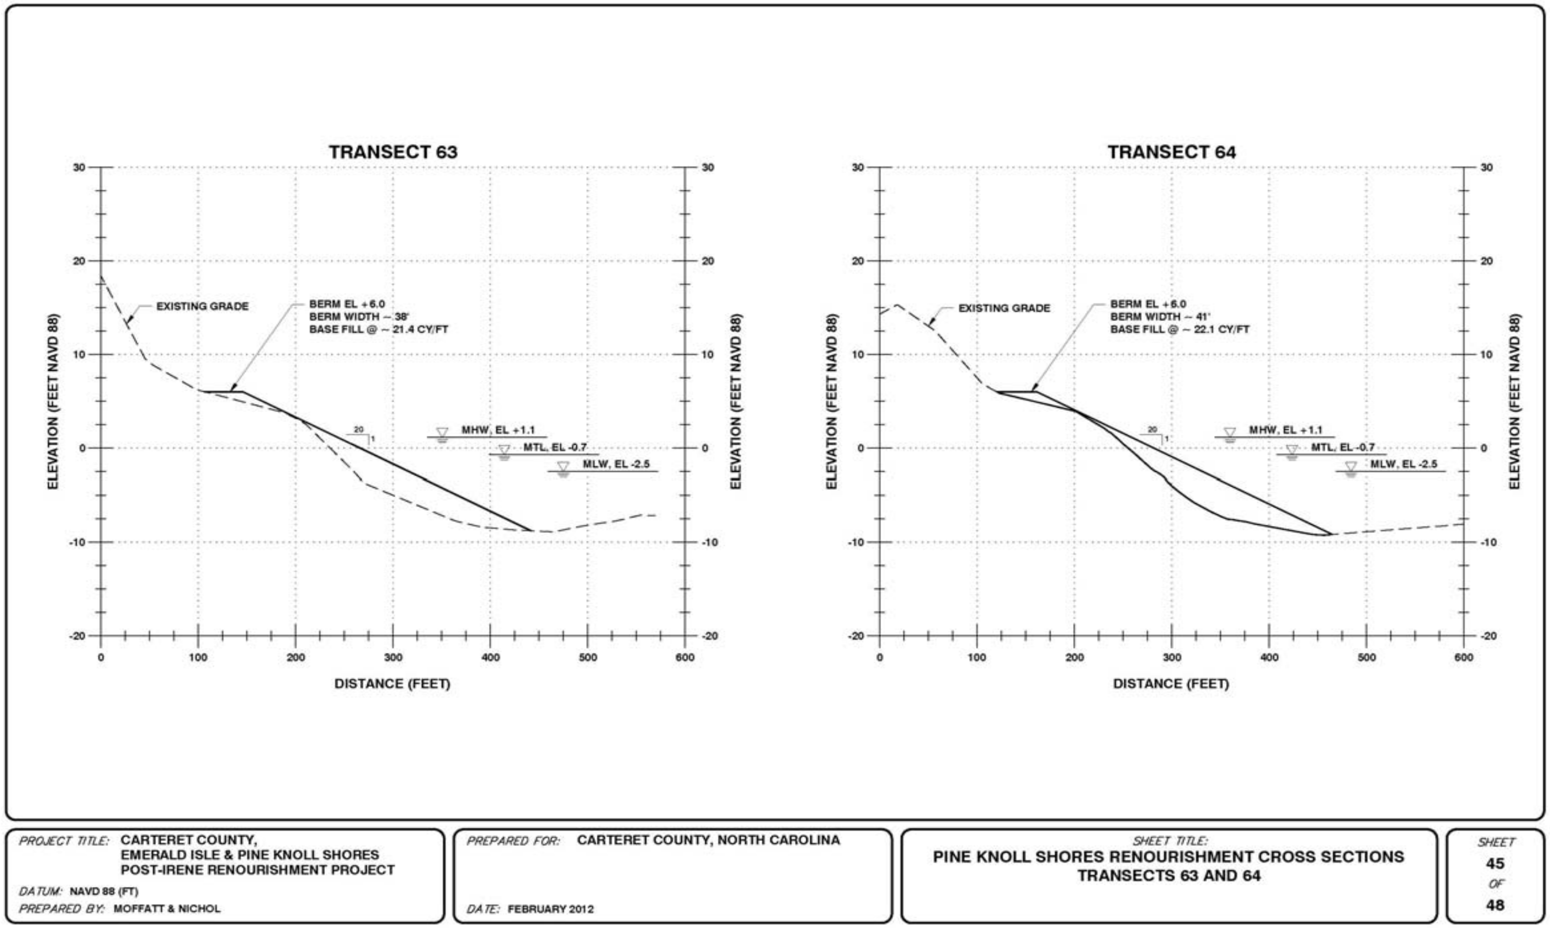

Figure 11. Pine Knoll Shores Fill Template (Typical)

hour period. Based on these estimated production rates, the project would require approximately two to three months for completion.

Consistent with previous permits for hopper dredge nourishment projects (NCDCM Permits #124-01, #181-06 and USACE Permit #200000362), construction would take place within the routinely approved environmental window (November 16 through March 31) (Appendices D and E).

4.2.2 Sediment Compatibility

Suitable sand sources within the ODMDS have been identified in accordance with State of North Carolina Technical Standards for Beach Fill Projects [15A North Carolina Administrative Code (NCAC) 07H .0312]. Sediment data summarizing the sand source and native beach characterization are provided in Section 5.2. The North Carolina Technical Standards require analysis and comparison of sediments from the recipient beach and the proposed borrow site. Sediment properties that are considered include percent weight of fine-grained sediment, percent weight of granular sediment, percent weight of gravel, and percent weight of calcium carbonate.

4.2.3 Rationale for Selection

The Proposed Action Alternative would achieve project objectives described in Section 3.0 and minimize potential environmental effects. The Proposed Action Alternative would allow the beneficial re-use of high quality dredged sand, minimize overall project costs, provide for sediment compatibility, and allow for a timely completion of the approximate seven miles of oceanfront shoreline renourishment.

5.0 AFFECTED ENVIRONMENT

The Cape Lookout area is more diverse than most marine areas along the United States Atlantic Coast due to the mixing of the Gulf Stream from the south with the Labrador Current from the north [United States Fish and Wildlife Service (USFWS) 2002]. As a result of this oceanographic mixing, the marine flora and fauna are a mixture of cold-water and warm-water species. Highly migratory aquatic species such as whales and recreationally important finfish are common. With the unique east-west orientation of Bogue and Shackleford Banks often providing the first or last landfall for north-south migrating birds, seabirds from the Arctic and the tropics co-mingle.

Bogue Banks is an east-west trending barrier island with a length of approximately 26 miles and an average width of approximately 2,000 ft. The island has an extensive beach ridge system with isolated elevations in excess of 39 ft (Cleary and Pilkey 1996). The southern shoreline of Bogue Banks fronts open waters of the Atlantic Ocean. The northern shoreline fronts Bogue Sound a shallow, open-water lagoon that separates the island from the mainland. Bogue Inlet separates the island from Bear Island to the west, and Beaufort Inlet separates the island from Shackleford Banks to the east. The major landforms that make up Bogue Banks include the intertidal and upper dry ocean beach, a system of active primary and secondary sand dunes, a series of interior forested relict dune ridges, and narrow intertidal marsh flats along the margins of Bogue Sound. Vegetation zones from the ocean to the sound include dune grass, maritime shrub, maritime forest, and salt marsh communities (Taggart 1980). The majority of the interior portion of Bogue Banks is heavily developed; and consequently, most of the remaining natural vegetation between the frontal dunes and the back barrier salt marshes is highly fragmented.

The Town of EI occupies the western end of Bogue Banks between Bogue Inlet and the Town of Indian Beach. The Town of PKS is east of the Town of Indian Beach and west of the Town of Atlantic Beach. As defined previously, the western boundary of the proposed Project is approximately two miles east of Bogue Inlet, and the eastern boundary of the Project is approximately eight miles west of Beaufort Inlet. The eastern EI target beach lies along a relatively narrow section of Bogue Banks where the width of the island ranges from approximately 900 to 1,150 ft. In contrast to the majority of Bogue Banks, this narrow section of the island is subject to rare overwash events during storms. Residential beachfront development is continuous along the entire project oceanfront. The total beach fill area would include portions of the upper supratidal beach, intertidal beach, and adjacent subtidal bottom. Project fill volumes would average approximately 27 cy per linear foot of beach, depending on reach-specific losses. The proposed beach profiles would average 45 ft in width seaward of the dune toe as a 6-ft-high NAVD level berm, and then continue seaward on a 1:20 slope to a depth of -8 ft NAVD. Since only the portion of the profile above high water is controllable during renourishment, intertidal and subtidal portions of the profile will be subject to natural adjustment by waves following placement of the beach fill. The existing condition of significant resources, found within the vicinity of the project area, in both the marine and terrestrial environment is described below. Physical resources, socioeconomic resources, recreation and aesthetic resources, cultural resources, and water quality conditions are also discussed below.

5.1 Coastal Processes

As described in Section 1, the study area is in Carteret County, NC centrally positioned on NC's coast south of Cape Lookout. Bogue Banks is an approximately 26-mile long barrier island located on the low-energy limb of the Cape Lookout foreland with a relatively unique east-west orientation. Beaufort Inlet borders the island to the east, separating Bogue Banks from Shackleford Banks. Bogue Inlet borders Bogue Banks to the west, separating the island from Bear Island. Shackleford Banks is part of the Cape Lookout National Seashore (CLNS), and Bear Island is part of the Hammocks Beach State Park. Bogue Sound, a relatively shallow embayment system encompassing reaches of the Atlantic Intracoastal Waterway (AIWW), separates Bogue Banks from the mainland and Onslow Bay (Atlantic Ocean). The island's width [land above mean high water (MHW)] varies from approximately 4,000 ft at the widest point to approximately 800 ft at the narrowest point; both dimensions are found on western EI and eastern EI respectively. Bogue Banks' geographical features and locations portend tropical storms, hurricanes, and erosional effects (USACE 2003).

The Morehead City ODMDS is located on the inner continental shelf of Onslow Bay at depths of -31 to -55 feet MLW. Physical oceanographic processes on the inner shelf of Onslow Bay are primarily driven by synoptic scale (2-14 days) wind events. In contrast to the middle and outer shelf regions, inner shelf processes are little affected by synoptic scale Gulf Stream events and seasonal forcing mechanisms (Pietrafesa et al. 1985). Studies have shown that significant sediment mobilization events on the inner and middle shelf of Onslow Bay are primarily driven by high-energy storms and associated increases in wave orbital velocities (Marshall 2004, Wren 2004). Marshall (2004) reported that fine-grained sediments (<0.2041 mm) were frequently suspended (even under average fair-weather conditions); however, full suspension conditions accounted for less than one percent of the total sediment suspension time over a period of 19 months. Furthermore, a single storm (Hurricane Irene) accounted for 72 percent of the full suspension conditions. During Hurricane Isabel, near-bottom wave orbital velocities were more than six times higher than the fair-weather average, and full sediment suspension conditions occurred for more than forty eight consecutive hours (Marshall 2004).

5.1.1 Tidal Conditions

Tide gauges at Atlantic Beach (ocean side on Triple S Pier); Morehead City; Duke Marine Lab (Beaufort); and Shell Point (Harkers Island) were used for succinct tidal studies during the 1960s and 1970s. However, the Duke Marine Lab has continuously measured soundside tide cycles since 1973 (USACE 2001a). Bogue Banks' ocean tides are semidiurnal with high and low tides approximately equal through consecutive cycle periods. The National Oceanic and Atmospheric Administration's (NOAA), National Ocean Service (NOS) has measured (at Atlantic Beach's Triple S Pier) the mean tide range as approximately 3.7 ft and a mean spring tide range as approximately 4.3 ft. The mean tide range inside the Beaufort Inlet at the Duke University Marine Laboratory and the NC State Port Authority, Port of Morehead City is approximately 3.0 ft (USACE 2001b). Within the Bogue Inlet system as measured at the United States Coast Guard Station, the semidiurnal mean tidal range is approximately 2.2 ft with a mean spring tide range of approximately 2.6 ft [United States Coast Guard (USCG) 2008].

5.1.2 Wave Climate

In general terms, the ocean waters in Bogue Banks' proximity are considered somewhat a mild-energy environment. Small waves less than three ft in height make up approximately two-thirds of the characteristic offshore wave climate with short period wind waves transferring the majority of the energy to Bogue Banks' shoreline. Important wave sheltering effects result from the Cape Lookout Shoal Complex and barrier island landforms (Shackleford Banks) proximal to Bogue Banks; primarily the east end near Fort Macon and Beaufort Inlet. Bogue Banks' sheltered effects wane as one moves east to west along the island toward Bogue Inlet. These geographic factors play a role in minimizing potential nor'easter wave generating effects. The dominant short-period southwest waves normally represent summer time wave conditions; however, occasional long-period waves originate from nor'easters formed south of NC primarily during the spring and winter months (CPE 2004).

Wave height estimations inferred from observations or calculated from offshore wind speeds and directions can have ranging accuracies as compared to wave measurements. A 1956-1975 data set of modeled waves from the USACE Wave Information Study (WIS) showed mean wave heights in the Project area of approximately 4.3 ft in approximately 30-foot water depths. Approximate depths between 60 ft and 90 ft at locations seven nm southeast of Cape Lookout and 25 nm south of EI respectively, indicated mean wave heights of 3.9 ft. However, the study did see a sheltering effect on the eastern end of Bogue Banks related to navigation maintenance (USACE 2001a). Additional WIS data (1980 - 1999) indicated approximately 50% of wave heights near the Beaufort Inlet area were 1.6 - 3.2 ft in height and typically from the south-southwest. However, waves during August to November were primarily from the east-southeast with the largest waves occurring in December-March [North Carolina Coastal Resource Commission (NCCRC) 2010].

Similarly, WIS data (1976-1995) for the Bogue Inlet area, based on the general shoreline alignment, indicated that onshore wave patterns develop from the north-northeast clockwise around to the west-southwest. Nearly 37% of the waves developed from the east-southeast through the south-southeast directions with an average wave height of 3.8 ft (CPE 2004).

As discussed in Section 1.0, Hurricane Irene was a Category 1 storm making landfall on the morning of August 27, 2011. Although Bogue Banks was located on the storm's "weak side" it was still considered a significant event. Based on preliminary review, wave conditions during Hurricane Irene [significant wave height (Hs)=28.4', peak wave time period (Tp)=16 sec] were considered more severe than those that occurred during Hurricane Ophelia (Hs=19', Tp= 11 sec). The duration of elevated wave conditions were similar for both storms (36 - 48 hours).

5.1.3 Shoreline Currents

An increasing gradient, or an increase in transport potential along a shoreline, is an indication of erosion potential; whereas a decrease in transport potential infers potential beach stability or accretion [North Carolina Department of Environment and Natural Resources (NCDENR) 2009]. Many versions of the USACE WIS data bases have been used in portending Bogue Banks' longshore transport. Based on the WIS data set used, sediment transport currents along Bogue Banks differ in magnitude and direction. Another approach describing sediment current movement and accumulation along Bogue Banks facilitates geological indicators. Such an approach infers Bogue Banks' net longshore transport rate as low supported by beach profiles and aerial photographic comparisons; the cycling of accretion and erosion on Emerald Isle's western end; and using USACE placed material (texture and color) on Atlantic Beach, as an indicator of a low net transport (USACE 2001a). However, storm events can exacerbate shoreline currents inducing severe erosion. These storm current induced effects can be temporary or can move sand considerable distances offshore. Storm wave induced currents can also act as a natural bypassing system moving sediment from one side of an inlet to another. Previous analyses indicate primarily a westerly-directed littoral drift with a reversal (nodal) point occurring near Triple S Pier on Atlantic Beach (USACE 2001a). Generally speaking, the scales of east and west transport are relatively similar and likely responsive to seasonal deviation and storm events.

Shoreline current transport in the vicinity of both Beaufort and Bogue Inlets is directed toward the inlets. A westerly current transport continues from western EI to Bogue Inlet (CPE 2004). Studies associated with the Bogue Inlet area's wave energy indicate a predominantly westward littoral current transport; yet, the analyses suggested a nearly balanced sediment transport during March through July. Shoreline studies along PKS and Salter Path/Indian Beach indicate several minor transport gradients and reversals within these shoreline areas (CPE 2004).

5.1.4 Wind/Climate

The National Climatic Data Center (NCDC) provides monthly climate summary data for the region, including Carteret County, North Carolina. Table 5 provides the monthly average wind speeds and directions from the Cherry Point Marine Corps Air Station (MCAS) and Cape Hatteras, North Carolina reporting stations. The period of record (POR) for this data is

Table 5. Monthly average wind directions and speeds.

Cherry Point MCAS, North Carolina	Jan	Feb	Mar	Apr	May	Jun	Jul	Aug	Sep	Oct	Nov	Dec	Annual
Prevailing Direction (DIR)	N	N	S	SSW	SSW	SSW	SSW	SSW	NNE	NNE	N	N	SSW

Mean Wind Speed (SPD)	12	12	12	12	11	11	10	10	11	11	12	11	11
Peak Gusts (PGU)	59	58	63	60	46	55	45	98	87	66	78	60	98

1930 to 1996. In the following table, prevailing wind directions (DIR) are stated in compass points; mean wind speeds (SPD) and peak gusts (PGU) are in miles per hour (NCDC 1998).

Recent wave hindcast studies (Jensen 2010) indicate that the wave climate along Bogue Banks is dominated by small (height <3 feet), short period (<8 second) wind waves out of the southeast to southwest sector. During the spring and summer, prevailing winds are out of the southwest and the predominant direction of wave approach is from the south. As the prevailing winds shift to the northeast in the fall, the predominant direction of wave approach shifts towards the east to southeast sector. As the prevailing winds shift to the north-northwest during the winter, the predominant direction of wave approach pattern shifts back towards the southeast to south sector. The wave climate along Bogue Banks is influenced by Cape Lookout, which shelters the area from the high energy northeast winds and waves that dominate the region (Heron et al. 1984). The sheltering effect results in a relatively low energy wave regime dominated by small, short-period, southerly waves. Although protected against northeast winds and storm waves, the area is highly exposed to tropical storms and hurricanes approaching from the south.

5.1.4.1 Hurricanes and Tropical Storms

Tropical cyclones are classified as tropical depressions, tropical storms, or hurricanes based on maximum sustained wind speeds of <39 miles per hour (mph), 39 to 73 mph, or ≥74 mph; respectively. The Saffir-Simpson Hurricane Scale, also based on maximum sustained wind speeds, is used to classify hurricanes on a scale ranging from one to five (Table 6). During the period 1900 through 2011, Carteret County received direct or indirect hits from 25 hurricanes (Zervas 2009) (Table 7). Direct hits are recorded when the innermost core of the hurricane passes over the County. Indirect hits are recorded when the County experiences hurricane force winds or when tides are 4 to 5 feet above normal. Hurricanes that hit Carteret County between 1900 through 2011 included ten Category 1 storms, six Category 2 storms, and eight Category 3 storms. During this same period, 32 tropical storms passed within 75 miles of Bogue Banks (State Climate Office of North Carolina 2010). The hurricane history of Carteret County is marked by periods of relatively intense hurricane activity. The County was hit by six hurricanes during the period 1953 through 1960, and five hurricanes hit the County during the period 1996 through 1999. In addition, the County experienced successive hurricane hits during 2003, 2004, 2005, 2008, 2010, and 2011. The hurricanes that hit the County during these relatively short time periods account for 64 percent of the total hits.

Knutson et al. (2010) summarized recent efforts to model the effects of climate change on the frequency and intensity of tropical cyclones. Models consistently indicate that the global frequency of tropical cyclones will either decrease or remain the same as the climate warms during the 21st century. However, storm intensity and precipitation levels are expected to increase. A recent modeling study conducted by the NOAA Geophysical Fluid Dynamics Laboratory suggests that the frequency of the most intense (Category 4 and 5) hurricanes in the Atlantic basin will nearly double by the end of the 21st century (Bender et al. 2010). This study estimates that the increase in intensity will outweigh the overall reduction in tropical cyclone frequency, resulting in a 30 percent increase in potential hurricane damage by 2100.

5.2 Geology and Sediment Characteristics

Bogue Banks is a relatively high elevation barrier island with characteristic large oceanfront dunes and extensive interior forested dune ridges that reach heights of over 39 feet. Portions of the island are also very wide, with maximum widths along PKS and western EI reaching 4,000 feet. These wide sections of the island contain multiple shore-parallel forested dune ridges. The island narrows to a minimum width of 800 to 1,000 feet along eastern EI. Although the central portion of Atlantic Beach reaches a width of over 5,000 feet, most of the width was created by filling tidal marshes on the back side of the island. The natural vegetation on Bogue Banks is characterized by the typical barrier island ocean-to-sound sequence of plant communities.

The large frontal dunes and forested dune ridges were formed during a period of seaward island migration that began approximately 4,000 years ago (Riggs et. al. 1996). During this period, an abundant supply of sand on the adjacent continental shelf fueled the formation of new oceanfront dunes. Eventually, the supply of sand on the adjacent continental shelf was exhausted, and the island ceased its seaward progression. Bogue Banks has since shifted to an erosional state and is currently experiencing active erosion along both the oceanfront and soundside shorelines. The average annual erosion rate along most of the oceanfront shoreline is approximately two - three feet per year. Due to the island's east-west orientation and the sheltering effect of Cape Lookout, Bogue Banks is protected against the high energy northeast wind and wave pattern that dominates the majority of the coast. However, the island is highly exposed to tropical storms and hurricanes approaching from the south, which can cause severe short-term erosion.

The affected marine environment, as defined for this EA, encompasses the subtidal seafloor and overlying ocean water column seaward of the mean low water line out to a depth of approximately 20 meters. As described by Hine and Snyder (1985), the mean low water line separates the intermittently exposed intertidal beach from the permanently submerged (subtidal) lower beach. The shoreface along Bogue Banks extends seaward out to a depth of approximately 12 meters (distance of 500 to 800 m from shore) where it flattens and matches the gentle slope of the inner continental shelf. Seaward of the shoreface on the inner shelf of Onslow Bay, a thin (1-2 meters) and discontinuous layer of modern sand is superimposed on ancient hard geological strata (rocks and cemented sediments). The ancient hard strata are frequently exposed on the inner shelf, forming structural habitats known as hard bottoms.

The Morehead City ODMDS occupies an area of eight nm^2 at depths of -31 to -55 feet MLW. Depths are generally shallowest in the northern inshore portion of the ODMDS and gradually deepen towards the southern offshore portion. Sediments are predominantly sands with varying amounts of silts and clays. The quantity of shell material varies from a trace to 25 percent. The seafloor is essentially flat, with the exception of dredged material mounds in the northeastern third and central portion of the ODMDS due to navigation maintenance dredging disposal events. Remote sensing surveys have not identified any potential hard bottom features or cultural resources at the ODMDS. Bathymetric surveys indicate that sandy and coarse dredged materials have the potential to mound appreciably when specific areas are repeatedly used for disposal (USACE and USEPA 2009).

5.2.1 Borrow Area Sediments

Vibracores were obtained in the ODMDS by Alpine Ocean Seismic Survey Inc. (Alpine) in December 2011, supporting sand source investigations for the MBNP. A portion of these vibracores were collected at the state-mandated 1,000 ft spacing and this area is being denoted as the borrow site for the proposed Post-Irene project (Figure 4). Shallow excavations (2-5 ft deep, typical) would be made by a hopper dredge and pumped via submerged pipe to the beach. Utilizing the portion of the ODMDS which has vibracore data at the state-mandated 1,000 ft spacing and assuming a potential cut depth down to elevation -52 ft NAVD (equal to the original offshore floor elevation), an area of approximately (~) 197 acres of the total ODMDS area of ~6,900 acres would meet the renourishment requirement of 1,000,000 cy (Appendix F). Appendix G (Permit Drawings) includes all engineering plan drawings of the entire project area as well as the ODMDS borrow source.
Detailed information regarding recent vibracore investigations and characteristics of the proposed ODMDS borrow sediment is provided in Appendix F. Moffatt & Nichol identified 27 samples from ten ODMDS vibracores representative of the proposed borrow area and material to be placed on the beach.

Sediment data summarizing the sand source are provided below in Table 8. Sand placed on the beach will meet NCDCM's sediment compatibility standards as detailed in Sediment Criteria Rule, contained in the Technical Standards for Beach Fill Projects (15A NCAC 07H .0312).

Table 8. Sand characterization comparisons.

Sand Characterization	Native Beach	ODMDS Borrow Site	NCDCM Standards	Compliance
Silt Percentage	1%	0.5%	+ 5% of Native	Within Standards
Sand Percentage	94%	98%	+ 5% of Native	Within Standards
Gravel Fraction	5%	1.5%	+ 5% of Native	Within Standards
Calcium Carbonate Fraction	15-20%	9-21%	+15% of Native	Within Standards

Sources: CSE, USACE, Alpine and NCDCM 15A NCAC 07H .0312 Technical Standards for Beach Fill Projects (3) (a through h).

The typical sediment type in the ODMDS borrow site is medium sand (average mean sediment size = 0.31 mm), moderately to poorly sorted (average standard deviation = 1.09 phi), and strongly coarse-skewed (coefficient of skewness < - 0.3). Less than 2% of the material is >2 mm in diameter. The native beach (composite 1999 - 2001) was also characterized as medium sand (mean size = 0.30 mm), moderately well sorted, and coarse-skewed. The comparison, depicted in Table 8, shows the proposed borrow area sediments to be similar to native (1999 - 2001 composite). Using the James 1975 overfill factor (RA), the borrow sediment has an RA = 1.14.

These ODMDS borrow area results compare more positively to the native beach than the previous sand used for the Post-Ophelia renourishment. Visual observations of the present borings indicate mud content is very low with only trace amounts seen in nearly every core. Only one sample tested contained greater than 5% fine grained sediment (vibracore O24 sample 1; 5.1% passing 200 sieve); all other samples were comprised of less than 1% fine grained material. Samples consisted of 9 - 21% calcium carbonate. The typical colors of ODMDS sediments are light-to-medium to dark gray-to-brown as described in the geological logs in Appendix F. The photos within Appendix F also show the sands to be gray to brown in color, which is very similar to the colors reported for the sand used in the Post-Ophelia project.

The Proposed Action Alternative (issuance of a non-competitive lease by BOEM) would authorize use of up to 1M cy of OCS material. The sand would be removed from the ODMDS (Figure 4) by a hopper dredge and transported to the three reaches for placement as fill (Figure 2). Given the distance from the ODMDS to the recipient beaches (ranging 7-21 mi), the borrow sand would be delivered via a hopper dredge facilitating offshore pump out stations. These stations would direct the sand slurry on the three reaches. The dredging footprint and ODMDS bottom-disturbing activities would be confined to the ODMDS as delineated through geotechnical testing (Appendix F), cultural investigation, and hardbottom confirmation.

5.2.2 Native Beach Sediments

Native beach sediments were sampled by CSE between 1999 and 2001 to establish native grain size distribution for purposes of a compatibility analyses. Details are described in the EA for Phases 1 and 2 (CSE-Stroud 2001) and in NCDCM Permit #124-01. Mean grain size of baseline samples (composites) was 0.302 millimeter (mm), standard deviation (sorting parameter) was 0.585 mm, and samples were coarse-skewed as a result of moderately high percentages of coarse material. The primary coarse fraction consists of shell fragments, most of which would be termed “shell hash” because grain sizes of the shell material are typically greater than 2 mm mean diameter. Native samples from 1999 to 2001 averaged approximately 15-20 percent shell and were classified as medium sand, moderately well-sorted, and coarse-skewed. This native size distribution has been approved and adopted for the proposed project.

Sediment data summarizing the native beach characterizations are provided above in Table 8. Sand placed on the beach will meet NCDCM’s sediment compatibility standards as detailed in Sediment Criteria Rule, contained in the Technical Standards for Beach Fill Projects (15A NCAC 07H .0312).

5.3 Water Quality

In NC, water quality is assessed primarily at the watershed or river basin (i.e., basinwide) level due to the watersheds’ interconnectedness. Basinwide water quality plans are prepared by the NCDWQ for each of the seventeen major river basins in the State and are updated at five-year intervals. The Proposed Action Alternative is contained within the White Oak River Basin; water quality plans were developed by NCDWQ in February 1997 and updated in November 2001. The Atlantic Ocean south of the proposed project reaches is also rated by NCDWQ, and has been designated “SB” for water quality classification. This means that ocean surface waters are used and suitable for recreation, including frequent or organized swimming. More limited stormwater controls are required under the Coastal Area

Management Act (CAMA) than the stormwater controls required under higher water quality designations. There are no categorical restrictions on wastewater discharges (NCDWQ 2003a).

Based on the above classification, water quality standards include: (1) turbidity in the receiving water shall not exceed 25 Nephelometric Turbidity Units (NTU), (2) changes in salinity due to hydrological modifications shall not result in the removal of the functions of a Primary Nursery Area (PNA), (3) temperature shall not be increased above the natural water temperature by more than 0.8 degrees centigrade (ºC) during the months of June, July, or August nor more than 2.2ºC during other months, and in no cases to exceed 32ºC due to the discharge of heated liquids, (4) dissolved oxygen cannot decrease below 5.0 milligrams per liter (mg/l), except in "poorly flushed tidally influenced streams or embayments, or estuarine bottom waters" which may have decreased values from natural causes, and (5) pH levels "shall be normal for the waters in the area, which generally range between 6.8 and 8.5 except that swamp waters may have a pH as low as 4.3 if it is the result of natural conditions" (NCDWQ 2003b).

Historically, infrequent water sampling has been conducted in the vicinity of the project area. Data collected by Searcy (2003) off the Highway 24 Bridge in Swansboro, from November 2002 through January 2003, reported a range of salinities from 24.0 to 28.6 ppt, with an average of 26.7 ppt in the area. During the same period, water temperatures ranged from 4.0ºC (39.2ºF) to 17.1ºC (62.8ºF), with an average of 9.8ºC (49.6ºF).

NCDENR Basinwide Assessment Report (2000) states turbidity levels taken adjacent to Swansboro from 1994 through 1999 ranged from 1.0 to 13.0 NTUs, with an average measurement of approximately 5.2 NTU. Elevated levels of turbidity are expected in the surf zone at the effluent discharge point on the beach. Schubel et al (1978) discovered that 97–99 percent of discharged slurry settled to the bottom within a few tens of meters from the discharge point. Other studies have found that the distribution of turbidity was confined to the discharge point (Nichols et al 1978; USACE 2001a).

In April 2002, Phase 1 of the Bogue Banks restoration project involved pumping 1.73 million cy of sand to renourish PKS and Indian Beach. During operations, turbidity was measured along two cross-shore transects (4,000 ft) – one inside the pumping zone and one away from the pumping zone. Turbidity was also measured along shore in the surf zone (3.8 miles) within the project area before pumping started and during sand pumping (CSE, unpublished data, April 2002).

The longshore turbidity measured before pumping provides background data with which to compare changes in turbidity. Background nearshore turbidity levels measured between 13.0 and 94.0 NTU with an average turbidity of ~50.0 NTU. After pumping started, turbidity in the surf zone showed a slight overall increase in the longshore direction (measurements averaged ~65 NTU) with a sharp increase at the point of sand discharge (>400 NTU). The sharp increase was seen only locally at the point of discharge and was drastically reduced within several hundred feet alongshore (CSE, unpublished data, April 2002). No offshore turbidity monitoring was required or conducted (Personal communication, Mickey Sugg, USACE SAW, 27 June 2012).

5.4 Air Quality

The Clean Air Act (CAA) of 1990 delineates the USEPA's responsibilities for improving and protecting the nation's air quality. The last significant amendments occurred in 1990 substantially enhancing the responsibility and authority of the federal government. The authority enhancements were through expanded regulatory authorizations, emphasizing implementation and enforcement while also considering a benefit-cost approach. USEPA is authorized to set air pollutant limits ensuring environmental and basic health protection standards for the United States; however, individual states have the option to enforce more stringent air pollution laws, if desired (USEPA 2010a).

The CAA's 1990 amendments basically included (USEPA 2010a):

- Acid Deposition Control Programs
- Control of an Additional 189 Air Toxics under National Emission Standards for Hazardous Air Pollutants
- Permit Program Requirements (Title V)
- Modified and Expanded Enforcement Authority
- Enhanced Attainment Provisions with the National Ambient Air Quality Standards (NAAQS)

The USEPA has set national ambient air quality standards for six common or "criteria pollutants" (Table 9). Ambient air is that portion of the atmosphere, external to buildings, which the general public has access. USEPA uses the term criteria because the allowable concentration levels of these six pollutants are human health-based and/or environmentally based limits. The human health-based limits are the primary standards and the environmental or property damage limits are the secondary standards. Currently, the six criteria air pollutants are: Ozone (O_3), Particulate Matter (PM_{25}), and (PM_{10}) particles with aerodynamic diameters of 2.5 or 10 microns or less, Carbon Monoxide (CO), Sulfur Dioxide (SO_2), Nitrogen Dioxide (NO_2), and Lead (Pb) (USEPA 2010b).

The NC Division of Air Quality (NCDAQ) maintains an ambient air monitoring network for those criteria pollutants requiring monitoring by USEPA. Areas that exceed USEPA's national ambient air quality standards, based on regional ambient air monitoring, are designated as non-attainment areas. Carteret County is included in the non-metropolitan statistical area of NC's southern coastal plain. Carteret County is also included within New Bern's micropolitan statistical area (MiSA) (NCDAQ 2010).

The NCDAQ operates two ambient air monitoring stations within this MiSA; one station in Kenansville and the other in Kinston at Lenoir Community College. The Kenansville, Duplin County site operates a fine particulate monitor (sampled each third day) and a high-volume particulate PM_{10} monitor (sampled each sixth day). The Kenansville site is considered a general/background ambient air monitoring site. The Lenoir Community College site operates a seasonal continuous ozone monitor and a fine particulate monitor (sampled each third day). The ozone monitor at Lenoir Community College is considered a rural ozone monitor in a MiSA (NCDAQ 2010).

Carteret County is designated as within attainment for all criteria pollutants (Personal communication, B. Newland, NCDAQ, March 2012). State Implementation Plans are not triggered for areas in attainment with the NAAQS.

Table 9. National ambient air quality standards.

Primary Standards				
Pollutant	**Level**	**Averaging Time**	**Level**	**Averaging Time**
Carbon Monoxide	9 parts per million (ppm) [10 milligram per cubic meter (mg/m^3)]	8-hour (1)	None	
	35 ppm ($40\ mg/m^3$)	1-hour (1)		
Lead	0.15 microgram per cubic meter ($\mu g/m^3$) (2)	Rolling 3-Month Average	Same as Primary	
	$1.5\ \mu g/m^3$	Quarterly Average	Same as Primary	
Nitrogen Dioxide	53 parts per billion (ppb) (3)	Annual (Arithmetic Average)	Same as Primary	
	100 ppb	1-hour (4)	None	
Particulate Matter (PM10)	150 µg/m3	24-hour (5)	Same as Primary	
Particulate Matter (PM2.5)	15.0 µg/m3	Annual (6) (Arithmetic Average)	Same as Primary	
	35 µg/m3	24-hour (7)	Same as Primary	
Ozone	0.075 ppm [2008 standard (std)]	8-hour (8)	Same as Primary	
	0.08 ppm (1997 std)	8-hour (9)	Same as Primary	
	0.12 ppm	1-hour (10)	Same as Primary	
Sulfur Dioxide	0.03 ppm	Annual (Arithmetic Average)	0.5 ppm	3-hour (1)
	0.14 ppm	24-hour (1)		

Source: USEPA 2010b

(1) Not to be exceeded more than once per year.
(2) Final rule signed October 15, 2008.
(3) The official level of the annual NO2 standard is 0.053 ppm, equal to 53 ppb, which is shown here for the purpose of clearer comparison to the 1-hour standard
(4) To attain this standard, the 3-year average of the 98th percentile of the daily maximum 1-hour average at each monitor within an area must not exceed 0.100 ppm (effective January 22, 2010).
(5) Not to be exceeded more than once per year on average over 3 years.
(6) To attain this standard, the 3-year average of the weighted annual mean PM2.5 concentrations from single or multiple community-oriented monitors must not exceed $15.0\ \mu g/m^3$.
(7) To attain this standard, the 3-year average of the 98th percentile of 24-hour concentrations at each population-oriented monitor within an area must not exceed $35\ \mu g/m^3$ (effective December 17, 2006).
(8) To attain this standard, the 3-year average of the fourth-highest daily maximum 8-hour average ozone concentrations measured at each monitor within an area over each year must not exceed 0.075 ppm. (effective May 27, 2008)
(9) (a) To attain this standard, the 3-year average of the fourth-highest daily maximum 8-hour average ozone concentrations measured at each monitor within an area over each year must not exceed 0.08 ppm.
(b) The 1997 standard—and the implementation rules for that standard—will remain in place for implementation purposes as EPA undertakes rulemaking to address the transition from the 1997 ozone standard to the 2008 ozone standard.
(c) EPA is in the process of reconsidering these standards (set in March 2008).
(10) (a) EPA revoked the 1-hour ozone standard in all areas, although some areas have continuing obligations under that standard ("anti-backsliding").
(b) The standard is attained when the expected number of days per calendar year with maximum hourly average concentrations above 0.12 ppm is < 1.

5.5 Noise

The beachfront's naturally occurring noise sources are similar along the entire 26-mile oceanfront shoreline. Naturally occurring noise sources are ocean waves, wind, and birds. Anthropogenic noise emission sources and receptors vary along Bogue Banks primarily by shoreline use, access, proximity, and season. Anthropogenic noise emission sources occurring on or near the beach would vary seasonally with the influx of the summer tourist, their transportation, and their shoreline use. These anthropogenic noise levels intensify in locations planned and developed for public use and shoreline access. Indirectly, landward infrastructure supporting the tourism industry and local municipalities would result in additional noise sources as well as receptors. Along the inlet shorelines, recreational and commercial vessels are additional anthropogenic noise sources.

Ambient sound in the ocean consists of the normally prevailing underwater sound emanating from natural and man-made sources. Hildebrand (2009) described the major natural and anthropogenic components of ambient ocean noise. Natural sources of noise include processes such as earthquakes, wind-driven waves, rainfall, bio-acoustic sound generation, and thermal agitation of seawater. Anthropogenic noise is generated by a variety of activities, including commercial shipping, oil and gas exploration, naval operations (e.g. sonar, communications, and explosions), fishing (e.g. sonar, acoustic deterrent and harassment devices), research (e.g. air-guns, sonar, telemetry, communication, and navigation) and other activities such as construction, icebreaking, and recreational boating. Ambient low-frequency ocean noise (10-500 Hz) is dominated primarily by commercial shipping and secondarily by seismic exploration. Ambient mid-frequency noise (500 Hz-25 kHz) is dominated by sea-surface agitation; including breaking waves, spray, bubble formation and collapse, and rainfall. Sonar (e.g. military and mapping) and small vessels also contribute to mid-frequency ambient noise. Due to rapid attenuation, high frequency noise (>25 kHz) is confined to an area close to the receiver. At frequencies greater than 60 kHz, thermal agitation of water molecules is the dominant source of ambient noise.

In a previous air noise assessment conducted on Radio Island, noise levels were documented for background and ambient levels. One sampling location was approximately 130 ft south of US 70 on the Morehead City to Beaufort causeway and another sampling location was the middle of Radio Island proper. The sampling period was April mid-morning; and the results were 61.9 and 44.9 a-weighted decibels (dBa), respectively [North Carolina State Ports Authority (NCSPA) 2001].

5.6 Archaeology/Cultural Resources

On 26 April 2010, the North Carolina Department of Cultural Resources, SHPO was requested to identify any known historical or archaeological sites that have been recorded along Bogue Banks. Pursuant to Section 106 of the National Historic Preservation Act and the Advisory Council on Historic Preservation's Regulations for Compliance with Section 106 codified at 36 CFR Part 800, comments and the last known positions of six archaeological sites were provided by SHPO. These are described in Table 10, depicted in Figure 12, and documented in Appendix H.

Table 10. Bogue Banks' known historical or archaeological sites.

SHPO ID	Site Name	Site Description
0001BBB	Iron Steamer Pier Wreck	Civil War, Blockade Runner, Pevensey
0002BBB	Gun Emplacement	World War II, Shore Battery
0003BBB	Salter Path	Ship Timbers with Iron Fasteners
0004BBB	Cupola	Ship Hull Portions with Planking
0005BBB	El Pier Wreck	Ship Timber with Iron Fasteners
0006BBB	Ocean Reef	Ship Wreckage with Extensive Remains

SHPO approves sand deposition as additional resource protection; however, if resources are exposed and construction is in close proximity, inspections by the Underwater Archaeology Branch would be required. Extensive borrow source assessments have been conducted along Bogue Banks and the assessments' findings and recommendations were considered during project alternative evaluation. Proposed borrow sources were assessed via remote-sensing and target identification techniques, identifying potential presence and significance of submerged archaeological remains (Hall 2011; Appendix J).

5.6.1 Known Archaeological and Historical Resources in the Project Area's Vicinity

A survey of historical and archaeological literature and archival background research confirmed considerable evidence of maritime activity along the southeastern NC coast. Historic maritime activity associated with the Beaufort Inlet area continues today in the form of commercial fishing and international shipping. Documented maritime activity dates from the sixteenth century when Spanish and English explorers visited the NC coast. As a consequence of nearly 300 years of navigation in the Cape Lookout coastal region, there is a high probability that historically submerged cultural resources are located in the area. That evidence suggests a high probability for submerged cultural resources in the waters around Beaufort and possibly Bogue Inlet.

The high probability of historical shipwrecks in the Beaufort Inlet vicinity is confirmed by location and identification of the remains of several historically significant vessels. The most significant Beaufort Inlet area shipwreck is Blackbeard's flagship the *Queen Anne's Revenge* (31CR314). A decade of investigation of the *Queen Anne's Revenge* has been carried out by the Underwater Archaeology Branch (UAB) and the shipwreck has been listed on the National Register of Historic Places (NRHP) (Lawrence 2007). Remains of the transport steamer *Quinnebaug* (0001BUI), a Civil War steamer lost off Shackleford Banks on 20 July 1865 (Berman 1972), were discovered by Tidewater Atlantic Research in 1992 (Watts 1992). While that wreck is not currently on the NRHP, the vessel meets criteria for inclusion. Remains of the schooner *L. A. Bailey* (0004BUI) and its cargo of railroad iron also lie near Beaufort Inlet. Like *Quinnebaug*, the L. A. Bailey is not on the NRHP, but meets several eligibility criteria. The 20th century remains of the trawler Parkins can also be considered potentially eligible. Parkins, a fishing trawler built in Pocomoke City, Maryland, in 1923 and owned by the Beaufort Fish-Scrap & Oil Company was lost during a storm on 21 December 1942 (Berman 1972).

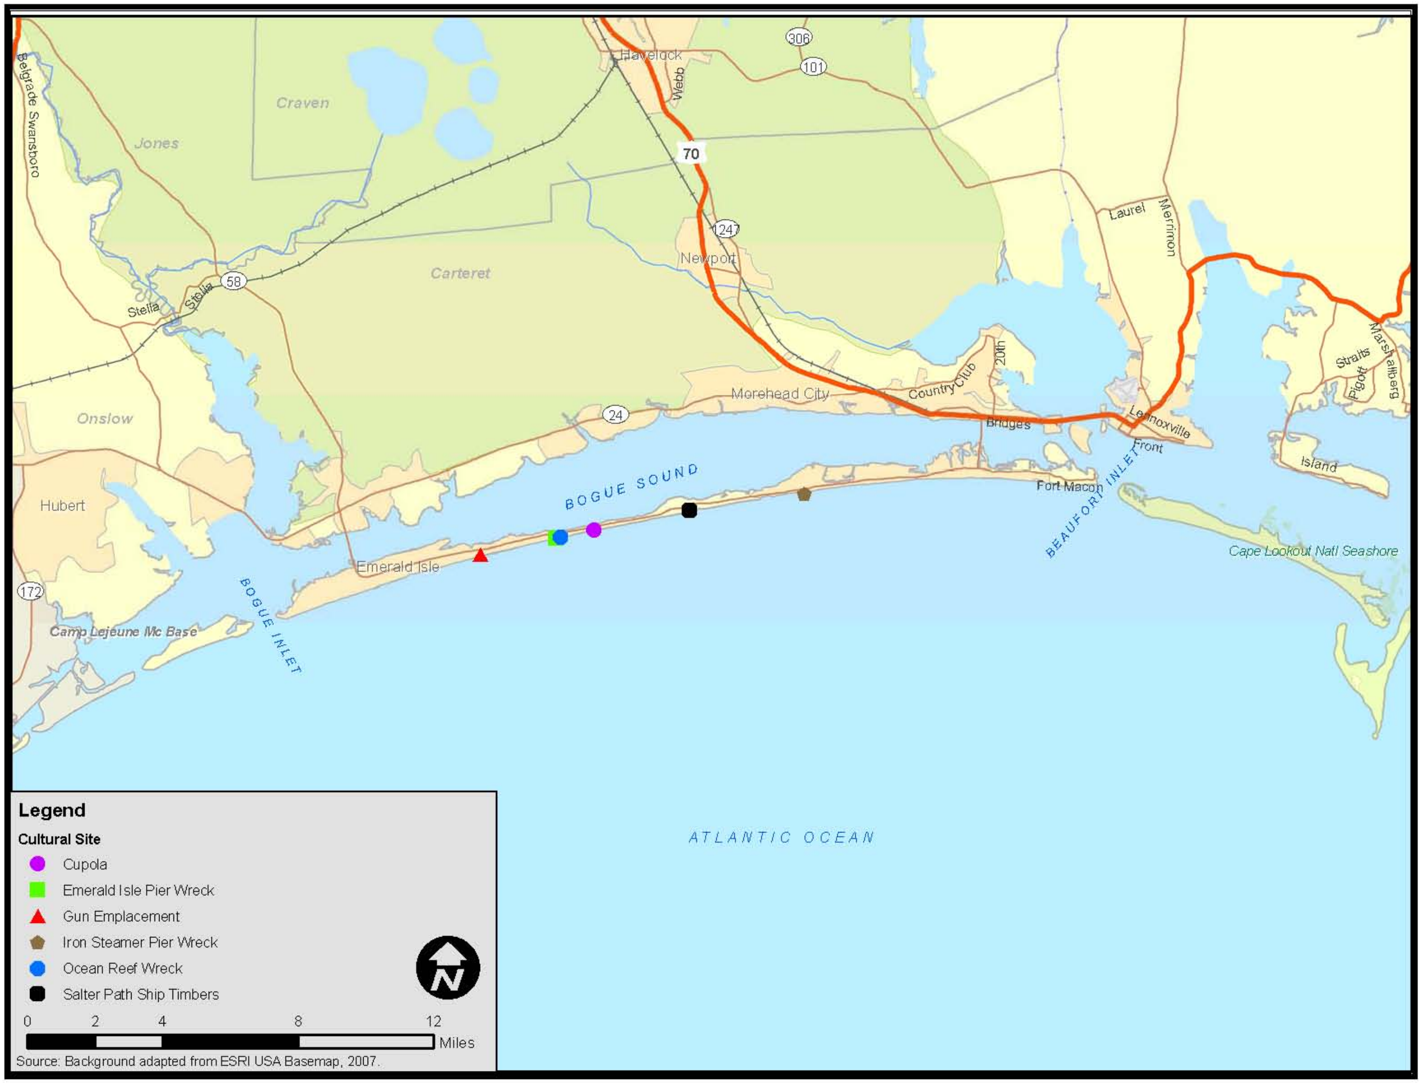

Figure 12. Known Cultural Resource Sites and Shipwrecks

A number of unidentified shipwrecks in the immediate project vicinity are listed with the UAB. These include a late nineteenth century site which produced copper sheathing and brick (0005BUI), a site containing a brass shoe buckle and pewter spoon dating to the first half of the eighteenth century (0006BUI), and a site comprised of seven eighteenth-century cannons (0007BUI). There are at least 144 shipwrecks recorded in coastal waters in the vicinity of Beaufort Inlet. Because of their association with the broad patterns of NC history, the remains of sunken vessels preserve important information about the maritime heritage of the NC coast.

The *Queen Anne's Revenge*, was declared a protected site by the NC Department of Cultural Resources. She is currently protected by additional sediment that has migrated into the area and a 300-yard perimeter established to restrict activities in the vicinity of the site. Access to the site, even for dredged material disposal, is not permitted unless separately coordinated between the NC Department of Cultural Resources and the USACE.

BOEM considers the area of potential effect to consist of the Morehead City ODMDS area (see Figure 1), which is an U.S. Environmental Protection Agency (USEPA) designated dredged material disposal site. While it is unlikely that significant submerged cultural resources would be contained within the previously dredged material of the ODMDS, Moffatt and Nichol Engineers contracted with Mid-Atlantic Technology and Environmental Research, Inc. to conduct an archaeological remote sensing survey in the Morehead City ODMDS dated September 08, 2011 (Hall 2011). The conclusions of the report are as follows:

- All of the targets identified during this project were found to be associated with modern debris that is either related to the present day ODMDS or past artificial reef systems such as the tire reefs created in the 1970s.

- Given the nature of re-deposited dredge material, the results of the 2011 archaeological survey indicating that no historic properties are present, and the fact that no original seafloor under the disposal site will be disturbed, BOEM has reached a determination of No Historic Properties Affected, pursuant to 36 CFR 800.4(d)(1).

The SHPO did not object within 30 days of receipt of BOEM's letter in reference to the ODMDS. Therefore, BOEM's Section 106 responsibilities have been fulfilled and there is a determination of no impact to historic or cultural resources at the proposed borrow site.

5.7 Benthic Resources

Benthic resources described in this section include macroinvertebrates associated with soft/sand bottom habitat located within the intertidal/surf zone and the subtidal/nearshore region located off Bogue Banks and the nearby Beaufort ebb shoal. No hardbottom habitat has been documented to occur in the nearshore areas off the recipient beaches or within the ODMDS (Hall 2011).

5.7.1 Intertidal/Surf Zone Benthic Communities

In NC, the dominant benthic macrofauna of the intertidal beach are mole crabs (*Emerita talpoida*), coquina clams (*Donax variablis, D. parvula*), several species of haustoriid amphipods, and the spionid polychaete *Scolelepis squamata* (Deaton et al. 2010). Leber (1982) documented seasonal changes in the intertidal macroinvertebrate community at Bogue Banks. Mole crabs and coquina clams dominated the macroinvertebrate community for most of the year. Mole crab densities were highest from April through October, and densities of the coquina clam *D. variabilis* were highest from May through November. Densities of both species declined sharply in the late fall and were completely absent between mid-January and mid-February. Recolonization by juveniles and adults of both species was evident by late February. Densities of the coquina clam *D. parvula* were highest from May through August. *D. parvula* disappeared from the intertidal zone in late August, and remained absent from the intertidal zone until the following March. Haustoriid amphipods (*Haustorius* sp. and *Amphiporeia virginiana*) dominated the benthic community for a brief period during early winter, but were present in low numbers throughout the remainder of the year. Peterson et al. (2006) detected seasonal changes in polychaete abundance at Bogue Banks. Densities of intertidal polychaetes (primarily *Scolelepis squamata*) increased after March, peaked during the warmer months, and declined in the fall.

More recent studies of the intertidal/shallow subtidal benthic community include those associated with a series of beach fill projects conducted between winter 2001-2005 (Peterson et al 2006, CSA 2002-2006). Peterson et al (2006) took advantage of the winter 2001-2002 beach nourishment project on Bogue Banks to evaluate the ecological impacts and recovery from large-scale sedimentation during the subsequent warm season as a function of the month of filling. He also utilized previous quantitative sampling data from 1998 (Manning 2003) at several localities along Bogue Banks, including areas to be filled and a control area outside but near the fill zone. Use of the temporal data before the project as well as sampling following the project allowed for a rigorous design that could use a "beyond BACI" (Underwood 1994) approach to control for natural temporal and spatial variation. Prior to the 2001-2002 beach nourishment, the Bogue Banks' beaches had not been modified by filling except for five smaller beach fill projects at Fort Macon and Atlantic Beach from 1973–1994 (Valverde et al. 1999) and dredge material disposal in spring 1990 along two small stretches of beach in PKS (Peterson et al. 2000). The 2001-2002 project dredged materials from offshore to place 100–176 m^3 of sediment per linear m along 10.8 km of shoreline from the western edge of Atlantic Beach to near the western boundary of Indian Beach. Nourishment of the beach began in November 2001, moving east to west until completed in April 2002. The temporal progression of fill allowed for a comparison of study sites that were filled in December, February, and early April to test for differences in impacts and rate of recovery as a function of date of disturbance (Peterson et al 2006). It should be noted that no biological sampling took place in January because of the dramatic seasonal depression of macrobenthic invertebrate abundances known to occur during the winter on Bogue Banks (Diaz 1980, Leber 1982).

Filling of the beach with much coarser sediments than occurred on the native beach caused dramatic suppression of beach macroinvertebrates for at least one warm season (Peterson et al 2006). As a result of the beach fill disturbance, invertebrate densities were depressed on filled beaches during the March-November time frame, with abundances of Donax spp. and haustoriid amphipods averaging less than 10% of control levels. Recovery on filled beaches was not initiated by either taxon during the March–November sampling. *Emerita talpoida*, an order of magnitude less abundant than Donax spp. on control beaches, showed a pattern of initial depression on filled beaches followed by recovery in mid-summer. Polychaetes, in particular *Scolelepis squamata*, experienced a warm-season increase in abundance of equal magnitude on filled and control beaches. Recruitment of ghost crabs appeared inhibited on filled beaches, likely due to the persistent shell hash. Intertidal shell cover on filled beaches averaged 25 – 50% in mid-summer as compared to 6 – 8% on control beaches. The author concluded that, despite adaptations of the benthic fauna to natural sediment dynamics, a high degree of sediment deposition, cumulative spatial disturbances along 10.8 km of beach, and the change in the coarse shelly character of the beach; beach fill resulted in a disturbance that exceeded biotic resilience of the benthic community for at least one warm season.

The Towns of Atlantic Beach, PKS, Indian Beach, and EI placed approximately 8.55 million cy of sand over approximately 21 miles of ocean shoreline along Bogue Banks in Carteret County from 2001 through 2005. The work was completed in several phases over a five-year period. Phases One and Two , which were completed during the winters of 2001/2002, 2002/2003, and 2003/2004 respectively, included nourishment of 12.5 miles of beach along PKS, Indian Beach, and EI with ~3.6 million cy of sand. Phase Three was completed between December 2004 and March 2005, including placement of ~700,000 cy from Bogue Inlet along about four miles of EI. Other smaller localized beach fill efforts also occurred during this period (see Section 2.0).

The biological monitoring plan for Phases One through Three of the Bogue Banks Renourishment Project (2001-2005) fulfilled the permit requirements set forth by federal and state resource agencies. The benthic sampling schedule performed over this period is summarized in Table 11. Monitoring was implemented to document the impact on invertebrates, fish, and endangered plants. The offshore borrow areas were left to adjust naturally and recolonize while other areas were being excavated. Fill sections were left to adjust naturally as soon as the required volumes were pumped into place and confirmed by surveys. Reports generated over the five year period were submitted as annual reports to the state and federal agencies (CSA 2002-2006). The monitoring plan scope (2001–2005) for benthic resources included the following goals:

Quantify the changes in benthic populations in the borrow areas.

Quantify the changes in benthic populations along the beach.

Compare impacted areas of the beach with unrestored areas.

Monitor the recovery and population of ghost crabs in the project area.

While the benthic sampling from 2001-2005 included all of Bogue Banks (CSA 2001-2006), the following summary is provided for only beaches affected by the proposed action alternative. Sampling was conducted twice annually (every June and November) for five years following the end of the Phase Two project on EI beach, or until organisms recovered to near or above baseline conditions. Two monitoring events were conducted in 2001 (June and November) to set baseline conditions for post-dredge monitoring comparison.

The seventh and final biological monitoring event for Phases One - Three took place in June 2005 (CSA 2006). For this monitoring event, spatial comparisons were made between dominant benthic invertebrates (mole crabs, coquina clams, and bristle worms). Baseline pre-dredge results from November 2001 were compared with the 2005 data in order to evaluate if the benthic community had returned to pre-dredge conditions.

Table 11. Summary on benthic monitoring events for Bogue Banks (2001-2005).

Date	Sample	Status
June 2001	Pre-Dredging, Spring Sample	Complete
November 2001	Pre-Dredging, Fall Sample	Complete
November 2001-April 2002	**Beach Nourishment, Phase 1**	Complete
June 2002	Post Dredging, Spring Sample	Complete
November 2002	Post Dredging, Fall Sample	Complete
November 2002-April 2003	**Beach Nourishment, Phase 2**	Complete
June 2003	Post Dredging, Spring Sample	Complete
November 2003	Post Dredging, Fall Sample	Complete
December 2004-March 2005	**Beach Nourishment, Phase 3**	Complete
June 2004	Post Dredging, Spring Sample	Complete
November 2004	Post Dredging, Fall Sample	Complete
June 2005	Post Dredging, Spring Sample	Complete
November 2005	Post Dredging, Spring Sample	Complete

Results of biological monitoring through June 2005 are summarized as follows:

PKS Beach – Four years after the beach fill events described above, species diversity and evenness returned to or above pre-dredge (baseline) levels. The numbers of mole crabs and bristle worms recovered to near or above baseline levels. Data showed that coquina clams and *A. virginiana* were still below baseline, but were recovering well.

Indian Beach – Species diversity and evenness decreased slightly since the previous annual post dredging monitoring event, but increased to near baseline levels. Species abundance was approaching baseline conditions.

EI Beach – Compared to previous pre-nourishment surveys, species diversity and evenness increased close to baseline levels. *A. virginiana* and mole crabs were below pre-dredge levels; however, abundance continued to increase. The numbers for coquina clams and bristle worms surpassed the baseline abundance values.

Control Sites – There were six control sites for Bogue Banks. Three control sites were located in EI (Stations 1–3). The other three control stations were located in Atlantic Beach (Stations 1–3). Three control sites were monitored for the final monitoring event, two from EI (Fairfax & Ocean, control Station 4), and one from Atlantic Beach (control Station 3). At Station 3, data revealed a decrease in species diversity and evenness since the previous annual sampling event. Total number of organisms increased since the last sampling event due to a spike in the bristle worm population. The abundance values for other species remained fairly constant throughout the study.

Both EI control stations showed a decrease in species diversity and evenness since the previous survey. There was an increase in number of organisms at the three stations due to spikes in populations from all four dominant species. Although species diversity, evenness, and abundance values were below baseline levels; data suggests that recovery of organisms were moving in a positive direction. The finalized biological monitoring (2005) for Phases One and Two confirmed that species present before nourishment had repopulated the nourished beaches by varying degrees, depending on the species (CSA 2006).

It is important to note, while the permit required benthic monitoring described above did qualitatively assess changes in abundance, species richness, and in species diversity and evenness over a 4-5 year period associated with three phases on beach construction, no quantitative analysis of temporal or spatial changes in the benthic community was performed. Due to all the pulsed cumulative disturbances across the 10.8 km area of beach fills over five years, accounting for observed temporal and spatial differences over time was not possible, nor was sorting out the effects of natural seasonal changes and spatial differences in sediment texture possible given the qualitative nature of the sampling design.

5.7.2 Nearshore and ODMDS Benthic Communities

Nearshore benthic communities between Morehead City and North Topsail Beach have been studied by Peterson et al. (1999), Coastal Science Associates Inc. (2006), the USACE (Hague and Massa 2010), CP&E (2004) and Dial Cordy (2012a). Although sampling sites and protocols varied, taxa in order of abundance remained relatively consistent including polychaetes, annelids, bivalve mollusks, amphipod crustaceans, echinoderms, and nematodes. The community of invertebrates sampled in each study is thought to be representative of those occupying this environment over a broad geographic area.

In association with the Bogue Banks 2001-2005 dredging and beach fill events (Section 2.0), CSA conducted a benthic study to assess effects of dredging benthic macroinvertebrates within borrow area B-2, located two miles south of Salter Path, Indian Beach offshore in an average depth of 35-42 ft. (CSA 2006). The three stations sampled within the borrow area and two outside controls were selected from those sampled by Peterson and Wells (2000). Sampling performed included a pre-dredging baseline study (November 2001) and annually for three years following dredging (CSA 2006). Summary results for borrow area B-2 are presented in Table 8 of the report and Tables 19-23 of Appendix 7.2. The dominant phyla found in this borrow area and the outside controls were polychaetes, crustaceans (amphipods), gastropods and bivalves. The benthic communities within the three borrow area stations showed a variable temporal and spatial response to dredging. Recovery in terms of species richness occurred within one year of dredging at two of the three stations, and in two-three years at the third station. Temporal changes in species richness were quite variable between dredged stations and between control stations, showing no definitive pattern. In terms of abundance, the population one year after dredging exceeded pre-dredge values within one year at two of the three stations. For the third dredged station, values never reached the baseline value but did increase each year. Abundance values on average were higher prior to dredging at the control stations than at the dredged stations. Species diversity and evenness showed similar trends with values exceeding baseline within one year of dredging at two of the three stations and in two-three years at the third station. Species richness and evenness values at the control stations were similar to those observed at the dredged stations. In summary, based on interpretation of the data contained in the report, the benthic community generally recovered within one year of dredging based on the metrics assessed.

In conjunction with the development of the Morehead City Harbor DMMP, the USACE Wilmington District investigated opportunities to expand the existing nearshore ODMDS off Bogue Banks (west of Beaufort Inlet) and create a new nearshore ODMDS off Shackleford Banks (east of Beaufort Inlet), in Carteret County, NC. To aid in the siting of the above locations, the benthic community was characterized over a broad area inshore of the existing Morehead ODMDS on the Beaufort Inlet ebb shoal (Hague and Massa 2010). This report included a description of macroinvertebrate and sediment sampling methods at 96 sample locations offshore of Beaufort; a summary of the laboratory analyses; a compilation of sediment and macroinvertebrate sampling results; and a determination of potentially least affected area(s). Using these results and associated index values, the stations were grouped based on similarity for low, medium, and high silt/clay content and corresponding fine sand content occurring within those groups. Stations with low species density (<627 number of species/m^2), diversity (<9.7), and/or richness (<2.8) were confirmed and presented within the groupings.

The faunal abundance of the major taxa is summarized below in Table 12. Dominant taxa based on percent composition included polychaetes (43%), crustaceans (25.7%), gastropods and bivalves (20.5 %), and echinoderms (1.6%). Based on single samples taken at the 96 stations, the total taxa collected was 260 species with 7,053 total individuals. The total number of individuals, total number of species, and density from the 96 stations ranged from 1-183 individuals, 1-57 total species, and 27.3-4,609 individuals/m^2, respectively. Simpson Diversity and Margelef's Richness ranged from 1-33.62 and 1.44-11.18, respectively.

Table 12. Summary of overall abundance of major benthic macroinfaunal taxonomic groups from the September 2009 sampling event.

Taxa	Total No. Taxa	% Total	Total No. Individuals	% Total
Annelida				
Oligochaeta	1	0.4	45	0.6
Polychaeta	88	33.8	3,098	43.9
Mollusca				
Bivalvia	38	14.6	744	10.5
Gastropoda	39	15.0	704	10.0
Scaphopoda	2	0.8	5	0.1
Arthropoda				
Malacostraca	66	25.4	1,814	25.7
Ostracoda	1	0.4	8	0.1
Echinodermata				
Asteroidea	1	0.4	1	0.0
Echinoidea	4	1.5	70	1.0
Holothuroidea	3	1.2	17	0.2
Ophiuroidea	2	0.8	29	0.4
Other Taxa	15	5.8	518	7.3
Total	**260**		**7,053**

5.7.3 Hardbottom Benthic Resources

In January 2009, as part of an ongoing USACE shoreline analysis, nearshore groundtruthing investigations for potential hardbottom resources were undertaken along Bogue Banks from Beaufort Inlet to Bogue Inlet. A USACE designed protocol was implemented inshore of -25 ft NGVD and offshore beyond depth of closure. The groundtruthing locations were determined from previous side-scan back-scatter anomalies denoted in earlier geophysical surveys (Figure 13). Each geophysical survey irregularity was investigated as potential hardbottom resources. Based on groundtruth corroboration, each target was classified as varying

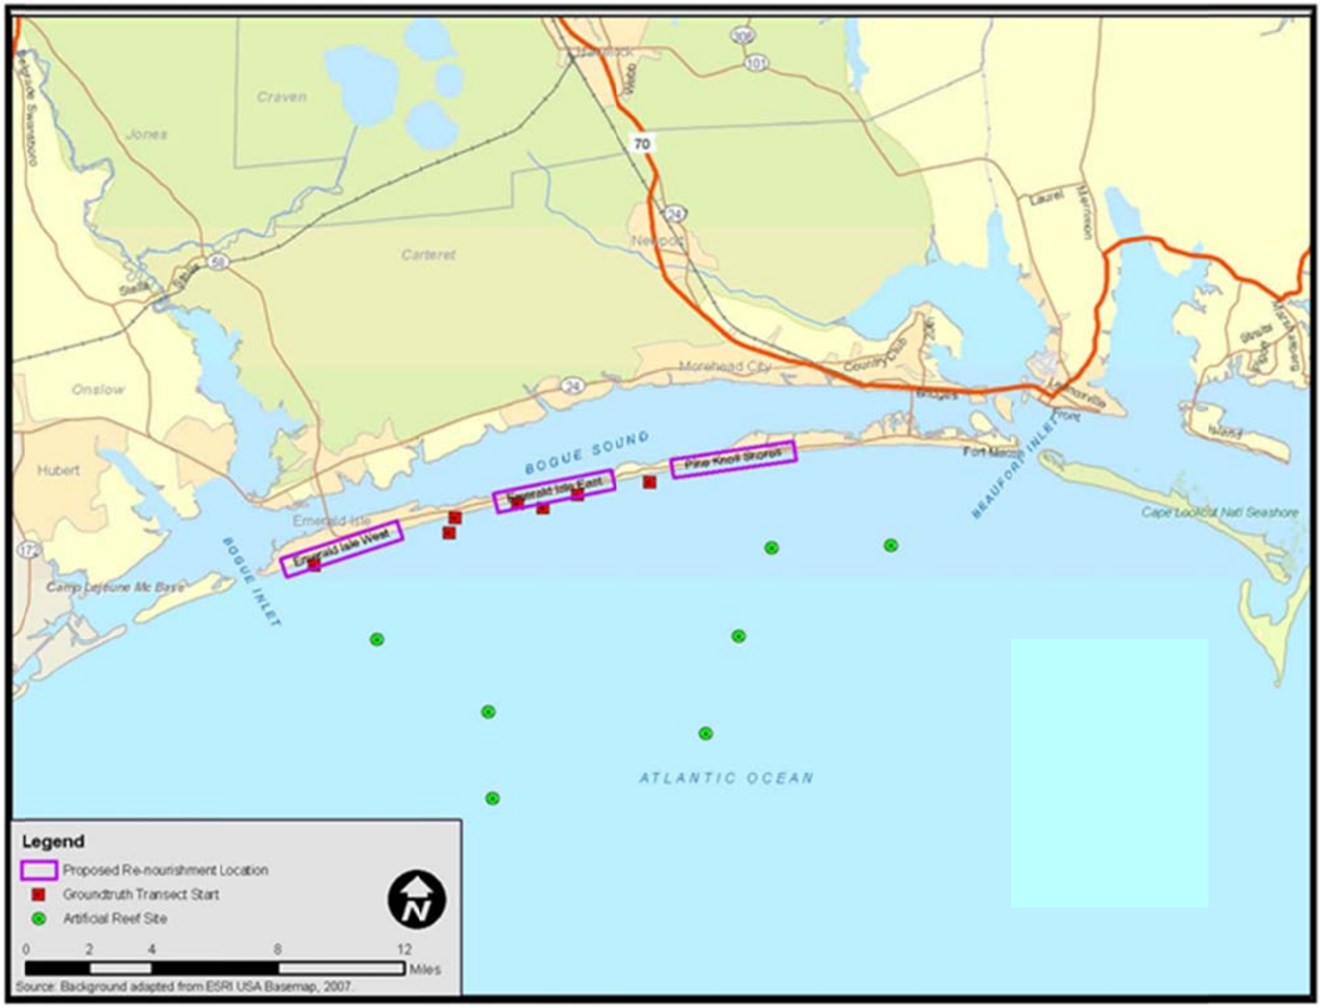

Figure 13. Hardbottom Groundtruthing and North Carolina Division of Marine Fisheries Artificial Reef Sites

textured sediments ranging from coarse shell-hash to fine dense clay and not as hardbottom resources (Anamar and CPE 2009). In addition, as part of a Carteret County 2011 archaeological remote sensing and target identification effort, the ODMDS was surveyed for cultural resources. This remote sensing effort confirmed no hardbottom resources are located within the ODMDS (Hall 2011). Based on the two studies discussed above (Anamar and CPE 2009, Hall 2011) no hardbottom benthic resources are located within the proposed Project area.

5.8 Fish and Wildlife Resources

5.8.1 Terrestrial

5.8.1.1 Maritime Shrub Thickets

The maritime shrub thicket community normally occurs landward of the dune where it is protected from salt spray and the full force of ocean winds. The maritime shrub thicket occurs sporadically along the backside of Bogue Banks; along the inlet spits, within upland disposal areas, and interspersed with marsh areas bordering the sound. However, a large portion of the maritime shrub thicket historically found within this barrier island community has been heavily impacted by development. Dominant shrubs and trees in the community are wax myrtle (*Myrica cerifera*), yaupon (*Ilex vomitoria*), red cedar (*Juniperus virginica*), live oak (*Quercus virginiana*), and loblolly pine (*Pinus taeda*). Vines are also common with greenbriar (*Smilax bonanox*), pepper-vine (*Ampelopsis arbore*a), and grape (*Vitus rotundifolia*) being particularly abundant. The community type offers excellent cover for neotropical migrating songbirds. Other important species that may be found in the maritime thicket include the seaside sparrow (*Ammodramus maritimus*), painted bunting (*Passerina ciris*), saltmarsh sharp-tailed sparrow (*A. caudacutus*), Nelson's sharp-tailed sparrow (*A. nelsoni*), as well as marsh wrens (*Cistothorus palustris*) and sedge wrens (*C. platensis*). Raptors may also be found during migration [e.g., American kestrel (*Falco sparverius*), merlin (*F. columbarius*), peregrine falcon (*F. peregrines*), bald eagle (*Haliaeetus leucocephalus*), and northern harrier (*Circus cyaneus*)].

5.8.1.2 Beach and Dune

Beach and dune communities that may be impacted occur adjacent to and within the beach placement areas of EI and PKS (approximately 78 acres). Terrestrial habitat types within these areas include sandy or sparsely vegetated beaches and vegetated dune communities. The first line of stable vegetation is outside or landward of the proposed project limits.

Mammals occurring in this environment are opossums (*Didelphis virginiana*), cottontails (*Sylvilagus* spp.), red foxes (*Vulpes vulpes*), gray foxes (*Urocyon cinereoargenteus*), raccoons (*Procyon lotor*), feral house cats (*Felis catus*), shrews (*Soricidae* spp.), moles (Talpidae), voles (*Microtus arvalis*), and house mice (Mysticeti).

The beach and dune community could be considered depauperate in both plants and animals. The beach environment is severe because of constant exposure to salt spray, shifting sands, wind, and sterile soils with low water retention capacity. Therefore, plant and animal species diversity within the beach and dune community is low. Common vegetation of the upper beach includes beach spurge (*Euphorbia polygonifolia*), sea rocket (*Cakile edentula*), and pennywort (*Hydrocotyle bonariensis*). The dunes are more heavily vegetated and common species are American beach grass (*Ammophila breviligulata*), panic grass (*Panicum amarum*), sea oats (*Uniola paniculata*), broom straw (*Andropogon virginicus*), seashore elder (*Iva imbricata*), and salt meadow hay (*Spartina patens*) (Nash 2003). Seabeach amaranth has been documented on Bogue Banks and is addressed in the BA [Dial Cordy and Associates Inc. (DC&A) 2012a]. Important macroinvertebrates of the beach/dune community are the mole crabs, coquina clams, and ghost crabs (*Ocypode quadrata*) (see Section 6.7)

Ghost crabs occupy the upper zone of the beach environment and function as an important predator in the beach community. Up to 60 percent of their diet consists of mole crabs and up to 25 percent consists of coquina clams (Wolcott 1978). During the sea turtle nesting season, ghost crabs are also known to prey on incubating sea turtle eggs and newly hatched sea turtle hatchlings. *O. quadrata* is the only ghost crab occurring in the southeastern United States and, though little is known regarding its life history, its reproductive and larval components most likely reflect that of other decapods. Although timing of recruitment is poorly understood, recruitment most likely occurs between late spring and early fall (Hackney et al. 1996).

5.8.2 Marine

Habitats within the Proposed Action Alternative borrow area (ODMDS) consist of both open-ocean water and bottom sediments; the latter includes coarse marls, sand, and silty sands deposited inside the ODMDS by previous and ongoing navigation maintenance disposal projects. Habitats along the transport pathway from the ODMDS to the placement area consist of nearshore water column and bottom habitat that ranges from soft muds to firm sands. The nearshore water column supports zooplankton and phytoplankton assemblages that serve as food for juvenile fish and commercially important invertebrates. Demersal and pelagic fish inhabit the water column (Section 5.9), including a number of federally managed species. Several species of marine mammals and sea turtles are seasonal residents (Section 5.10).

Marine waters in the vicinity of the beach nourishment placement areas and offshore borrow site provide habitat for a variety of commercial and recreational fish. Kingfish (Sciaenidae), spot (*Leiostomus xanthurus*), bluefish (*Pomatomus saltatrix*), weakfish (*Cynoscion regalis*), spotted sea trout (*Cynoscion nebulosus*), southern flounder (*Paralichthys lethostigma*), red drum (*Sciaenops ocellatus*), king mackerel (*Scomberomorus cavalla*), and Spanish mackerel (*S. maculates*) are actively fished from boats, the beach, and local piers. According to the NCDMF commercial and recreational harvest statistics, the species noted above compose an average of approximately 28 percent of the total pounds of fish landed in NC in 2007 (http://www.ncfisheries.net/statistics/index.html). The surf zone typically exhibits a high diversity of fish fauna. According to data collected from surf zone seine sampling along the SAB, 130 fish species are known from the surf zone between NC and southern Georgia; of which, 47 species have been recorded from NC beaches. The major recruitment period for juvenile fishes to surf zone nurseries is late spring through early summer. The waters also accumulate juvenile, ocean spawning, and estuarine-dependent fish and invertebrates in the late winter and early spring before their transport through the inlets (Hackney et al. 1996).

As discussed in the above sections, the total placement includes 267 acres of which 78 acres is the dry sand beach and the intertidal zone area (approximately 189 acres below MHW, approximately 147 acres below MLW) serves as the primary habitat for invertebrates. These invertebrates, which are adapted to the high-energy, sandy-beach environment include: ghost crabs, mole crabs, coquina clams, amphipods, isopods, and polychaetes. The species are not commercially important; however, they provide an important food source for surf-feeding fish and shore birds. Offshore bottoms also provide habitat for benthic-oriented organisms as described in Section 5.7 Habitat Areas of Particular Concern (HAPCs) include hardbottom areas which generally support a diversity of soft corals, anemones, and sponges; providing habitat for reef fish such as black sea bass (*Centropristis striata*), red porgy (*Pagrus pagrus*), and groupers (*Epinephelus* spp.). Hardbottoms are also attractive to pelagic species such as king mackerel, Spanish mackerel, amberjack (*Seriola dumerili*), and cobia (*Rachycentron canadum*).

5.8.2.1 Non-ESA-Listed Marine Mammals

A total of 38 marine mammal species have been reported from coastal waters between Cape Hatteras and New River Inlet (Department of the Navy 2008). These species include 33 cetaceans (whales, dolphins, and porpoises), four pennipeds (seals, sea lions, and fur seals), and one sirenian (West Indian manatee) (Table 13). All marine mammals are protected under the Marine Mammal Protection Act (MMPA) of 1972, which prohibits the take (harassment or injury) of marine mammals in United States waters. A number of these 38 species are federally listed as threatened or endangered, including the North Atlantic right whale, humpback whale, sei whale, fin whale, blue whale, sperm whale, and West Indian manatee. These federally listed species are addressed in-depth in Section 5.10 and in the BA (DC&A 2012a). The vast majority of the remaining 26 non-listed species are not expected to occur in nearshore waters. Many of these species are typically found in offshore waters near the continental shelf break or beyond. A number of other species are known only from stranding records or rare sightings considered extralimital to their normal distribution. Marine mammal occurrence data compiled by the Department of the Navy (2003, 2008) indicate that the only non-listed species that are expected to occur regularly in the project area are the bottlenose dolphin and Atlantic spotted dolphin.

Bottlenose dolphins may be present in both estuarine and nearshore marine waters throughout the year, although estuarine occurrences peak during summer and most winter sightings are from the nearshore ocean (Department of the Navy 2003, 2008). Bottlenose dolphins along the South Atlantic coast include both resident and migratory populations. Studies indicate the presence of a year-round resident bottlenose dolphin population in the vicinity of Beaufort, North Carolina. This resident Beaufort population is the northernmost documented site of year-round bottlenose dolphin residency in the western North Atlantic (Koster et al. 2000). Atlantic spotted dolphins regularly occur in inshore waters south of Chesapeake Bay (Mullin and Fulling 2003). Nearshore sightings of Atlantic spotted dolphins have been recorded in the vicinity of the project area during winter, spring, and summer (Department of the Navy 2008).

Table 13. Marine mammals reported from coastal waters between Cape Hatteras and New River Inlet.

Common Name	Species Name	Status
North Atlantic right whale	*Eubalaena glacialis*	Endangered
Humpback whale	*Megaptera novaeangliae*	Endangered
Minke whale	*Balaenoptera acutorostrata*	
Bryde's whale	*Balaenoptera edeni*	
Sei whale	*Balaenoptera borealis*	Endangered
Fin whale	*Balaenoptera physalus*	Endangered
Blue whale	*Balaenoptera musculus*	Endangered
Sperm whale	*Physeter macrocephalus*	Endangered
Pygmy sperm whale	*Kogia breviceps*	
Dwarf sperm whale	*Kogia sima*	
Cuvier's beaked whale	*Ziphius cavirostris*	
True's beaked whale	*Mesoplodon mirus*	
Gervais' beaked whale	*Mesoplodon europaeus*	
Blainville's beaked whale	*Mesoplodon densirostris*	
Sowerby's beaked whale	*Mesoplodon bidens*	
Northern bottlenose whale	*Hyperoodon ampullatus*	
Rough-toothed dolphin	*Steno bredanensis*	
Bottlenose dolphin	*Tursiops truncatus*	
Pantropical spotted dolphin	*Stenella attenuata*	
Atlantic spotted dolphin	*Stenella frontalis*	
Spinner dolphin	*Stenella longirostris*	
Striped dolphin	*Stenella coeruleoalba*	
Clymene dolphin	*Stenella clymene*	
Short-beaked common dolphin	*Delphinus delphis*	
Fraser's dolphin	*Lagenodelphis hosei*	
Risso's dolphin	*Grampus griseus*	
Melon-headed whale	*Peponocephala electra*	
Pygmy killer whale	*Feresa attenuate*	
False killer whale	*Pseudorca crassidens*	
Killer whale	*Orcinus orca*	
Long-finned pilot whale	*Globicephala melas*	
Short-finned pilot whale	*Globicephala macrorhynchus*	
Harbor porpoise	*Phocoena phocoena*	
Harbor seal	*Phoca vitulina*	
Gray seal	*Halichoerus grypus*	
Harp seal	*Pagophilus groenlandicus*	
Hooded seal	*Cystophora cristata*	
West Indian manatee	*Trichechus manatus*	Endangered

Source: Geo-Marine 2008
Note: Those species identified as endangered under the ESA are addressed in the BA (DC&A 2012a).

5.8.3 Avian

Birds common to the project areas' nearshore ocean are loons (*Gavia* spp.), grebes (*Podilymbus* spp.), northern gannets (*Morus bassanus*), cormorants (*Phalacrocorax* spp.), scoters (*Melanitta* spp.), red-breasted mergansers (*Mergus serrator*), gulls (*Larus* spp.), and terns (*Sterna* spp.) (LeGrand 1983, USACE 2007, Sauer et al. 2008). The habitats and food sources of such seabirds are within the marine environment; whether nearshore, offshore, or pelagic. The species can be divided into four groups by their feeding strategies which are reflected in their anatomy, physiology, and habitat niche: surface feeders; surface swimmers/pursuit divers; plunge-divers; and scavengers/pirates (i.e., steal from other birds). The waters in proximity of the proposed action area are very important to migrating and wintering northern gannets, loons, and grebes because of the abundant resources associated with inlet shoal features and Cape Lookout/Shackelford Banks. These inlet areas and associated shoals are considered EFH for several managed fish and shrimp (Caridea) species and are also considered HAPCs [South Atlantic Fishery Management Council (SAFMC) 1998, South Atlantic Region 2008a and 2008b]. These diverse marine and estuarine communities support a variety of fish species that provide a forage base for migrating and wintering sea birds. Terns feed by diving on insects and small fish and the black skimmer (*Rynchops niger*) feeds on shrimp or small fish by flying just above the water with the tip of its long lower mandible shearing the surface. The USFWS indicates that sea ducks raft in large numbers in the nearshore ocean waters of the project area during spring and fall migrations. Ducks, geese, and many kinds of shorebirds may also be found here during the spring and fall (Sauer et al. 2008).

The beaches and inlets of the project vicinity are heavily used by migrating shorebirds. However, dense development and high public use of project area oceanfront beaches may reduce the beachfront value to shorebirds. Though most of the project area is heavily developed, the spits at each end of the island provide important habitat adjacent to the inlets and associated intertidal shoals. These areas offer high value habitat for breeding birds including terns, black skimmers, piping plovers (*Charadrius melodus*), Wilson's plovers (*C. wilsonia*), and American oystercatchers (*Haematopus palliatus*). Additionally along the ocean beach, black-bellied plovers (*Pluvialis squatarola*), ruddy turnstones (*Arenaria interpres*), whimbrels (*Numenius phaeopus*), willets (*Tringa semipalmata*), red knots (*Calidris canutus*), semi-palmated sandpipers (*C. pusilla*), and sanderlings (*C. alba*) may be found (LeGrand 1983, USACE 2007, and Sauer et al. 2008). Table 15 provides a more complete list of waterbirds found in the project vicinity. The project area dunes support fewer numbers of birds, but can be very important habitats for resident species and migratory songbirds. The maritime forest nearby the project area is important for painted buntings; in the herbaceous dune areas, the American kestrel, merlin, bald eagle, peregrine falcon, northern harrier, and other raptors may be found during migration. Other birds occurring in the area are mourning doves (*Zenaida macroura*), swallows (Hirundinidae), fish crows (*Corvus ossifragus*), starlings (Sturnidae), meadowlarks (*Sturnella magna*), red-winged blackbirds (*Agelaius phoeniceus*), boat-tailed grackles (*Quiscalus major*), and savannah sparrows (*Passerculus sandwichensis*) (Johnson and Dechant-Shaffer 2002, Sauer et al. 2008).

The piping plover is federally listed as threatened under the ESA. Additional information regarding piping plover occurrences in the project area is provided in Section 5.10.3 and in the BA (DC&A 2012a). The red knot is currently a candidate for federal listing, and a number of additional shorebirds and waterbirds are listed by the State of NC as endangered threatened, special concern, or significantly rare (Table 14). These species may be found year-round in the study area during the breeding, migration, and wintering seasons with peak abundance occurring in the summer months. All these bird species may use the project area for roosting, foraging, breeding, and nesting (Potter et al. 1980).

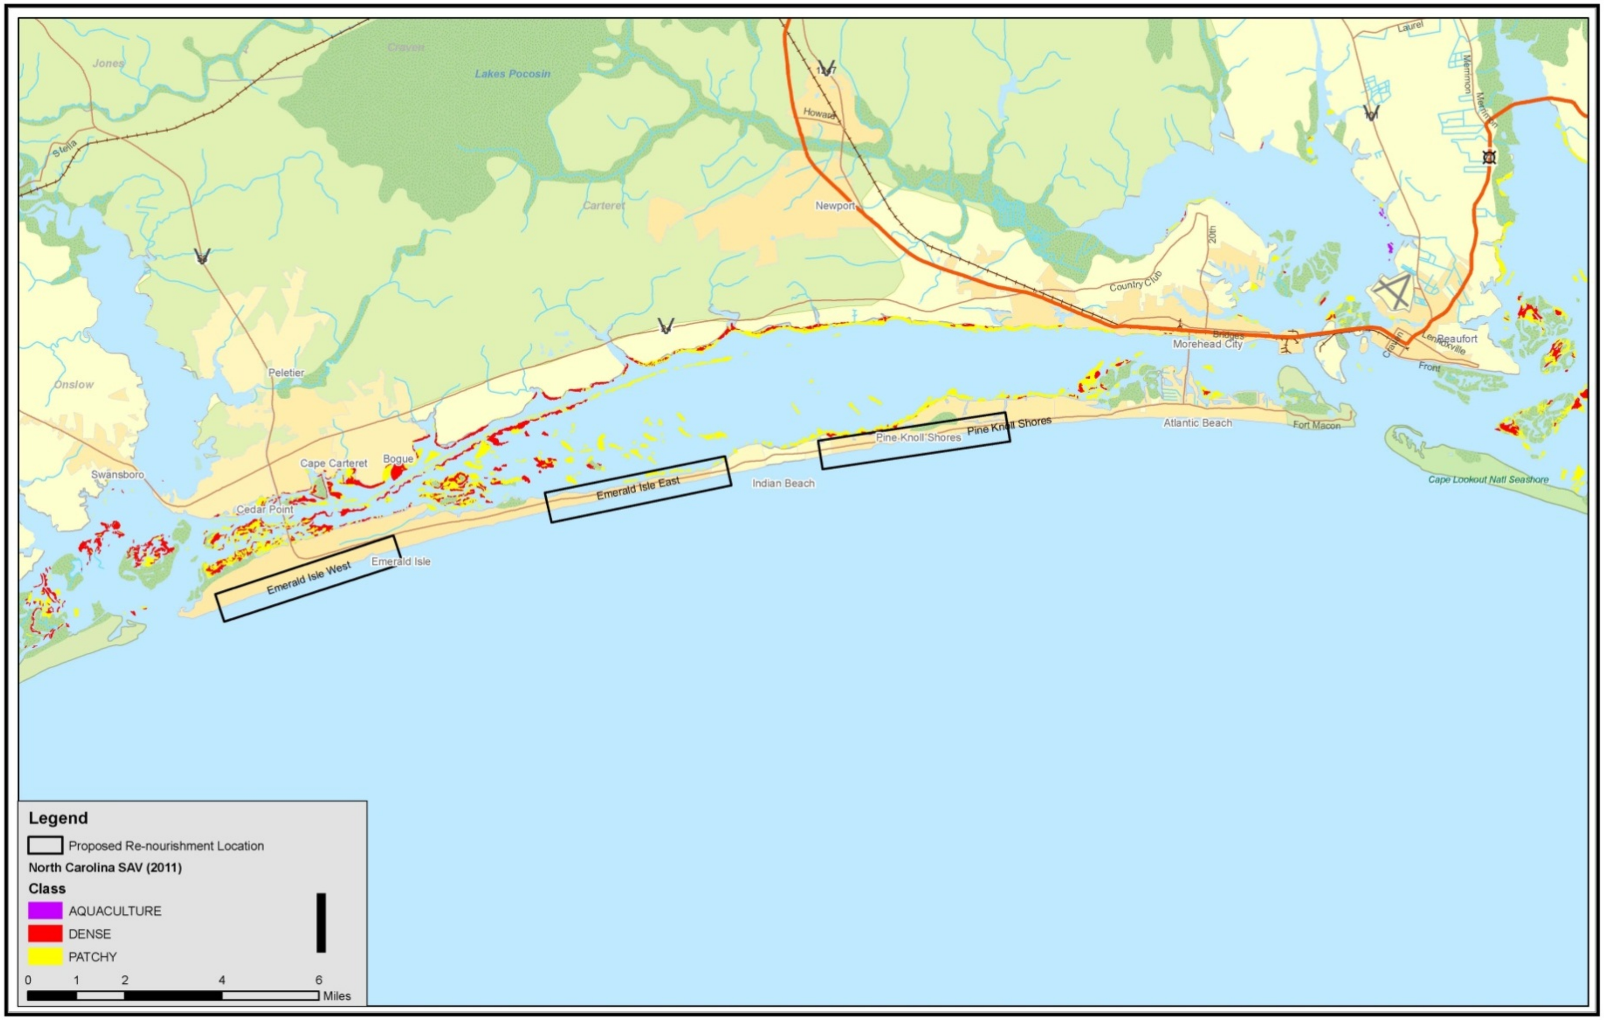
[a]. Season: B = Breeding, M = Migrating, W = Wintering
[b]. Federal status: Endangered (E), Threatened (T), Candidate (C) (http://www.fws.gov/endangered/).
*Two distinct piping plover populations are recognized under the ESA. The piping plover in the Great Lakes is an endangered species and the Northern Great Plains and Atlantic Coast piping plovers are threatened. Both populations are found on the North Carolina coast.
[c]. North Carolina Status: Endangered (E), Threatened (T), Special Concern (SC), Significantly Rare (SR).
E, T, and SC status species are given legal protection status by the NCWRC. SR status is defined as any species which has not been listed by the NCWRC as E, T, or SC species; but which exists in the state in small numbers and has been determined by the North Carolina Natural Heritage Program to need monitoring (http://www.ncnhp.org/Pages/heritagedata.html).

5.9 Essential Fish Habitat and Managed Species

As amended, the MSFCMA (P.L. 94-265) set forth new requirements for the NMFS, regional fishery management councils (FMC), and other federal agencies to identify and protect important marine and anadromous fish habitat. Those amendments established procedures for identifying EFH and a requirement for interagency coordination to further the conservation of federally managed fisheries. As mandated in the Magnuson-Stevens Act and in coordination with NMFS, several fishery management councils the SAFMC, Mid-Atlantic Fishery Management Council (MAFMC), and the Atlantic States Marine Fishery Commission oversee and manage species and EFHs found within the Project area.

The SAFMC manages marine areas including live/hardbottoms, coral and coral reefs, artificial/manmade reefs, *Sargassum*, and the marine water column as well as many estuarine features. Similarly, the MAFMC manages the marine water column as well as estuarine areas (SAR 2008a, MAFMC 2011). The ASMFC coordinates conservation and management between states sharing near shore fishery resources while working cooperatively with the United States East Coast Fishery Management Councils (ASMFC 2011). As discussed in DC&A 2012b, the estuarine marshes are essential habitat to many managed species and serve multiple functions to various finfish life-stages (Street et.al. 2005). Considered HAPCs, the nearest North Carolina Division of Marine Fisheries (NCDMF) designated primary nursery areas (PNA) are approximately three miles from Bogue and Beaufort Inlets; Hawkins and Dicks Creek, Calico and Turner Creek, respectively. Archer Creek is approximately 0.5 miles from a recipient beach location, but separated by EI proper and the nearest SAV's are approximately 0.5 miles from both Bogue and Beaufort Inlets (NCDMF 2011) (Figure 14).



Source: NCDMF 2011

Figure 14. Existing SAV areas within the vicinity of Bogue Banks

The Project Action Alternative proposes no efforts within Beaufort or Bogue Inlets, offshore relief areas, or within Bogue or Back Sounds where the above EFH locations would or could exist. The EFH areas within the Project area include the marine water column and unvegetated sandy bottoms.

Table 15 lists the federally managed fish species potentially found in the Project area for which Fishery Management Plans (FMP) have been developed by the SAFMC, MAFMC, and NMFS. In addition, Table 8 lists the species' life stages and area locations that have designated EFH. The categories of EFH and HAPC as well as a description of specific HAPC resources (i.e., hardbottom, coral, artificial reef, and *Sargassum*) in the Project area are provided in the March 2012 EFH Assessment prepared by DC&A. The fish species and habitats shown require special consideration to promote their viability and sustainability. This section briefly summarizes what can be found in more detail in the EFH Assessment (DC&A 2012b).

5.9.1 State Managed Fish Species

The state has prepared FMPs for several fish species that utilize resources within the study area. These species include striped mullet (*Mugil cephalus*), spotted sea trout, southern flounder, three species of sea mullet or southern kingfish (*Menticirrhus americanus*), gulf kingfish (*M. littoralis*), and northern kingfish (*M. saxatilis*), striped bass (*Morone saxatilis*), and red drum. Of these species, the red drum and southern flounder are also federally managed by the SAFMC. All of these species use the project area during a portion of their life cycle. The following subsections contain a summary of excerpts contained in the state FMPs (http://www.ncdmf.net/fmps/index.html) and provide detail pertaining to life cycle requirements and habitat use of each species within the study area.

5.9.1.1 Striped Mullet

The striped mullet fishery has played a significant role in the history of the NC commercial and recreational fishing industry and was ranked as the most abundant and important saltwater fish of NC in the early 1900's (NCDMF 2006a). Currently, the NC striped mullet commercial fishery is the largest along the United States Atlantic seaboard. However, recognizing the increased fishing pressure, the NC stock has been designated a species of concern since 1999.

Striped mullet are found in almost all shallow marine and estuarine habitats including beaches, tidal flats, lagoons, bays, rivers, channels, marshes, and grass beds. Habitat use varies greatly based on life history stages, seasons, and location (NCDMF 2006a).

Adult spawning migration occurs in fall and winter months in the southeastern United States, with larvae mostly found within the offshore surface waters during the winter and spring months. Larval shoreward migration is likely facilitated by onshore, wind-driven, (Ekman) drift; characteristic of southeastern United States winter wind patterns.

5.9.1.2 Spotted Sea Trout

Spotted sea trout, also known as speckled trout, is a highly sought after commercial and recreational fish in NC (NCDMF 2010). They are harvested throughout the year with a large peak in the fall/winter (October – February) and a small peak in the spring (April – May). The spawning season for spotted seatrout varies depending on location. In NC, spawning occurs from April to October, with a peak in May through June. Spawning takes place on or near seagrass beds, sandy banks, shell reefs, near the mouths of inlets, and off the beach (NCDMF 2010). Larvae utilize the passive transport of tidal flow to migrate into and within estuaries for settlement. Spotted seatrout have distinct seasonal migrations and migrate to deeper, warmer water in the estuaries and ocean during winter months and return to oyster beds and shallow bays and flats as the water warms.

The diet of seatrout varies and consists of copepods, mysids, amphipods, polychaetes, and shrimp within the small size class (<5.5 inches) and a variety of fishes [i.e. menhaden (*Brevoortia* spp.), spot, striped mullet] and shrimp as they get larger (>5.5. inches). Spotted seatrout use the water column habitat for spawning, egg and larval transport, foraging, and movement throughout the estuary and nearshore coastal areas. Of the available habitats, marine soft bottom has been noted to function as important habitat for spotted seatrout, especially during summer and winter estuarine temperature extremes. The complex structure of shell bottom also functions as an important nursery, foraging area, and refuge for this species. The invertebrates and small resident finfish living on and among shell bottom provide juvenile and adult spotted seatrout with an important forage base.

5.9.1.3 Southern Flounder

NCDMF (2005) considers the southern flounder the most economically important commercial finfish species in NC and it is a significant component of the recreational fishery. Summer flounder was historically the primary flounder species landed in the State until the decline in the fishery in the mid-1980s, at which point the harvest of southern flounder began to increase. Summer Flounder are currently federally managed by the MAFMC. The majority of the landings of southern flounder in NC have historically come from Pamlico, Albemarle, and Core sounds.

Habitat use patterns of southern flounder vary among riverine, estuarine, and coastal waters depending on life stage. In NC, adult southern flounder inhabit estuarine waters during the spring and summer; preferring the lower salinity portions of the sounds, rivers, and bays. Adults typically migrate out of the rivers and estuaries in the fall in order to spawn over soft bottom shoals in the ocean during the winter months. Following the spawning period, adult flounder return through the inlets to the estuaries and rivers. Planktonic larvae remain in the offshore waters for between 30 to 60 days before they are carried through ocean inlets into estuaries through passive transport in late winter. The southern flounder's diet consists of mainly fish [including mullet, menhaden, shad (*Alosa sapidissima*), anchovies (*Engraulis* spp.), pinfish (*Lagodon rhomboides*), mojarra (*Eucinostomus gula*), and Atlantic croaker (*Micropogonias undulatus*)], crabs [including blue (*Callinectes sapidus*), mud (*Scylla serrata*), and stone crabs (*Menippe mercenaria*)], mysids, mollusks, penaeid shrimp (*Penaeus* spp.), and amphipods - depending on life stage.

5.9.1.4 Sea Mullet

Three species of kingfish occur in NC: southern kingfish, gulf kingfish, and northern kingfish. Kingfish are demersal members of the drum family (Sciaenidae). Southern kingfish is the most abundant kingfish in the SAB, including the project area, and Gulf of Mexico. These species support significant recreational and commercial fisheries (NCDMF 2007).

All three species are short-lived demersal fish that inhabit nearshore ocean and estuarine habitats ranging from nearly fresh [2.0 parts per thousand (ppt)] to hypersaline (36.6 ppt) waters depending on the species. Kingfish spawn during early spring to early fall, and as temperatures cool; southern kingfish move to deeper, warmer water or migrate south. Spawning locations are unknown off NC; however, anecdotal evidence suggests spawning occurs in soft bottom habitat of the nearshore ocean and possibly inshore (NCDMF 2007). Juvenile kingfish are spring-summer residents of the surf zone with abundances peaking in the spring.

The kingfish are opportunistic epi-benthic or planktonic feeders; feeding predominantly on polychaetes, crustaceans, copepods, and small fishes as adults. The re-suspension and retention of inorganic nutrients in the surf zone, an important nursery area for kingfish, creates a food rich environment for larvae and juveniles. Additionally; intertidal flats, ocean beaches, and inlets are dynamic soft bottom features comprised of shifting sands; which also serve as a highly valuable foraging area.

5.9.1.5 Striped Bass

Striped bass which inhabit coastal rivers and estuaries in NC exhibit two differing life history strategies (NCDMF 2004a). Some portion of the stock is migratory; with mature adults residing in the Atlantic Ocean, returning to the river to spawn in the spring, and migrating back to the ocean for the summer and fall months. Both migratory and resident life history strategies necessitate use of river segments with sufficiently flowing waters for spawning, riverine and estuarine nursery habitat for egg; larval; and early juvenile stages. Estuarine as well as oceanic habitats are used by sub-adults and mature adult fish.

Migratory striped bass use the water column of inland and coastal rivers for spawning. They migrate to and from the spawning grounds of rivers and adjacent estuaries and inlets to the Atlantic Ocean, where they spend much of the spring, summer, and fall. Striped bass adults are reported to remain relatively close (4-5 mi) to shore when in the ocean.

5.9.1.6 Red Drum

As described by NCDMF (2008), red drum is common along the Atlantic coast over a wide range of habitats from Chesapeake Bay to Key West, Florida. Red drum spawning occurs at night in or around major estuaries and inlets within a salinity range of 25-35 ppt and temperatures between 22-30 °C. In NC, larvae are found over a wide range of salinities (0-33 ppt). Fertilized eggs and larvae are passively transported through the water column from the spawning sites to shallow bays and estuaries via wind and tidal currents. The majority are transported to the upper reaches of the estuary where they settle out in shallow, low-salinity nursery areas with abundant food supplies, such as coastal creeks, protected bays with sandy or muddy bottoms, and grass beds.

Red drum are eurythermal and in NC they have been collected over a wide range of habitat types and associated temperature and salinity ranges. During extreme cold conditions in the winter, small juvenile red drum leave the shallow water habitats for channels and other deep water areas and then return to shallow water areas the following spring as water temperatures rise. Once mature, red drum tend to spend more time in the ocean; but are still estuarine dependent as they come inshore to feed, develop, and spawn. Red drum forage on a variety of prey items, depending on their life stage and associated habitat preference.

In the fall, a portion of the sub-adult fish residing in the rivers move toward higher salinity areas such as the barrier islands' grass flats and shoals, inlets, and the surf. Sub-adults residing near coastal inlets and barrier islands during the summer likely enter the surf in the fall. During the spring, adult red drum occur along the beaches and inlets for one to two months as they move from offshore wintering grounds. By late September, most adult drum are found around the coastal inlets, outer bars, shoals, and along the beaches where they remain through November before moving offshore for winter. The EFH prepared for this project describes habitats for this species in detail (DC&A 2012b).

5.9.1.7 Shellfish

The commercial fishing industry is a very important economic component to NC. According to Burgess and Bianchi (2004), shellfish (i.e., bivalves, crustaceans, and others) as a whole are more economically important than finfish in NC. The commercial shell fishing industry in NC consists of Eastern oysters (*Crassostrea virginica*), hard clams (*Mercenaria mercenaria*), bay scallops (*Argopecten irradians*), blue crabs, and shrimp. Between 1972 and 2002, the total shellfish composition of NC commercial landings has varied. Total shellfish landings have exhibited an overall increase, and the value for shellfish landed exhibited an overall increase. From 1994 to 2002, the majority of shellfish landings and revenue was attributable to hard blue crabs and shrimp (Burgess and Bianchi 2004). Although important resources in and around Bogue Banks, the Proposed Action Alternative does not include estuarine habitats associated with shellfish species other than blue crabs and shrimp. Therefore, other species such as hard clams and eastern oysters are not further discussed or evaluated within this document.

5.9.1.8 Blue Crabs

Blue crabs are managed under the NC blue crab FMP dated December 2004 (NCDMF 2004b). With increasing concerns over fluctuating blue crab landings and increasing fishing effort, numerous requests have been made to further protect the spawning stock of blue crabs in NC. The blue crab life cycle consists of an offshore phase and an estuarine phase. Blue crabs use a wide range of habitats depending on their life stage, sex, maturity, and associated salinity preferences (NCDMF 2004b). After mating, females migrate to high-salinity waters in lower estuaries, sounds, and nearshore spawning areas. Most females spawn for the first time two to nine months after mating, usually from May through August the following season. Juveniles (i.e., typically 2.5 millimeters [mm] wide) gradually migrate into shallower, less-saline waters in upper estuaries and rivers where they grow and mature. When air temperatures drop below 50 °F, adult crabs leave shallow, inshore waters and seek deeper areas where they bury themselves in mud and remain in a state of torpor throughout the winter (Zinski 2006).

5.9.1.9 Shrimp

Shrimp are managed under the NC shrimp FMP dated April 2006 (NCDMF 2006b). The most common commercially important species in NC are the Penaeid shrimp: white shrimp (*Litopenaues setiferus*), pink shrimp (*Farfantepenaeus duorarum*), and brown shrimp (*F. aztecus*). Penaeid shrimp are spawned in the ocean and carried by tides and wind driven currents into the estuaries. By late summer and fall, they return to the ocean to spawn (NCDMF 2009). The most significant threat to shrimp stocks is loss or degradation of habitat from pollution or physical alteration. Critical habitat types that support juvenile shrimp nursery areas include salt marsh and inshore seagrass habitat (NCDMF 2006b). The EFH prepared for this project described in detail habitats for this species (DC&A 2012b).

5.10 Threatened and Endangered Species

The ESA of 1973, as amended (16 U.S.C. 1531–1543), provides a program for the conservation of threatened and endangered (T&E) plants and animals and the habitats in which they are found. The lead federal agencies for implementing the ESA are the U.S. Fish and Wildlife Service (USFWS) (http://www.fws.gov/) and the National Marine Fisheries Service (NMFS) (http://www.nmfs.noaa.gov/). The USFWS has primary responsibility for terrestrial organisms (including sea turtles on land) as well as some marine species such as manatees, while the responsibilities of NMFS are mainly marine wildlife such as whales, dolphins, pinnipeds, sea turtles and anadromous fish [i.e., shortnose (*Acipenser brevirostrum*) and Atlantic sturgeons (A. oxyrhynchus)]. Section 7 of the ESA requires federal agencies to use their legal authorities to promote the conservation purposes of the ESA and to consult with the USFWS and NMFS, as appropriate, to ensure that effects of actions they authorize, fund, or carry out will not jeopardize the continued existence of listed species or result in the destruction or adverse modification of designated critical habitat of such species.

In accordance with Section 7 (a)(2) of the ESA, BOEM and the USACE have been in consultation with the USFWS and NMFS to ensure that effects of the proposed Post-Irene Renourishment Project would not jeopardize the continued existence of listed species or result in the destruction or adverse modification of designated critical habitat of such species.

Updated lists of T&E species for the project area (Carteret County, NC) were obtained from the NMFS (Southeast Regional Office, St. Petersburg, FL) (http://sero.nmfs.noaa.gov/pr/endangered%20species/specieslist/PDF2010/South%20Atlantic.pdf) and the USFWS (Field Office, Raleigh, NC) (http://www.fws.gov/raleigh/es_tes.html) websites. These lists were combined to develop a composite list of T&E species that could be present in the project area based upon their geographic range. However, an actual species occurrence in the area would depend upon the availability of suitable habitat, the season of the year relative to a species' temperature tolerance, and migratory habits. A summary of the likelihood of occurrence for protected species is provided below. Additional information is provided in the BA (DC&A 2012a).

5.10.1 Whales

5.10.1.1 North Atlantic Right Whale (Endangered)

The North Atlantic right whale (*Eubalaena glacialis*) population is divided into a western North Atlantic population, which numbers approximately 300 animals, and an eastern North Atlantic population that is nearly extinct (these whales would not be present in the proposed action area). Western North Atlantic right whales range from wintering and calving areas off the coast of the southeastern United States to summer feeding and nursery areas that extend northward from New England to Nova Scotia. Important summer feeding and nursery areas are located in Massachusetts Bay, Cape Cod Bay, the Great South Channel (east of Cape Cod), as well as the Bay of Fundy and the Scotian Shelf in Canada. In the fall, a portion of the western North Atlantic population (consisting primarily of pregnant females, females with young calves, and some juveniles) migrate southward to nearshore continental shelf waters off the coast of southern Georgia and northern Florida. Calving takes place from December through March, and the peak migration periods are November/December and March/April. Recent surveys along the mid-Atlantic coast indicate that some mother-calf pairs may also use the area from Cape Fear, NC, to South Carolina as a wintering/calving area (NMFS 2005). Designated critical habitat units for the right whale include the Great South Channel (east of Cape Cod), Massachusetts Bay, Cape Cod Bay, and near shore ocean waters from the Altamaha River in Georgia, south to central Florida [59 Federal Register (FR) 28793].

In an effort to better define the geographic and temporal extent of the right whale mid-Atlantic migratory corridor, Knowlton et. al (2002) analyzed 489 right whale sightings that occurred between 1974 and 2002. The largest number of sightings (34.4 percent) occurred within 0 to 5 nm of land, and well over half of the sightings (63.8 percent) occurred within 0 to 10 nm of land. Nearly all of the sightings (94.1 percent) were within 0 to 30 nautical miles (nm) of land. A total of 17 sightings were within a 35 nm radius of the Port of Morehead City, and 15 of these sightings were within a 20 nm radius of the port. Sightings in the vicinity of the Port of Morehead City occurred from October through April, with a peak during February and March. This same pattern also occurred in the vicinity of the Port of Wilmington. It is assumed that migrating right whales may be present in the vicinity of the ODMDS from October through April as they move back and forth between the summer feeding/nursery areas and winter calving sites.

5.10.1.2 Humpback Whale (Endangered)

Humpback whales (*Megaptera novaeangliae*) have a worldwide distribution that encompasses all oceans in both hemispheres (NMFS 1991a). The western North Atlantic population ranges from summer feeding grounds in the northeastern United States, Canada, and Greenland to winter mating and calving grounds in the West Indies. In the western North Atlantic, humpback whales spend the spring, summer, and fall within foraging grounds in the Gulf of Maine, the Gulf of St. Lawrence, Newfoundland/Labrador, and western Greenland. During the winter, most whales from the North Atlantic foraging grounds migrate to the West Indies where mating and calving occur (Waring et al. 2011). Significant numbers of whales are also sighted along the mid-Atlantic coast from New Jersey to NC during the winter, and it has been suggested that the mid-Atlantic areas represent supplemental foraging habitat for juvenile as well as mature humpback whales (Barco et al. 2002). No critical habitat has been designated for the humpback whale

Humpback whales occur in nearshore and offshore waters of North Carolina during the fall, winter, and spring as they migrate between the northern feeding grounds and the southern calving areas. As described above, there is also evidence that some humpbacks may overwinter along the mid-Atlantic coast between North Carolina and New Jersey (Barco et al. 2002). In North Carolina, humpback whale sightings are concentrated in the waters off of Cape Hatteras, primarily during the winter. An analysis of historical sighting and stranding data from the project area revealed two sightings in the nearshore ocean off of Bogue Banks, several sightings in the nearshore ocean off of Cape Lookout, and ten strandings between Cape Lookout and Bogue Inlet (Department of the Navy 2008). It is assumed that humpback whales may be present in the vicinity of the ODMDS during periods of winter migration.

5.10.2 West Indian Manatee (Endangered)

West Indian manatees (*Trichechus manatus*) are intolerant of cold water temperatures; and consequently, are generally restricted to inland and coastal waters of peninsular Florida during the winter. In the fall as water temperatures fall below 68°F, manatees aggregate at natural thermal refugia in the southern two-thirds of Florida or take up residence at power plants, paper mills, or other warm water industrial outfalls in Florida. In the spring, as water temperatures reach 68°F, manatees disperse from winter aggregation sites. Some remain near their thermal refuges, while others undertake extensive movements along the coast and up rivers and canals. Warm weather sightings are most common in Florida and Georgia. Summer sightings drop off rapidly north of Georgia, and sightings north of Cape Hatteras are rare (USFWS 2001). The current best estimate of population size is 3,807 animals based on aerial surveys of warm water refugia in 2009 (USFWS 2009a). Numerous coastal water bodies in Florida have been designated as critical habitat for the manatee. Critical habitat has been designated as far north as Nassau County on the east coast of Florida and as far north as Citrus County on the west coast of Florida (42 FR 47840-47845).

Manatee occurrences in NC are primarily restricted to the months of June through October. Sightings in the vicinity of Bogue Banks have been reported from the AIWW north of State Highway 101 (July 2000), Calico Creek (August 1999), the Beaufort waterfront (August 1999), Hammocks Beach State Park (June 1998), the Sportsman Pier in Atlantic Beach (August 1994), the United States Coast Guard Station at Fort Macon (August 1994), Barden Inlet (November 1992), Peletier Creek (October 1990), and the western end of Shackleford Banks (August 1983) (USFWS 2002).

Manatees inhabit marine, brackish, and freshwater environments where they are found in seagrass beds, salt marshes, freshwater bottom areas, and many other habitat types. Manatees feed on a wide variety of submerged, floating, and emergent vegetation. Seagrasses are a staple in coastal habitats and preferred foraging habitat consists of shallow seagrass beds with access to deep water. Manatees, in the vicinity of the Florida-Georgia border, feed on salt marsh vegetation [i.e., smooth cordgrass (*Spartina alterniflora*)] which they access at high tide. Although manatees tolerate a wide range of salinities; they prefer areas where osmotic stress is minimal, or areas that have a natural or artificial source of fresh water (USFWS 2001).

5.10.3 Piping Plover (Threatened)

Piping plovers are divided into three distinct breeding populations: the Atlantic Coast population (NC to Canada), the Great Lakes population, and the Northern Great Plains population. The Great Lakes breeding population is currently listed as endangered; whereas, the Northern Great Plains and Atlantic Coast breeding populations are currently listed as threatened. The estimated number of Atlantic Coast breeding pairs has increased steadily from 790 pairs in 1986 to 1,849 pairs in 2009 (USFWS 2011). The number of Great Lakes breeding pairs increased slightly from 51 pairs in 2003 to 63 pairs in 2008, while the United States Northern Great Plains breeding population increased from 586 pairs in 1996 to 1,212 pairs in 2006 (USFWS 2009b). The breeding range of the Atlantic Coast population extends from NC to Newfoundland, Canada. Piping plovers arrive on the Atlantic Coast breeding grounds and initiate courtship in late March or early April. Along the Atlantic Coast, most chicks fledge by the end of July, although flightless chicks may be present through late August (USFWS 1996a).

Southward migration to the wintering grounds occurs during late July, August, and September. The wintering ranges of the three breeding populations overlap, including coastal areas from NC to Texas, as well as northern Mexico and the Caribbean (USFWS 1996a). All piping plovers on the wintering grounds are considered threatened under the

ESA, regardless of breeding origin. The breeding, migratory, and wintering ranges overlap in NC; and consequently, piping plovers can be found in the state during every month of the year (Cameron et al. 2006). In NC, breeding sites are confined to undeveloped and unstabilized portions of barrier islands, most notably within the CLNS, Cape Hatteras National Seashore, Pea Island National Wildlife Refuge, and on Lea and Hutaff Islands (USFWS 2009b). Since 1986, the estimated number of breeding pairs in NC has ranged from 20 to 64 pairs (USFWS 2011). NC's barrier islands serve as important migratory stop over and wintering sites. Piping plovers from all three breeding populations utilize the NC coastline during the non-breeding season. Important stop over and wintering sites in NC include undeveloped beaches along Cape Hatteras National Seashore, CLNS, Bear Island, Bird Shoals, and Lea/Hutaff Island; as well as some sites on developed islands, such as the west end of Bogue Banks and the south end of Topsail Island (Cameron et al. 2006).

5.10.3.1 Breeding Habitat

Atlantic Coast nest sites are located above the high tide line on coastal beaches, sandflats at the end of sand spits, gently sloping foredunes, blowout areas behind primary dunes, and washover areas between dunes. Suitable dredge material deposits may also be used as nest sites (USFWS 1996a). Breeding piping plovers within the southern recovery unit are almost completely restricted to undeveloped, unstabilized, low lying barrier island flats and spits. Important nesting habitats include wide, flat, sparsely vegetated beaches with access to abundant moist substrate habitats for foraging. Nesting habitats at CLNS include the highly dynamic ends of barrier islands, recently closed and sparsely vegetated old inlets, expansive barrier mudflats, and newly created ocean-to-sound overwash sites (USFWS 2009b).

Foraging habitats include the intertidal zone of ocean beaches, overwash sites, mud flats, sand flats, wrack lines, and the shorelines of coastal ponds, lagoons, and salt marshes (USFWS 1996a). Of particular importance are moist substrate foraging habitats associated with blowouts, washover areas, spits, unstabilized and recently closed inlets, ephemeral pools, and sparsely vegetated dunes (USFWS 2009b). Broods exhibit a preference for mud flats, sand flats, ephemeral pools, and wrack (Cohen et al. 2010). Primary prey includes polychaete marine worms, insects, crustaceans, and bivalve mollusks (USFWS 1996a).

5.10.3.2 Wintering Habitat

Generally, wintering plovers on the Atlantic Coast are found at accreting ends of barrier islands; along sandy peninsulas, and near coastal inlets. Preferred foraging habitats include sandflats adjacent to inlets or passes, sandy mudflats along prograding spits, and overwash areas. Roosting sites generally include inlet and adjacent ocean and estuarine shorelines and nearby exposed tidal flats (USFWS 1996a). Piping plovers on the wintering grounds spend the majority of their time foraging. Their primary prey includes polychaete marine worms, crustaceans, insects, and bivalve mollusks. Adjacent habitats consisting of sand flats, mud flats, and algal mats above the high tide line are also important, especially for roosting plovers. Debris, detritus, and/or microtopographic relief provide refuge from high winds and cold weather. Important components of beach/dune habitats include surf-cast algae for foraging, sparsely vegetated backbeach habitats above high tide and seaward of the dune line for roosting, and spits and overwash sites for feeding and roosting. Plovers may also use flat, sparsely vegetated dredge disposal islands that mimic natural habitats. Piping plover habitats are constantly changing in response to dynamic coastal processes (erosion, accretion, succession, and sea level change) with habitats disappearing and being proximally reformed. The availability of suitable habitat is dependent on natural sediment transport processes and major storm events that control the formation and movement of barrier islands, inlets, and other coastal landforms (USFWS 2003).

5.10.3.3 Critical Habitat

Critical habitat has not been designated for the Atlantic Coast breeding population; however, critical habitat units for the wintering population have been designated along the Atlantic and Gulf coasts from NC to Texas (66 FR 36038 36143). In NC, a total of 18 critical habitat units have been designated from Dare County south to Brunswick County. Constituent elements of critical wintering habitat are those habitat components that are essential for the primary biological needs of foraging, sheltering, and roosting plovers. The primary constituent elements are associated with intertidal beaches and flats (mud flats, sand flats, algal flats, and washover passes) and associated dune systems and flats above high tide. Important components of intertidal flats include sand and/or mudflats with little or no emergent vegetation. Adjacent exposed or sparsely vegetated sand, mud, and algal flats above high tide are also important, especially for roosting plovers. Important components of the beach/dune ecosystem include surf cast algae, sparsely vegetated back beach habitats, salterns, spits, and washover areas. Only areas containing these primary constituent elements within the designated boundaries are considered critical habitat.

5.10.4 Sea Turtles

5.10.4.1 Loggerhead Sea Turtle (Threatened)

Loggerhead sea turtles (*Caretta caretta*) occur throughout temperate and tropical waters of the Atlantic, Pacific, and Indian Oceans. In the United States, loggerheads nest from Texas to Virginia; however, most nesting occurs from Alabama to NC. Loggerheads are commonly found throughout the North Atlantic, the northern Caribbean, the Bahamas; and east to the west coast of Africa, the western Mediterranean, and the west coast of Europe. During non-nesting years, adult females from United States nesting beaches occupy waters off the eastern coast of the United States, the Bahamas, the Greater Antilles, Yucatán, and the Gulf of Mexico. Adult loggerheads undertake extensive migrations between foraging grounds and nesting beaches (NMFS and USFWS 2007a, 2008).

Loggerheads are found in a wide variety of habitats that include nesting beaches, neritic waters (nearshore waters with depths < 600 ft), and oceanic waters (depths >600 ft). Loggerheads nest on ocean beaches, with nests typically positioned between the high tide line and the dune front. Relatively narrow, steeply sloped, coarse-grained beaches are the preferred nesting habitat. Estuarine waters represent important inshore habitat during the juvenile neritic stage. During this stage, loggerheads inhabit essentially all continental shelf waters off the coast of the eastern United States and in the Gulf of Mexico. Adults also inhabit nearshore waters, but are less likely to utilize enclosed, shallow estuarine waters. Shallow water habitats with expansive ocean access represent important foraging habitat for adults. Adults also inhabit offshore continental shelf waters from New York south throughout Florida and the Gulf of Mexico (NMFS and USFWS 2008). No critical habitat has been designated for the loggerhead sea turtle.

5.10.4.2 Green Sea Turtle (Threatened)

Green sea turtles (*Chelonia mydas*) are distributed circum-globally in tropical, subtropical, and to a lesser extent, temperate waters. In the United States, green sea turtles are distributed from Massachusetts to Texas. Nesting in the United States is limited primarily to the east coast of Florida, although green turtles nest in small numbers in Georgia, South Carolina, and NC. Habitats include ocean beaches, convergence zones in the open ocean, and foraging grounds in shallow protected waters (NMFS and USFWS 1991). Generally, adults remain in the nearshore environment, but may enter the oceanic zone when migrating between foraging grounds and nesting beaches. Recent studies indicate that some adults may also reside in the oceanic zone (NMFS and USFWS 2007b). Coastal waters that surround Culebra Island, Puerto Rico have been designated as critical habitat for the green sea turtle (63 FR 46693).

5.10.4.3 Kemp's Ridley Sea Turtle (Endangered)

Kemp's ridley sea turtles (*Lepidochelys kempii*) occur primarily in coastal waters of the Gulf of Mexico and the western North Atlantic Ocean. Data indicate that adults utilize coastal habitats of the Gulf of Mexico and the southeastern United States. Adults inhabit nearshore waters and are commonly found over crab-rich sandy or muddy bottoms. Nesting is limited primarily to the northeastern coast of Mexico, although rare nesting events have been recorded from the southeastern United States. Juveniles utilize a wide range of bottom substrates, but apparently depend on an abundance of crabs and other invertebrates (NMFS and USFWS 2007c). No critical habitat has been designated for the Kemp's ridley sea turtle.

5.10.4.4 Hawksbill Sea Turtle (Endangered)

Hawksbill sea turtles (*Eretmochelys imbricate*) are distributed circum-globally in tropical, and to a lesser extent, subtropical waters of the Atlantic; Indian; and Pacific Oceans. Nesting occurs on ocean beaches throughout the tropics and subtropics. In the continental United States, hawksbill sea turtles have been reported from all of the Gulf States and along the east coast as far north as Massachusetts; however, sightings north of Florida are rare. Hawksbill sea turtles are regularly sighted in the Florida Keys and on reefs off the coast of Palm Beach County. Major nesting areas in the western North Atlantic Ocean include the insular Caribbean, the Yucatan Peninsula in Mexico, and Panama. Nesting in the continental United States is restricted to the southeastern coast of Florida and the Florida Keys (NMFS and USFWS 1993). Juveniles and adults are most commonly associated with coral reef habitats; however, additional habitats may include other hardbottom habitats, seagrass beds, algal beds, mangrove bays and creeks, or mud flats. Post pelagic juveniles and adults utilize a variety of food items that include sponges and other invertebrates, as well as marine macroalgae. Adults undertake extensive migrations up to hundreds or thousands of miles between foraging grounds and nesting beaches (NMFS and USFWS 2007d). Critical habitat for the hawksbill sea turtle includes coastal waters that surround Mona and Monito Islands, Puerto Rico (63 FR 46693).

5.10.4.5 Leatherback Sea Turtle (Endangered)

The leatherback sea turtle (*Dermochelys coriacea*) occurs in all oceans of the world and has the largest geographic range of any sea turtle. Nesting occurs on beaches throughout tropical and subtropical regions; foraging turtles are distributed north and south into sub-polar regions. Major nesting areas in the western North Atlantic Ocean and Caribbean Sea include Florida, St. Croix, the United States Virgin Islands, Puerto Rico, Costa Rica, Panama, Columbia, Trinidad and Tobago, Guyana, Surinam, and French Guiana. Adults and sub-adults migrate seasonally to foraging areas in the northern latitudes. During the summer and fall, the highest densities of leatherbacks in the north Atlantic are located in Canadian waters (NMFS and USFWS 2007e). Although leatherback sea turtles are commonly known as highly pelagic animals, recent telemetry studies have documented high use foraging sites in continental shelf and slope waters (James et al. 2005). Leatherback sea turtles undertake extensive migrations between northern foraging grounds and tropical and subtropical nesting beaches (NMFS and USFWS 2007e). Coastal waters along the southwest coast of St. Croix, U.S. Virgin Islands have designated as critical habitat for the leatherback sea turtle (63 FR 46693).

5.10.4.6 Occurrence within the Project Area

NC's sounds and estuaries provide important developmental and foraging habitats for post-pelagic juvenile loggerhead, green, and Kemp's ridley sea turtles. Most of the information regarding the inshore distribution of sea turtles in NC has been generated by studies in the Pamlico-Albemarle estuarine complex. Large numbers of loggerhead, green, and Kemp's ridley sea turtles are incidentally captured each year during commercial fishing operations in the Pamlico-Albemarle estuarine complex. All three species are represented primarily by juveniles, with few reported captures of older juveniles and adults (Epperly et al. 2007). All three species move inshore during the spring, disperse throughout the sounds during the summer, then leave the sounds and move offshore during the late fall and early winter. Epperly et al. (1995a) reported the presence of sea turtles in inshore waters from April through December. Goodman et al. (2007) reported inshore and nearshore ocean occurrences from April through November.

Leatherback sea turtles are primarily a pelagic species preferring deep, offshore waters. Leatherbacks may be present in nearshore ocean waters during certain times of the year; however, they rarely enter inshore waters. Epperly (1995b) reported the appearance of significant numbers of leatherback turtles in nearshore ocean waters during May, coincident with the appearance of jellyfish prey. Sightings declined sharply after four weeks and only a few sightings were reported after late June. Leatherbacks were infrequently observed in inshore waters during this period. The surveys conducted by Goodman et al. (2007) recorded only one leatherback observation which occurred during the summer in the nearshore ocean south of Cape Hatteras. Epperly et al. (1995a) reported the occurrence of three leatherbacks in Core and Pamlico Sounds during December 1989.

Hawksbill sea turtles are very rare in NC waters and they rarely enter inshore waters (Epperly et al. 1995a). A total of nine hawksbill stranding incidents were reported along NC beaches between 1998 and 2009 (Seaturtle.org 2011). Strandings were reported during the months of January, March, April, and November. Epperly et al. (1995b) reported the incidental capture of one hawksbill in Pamlico Sound.

Several studies have reported a strong relationship between sea turtle distribution and sea surface temperature. Goodman et al. (2007) conducted aerial sea turtle surveys and sea surface temperature monitoring in Core Sound, Pamlico Sound, and adjacent nearshore ocean waters from July 2004 to April 2006. All but one of the 92 sea turtle observations occurred in waters where sea surface temperatures were above 11°C. All sightings in the sounds occurred between 16 April and 20 November; all sightings in the nearshore ocean occurred between 23 April and 27 November. The winter distribution of sea turtles offshore of Cape Hatteras was also correlated with sea surface temperatures above 11°C (Epperly et al. 1995c). In a similar study by Coles and Musick (2000), sea turtle distribution offshore of Cape Hatteras was restricted to sea surface temperatures ≥13.3°C.

In NC, the sea turtle nesting and hatching season extends from May 1 through November 15 (Holloman and Godfrey 2008). Loggerheads account for the majority of the sea turtle nests in NC. Green sea turtles nest consistently in low numbers along the NC coast; while leatherback sea turtle nesting is rare in NC. NC nesting records for the period of 2000 through 2009 included 6,575 loggerhead sea turtle nests, 116 green sea turtle nests, and 33 leatherback sea turtle nests. Kemp's ridley sea turtle nesting is extremely rare in NC, with only five nesting records for the state. There are no records of hawksbill sea turtle nesting in NC. Sea turtles nest along the entire Bogue Banks ocean-facing beach. Since 1996, annual surveys have documented an average of 30 nests on Bogue Banks. Nearly all of the records are loggerhead nests; although two leatherback sea turtle nests and one green sea turtle nest were recorded in 2005 (Holloman and Godfrey 2008).

Permit stipulations for the three-phased Bogue Banks Restoration Project constructed in the mid-2000s included its own distinct sea turtle nesting monitoring program that was administered by the NC Wildlife Resources Commission. The complete suite of reports for this six-year effort (2002-07) were reviewed and a summary sheet for the 1996-2010 nesting seasons is available below (Table 16).

Table 16. Summary of turtle nestings and false crawls Bogue Banks, NC. 1996-2010.

Notes:
(a) NR = No Report.
(b) ~Twenty-two nests lost because of Hurricanes Dennis & Floyd, erosion.
(c) Two nests lost because of Hurricane Bonnie.
(d) Two nest lost because of Hurricane Bonnie.
(e) ~Nine nests lost because of Hurricane Bonnie and erosion.
(f) One nest lost because of Hurricane Fran.
(g) Fifteen nests lost because of Hurricanes Bertha and Fran.
(h) Two nests lost because of Hurricane Ophelia.
(i) One nest lost because of Hurricane Ophelia.
(j) Six nests lost because of Hurricane Ophelia.
(k) One nest lost because of Tropical Storm Ernesto.
(l) One nest lost because of Tropical Storm Ernesto.
(m) Four nests lost because of Tropical Storm Ernesto.

5.10.5 Shortnose Sturgeon and Atlantic Sturgeon

5.10.5.1 Shortnose Sturgeon (Endangered)

The shortnose sturgeon inhabits large Atlantic Coast rivers from the St. Johns River in northeastern Florida to the Saint John River in New Brunswick, Canada. Shortnose sturgeon occur primarily in slower moving rivers or nearshore estuaries associated with large river systems. Adults in southern rivers are estuarine anadromous, foraging at the freshwater-saltwater interface and moving upstream to spawn in the early spring. Shortnose sturgeons spend most of their life in their natal river systems and rarely migrate to marine environments. Spawning habitats include river channels with gravel, gravel/boulder, rubble/boulder, and gravel/sand/log substrates. Spawning in southern rivers begins in later winter or early spring and lasts from a few days to several weeks. Shortnose sturgeons are benthic omnivores, feeding on crustaceans, insect larvae, worms, and mollusks. Juveniles randomly vacuum the bottom and consume mostly insect larvae and small crustaceans. Adults are more selective feeders, feeding primarily on small mollusks (NMFS 1998).

Hall et al. (1991) and Collins et al. (2001) used telemetry studies to characterize the movements and habitats of the shortnose sturgeon in the Savannah River. According to Hall et al. (1991), spawning migrations began in late January and continued through March. Spawning areas were characterized by submerged timber with scoured sand, clay, and gravel substrate. After spawning, fish moved downstream and returned to brackish water within two weeks of spawning. Data indicated that most or all sturgeon left the freshwater reaches of the river by early May. The freshwater-saltwater interface was identified as an apparent feeding ground for sturgeon. Depths in the feeding areas ranged from 20 to 35 ft, and salinities ranged from zero to six ppt, depending on tidal stage. Foraging habitat substrate consisted of coarse sand and small gravel with some mud.

5.10.5.2 Atlantic Sturgeon (Endangered)

On 6 February 2012, NFMS published the Final Listing Rules for five distinct Atlantic sturgeon population segments along the Atlantic Coast (77 FR 5914, 77 FR 5880). The New York Bight, Chesapeake Bay, Carolina, and South Atlantic distinct population segments were listed as endangered; and the Gulf of Maine distinct population segment was listed as threatened. The historic range of the Atlantic sturgeon included estuarine and riverine systems from Labrador, Canada to the Saint Johns River in Florida. The historical distribution in the United States included approximately 38 rivers from Saint Croix River in Maine to the Saint Johns River in Florida, including spawning populations in at least 35 rivers. The current distribution in the United States includes 35 rivers, with spawning known to occur in at least 20 rivers. Atlantic sturgeon spawn in freshwater, but spend most of their adult life in the marine environment. Spawning adults generally migrate upriver in the spring/early summer. A fall spawning migration may also occur in some southern rivers. Subadult and adult Atlantic sturgeons emigrate from rivers into coastal waters, where they may undertake long range migrations. Migratory subadult and adult sturgeon are typically found in shallow (33 - 164 ft) near shore waters with gravel and sand substrates. Although extensive mixing occurs in coastal waters, Atlantic sturgeons return to their natal river to spawn (Atlantic Sturgeon Status Review Team 2007). No critical habitat has been designated for the shortnose sturgeon or the Atlantic sturgeon.

5.10.6 Seabeach Amaranth (Threatened)

5.10.6.1 Status, Distribution, and Habitat

Seabeach amaranth was listed as threatened throughout its range in 1993 (58 FR 18035 18042). Historically, this species occurred on coastal barrier island beaches from Massachusetts to South Carolina. Extant populations are currently known from South Carolina, NC, Virginia, Delaware, Maryland, New Jersey, and New York. The number of plants and populations has increased in all states since it was listed in 1993; however, recent trends since 2002 generally show a decline in all states. In contrast, populations in NC have generally been increasing since 2002.

Primary habitats include overwash flats on the accreting ends of islands, lower foredunes, and the upper strand on non-eroding beaches. Seabeach amaranth is an annual, meaning that the presence of plants in any given year is dependent on seed production and dispersal during previous years. Seeds germinate from April through July. Flowering begins as early as June and seed production begins in July or August. Seeds are dispersed by wind and water. Seabeach amaranth is intolerant of competition; consequently, its survival depends on the continuous creation of newly disturbed habitats. Prolific seed production and dispersal enable the colonization of new habitats as they become available. A continuous supply of newly created habitats is dependent on dynamic and naturally functioning barrier island beaches and inlets (USFWS 1996b).

Seabeach amaranth has been found along the entire ocean facing beach and inlet shorelines of Bogue Banks; distribution shifts from year to year. Annual surveys have been conducted on Bogue Banks since 1991. The entire island was surveyed from 1992 through 1995 and 2001 through 2009. Partial surveys were conducted in 1991 and 1997-2000. No surveys were conducted during 1996 due to the occurrence of Hurricanes Bertha and Fran. The total number of plants observed during complete survey years has varied widely, ranging from 130 to 23,180 plants. The Bogue Banks population increased from 2,935 plants in 2004 to 23,180 plants in 2005, and subsequently declined to 251 plants in 2006.

5.11 Recreation and Tourism

5.11.1 Commercial and Recreational Fishing

According to the NC commercial fish landings report produced annually by the NCDMF, the commercial finfish harvest was up 17 percent from 2008 to 2009. However, the commercial shellfish harvest was down 7.3 million pounds in 2009 mostly because of a 43 percent decrease in shrimp harvest from 2009. Total commercial landings in 2009 were 68.6 million pounds which is about 2.5 million pounds lower than in 2008 (NCDMF 2009). NCDMF reported approximately 1,877,577 pounds of commercial seafood landings in Carteret County in 2009 (NCDMF 2010). The top five species included blue crabs, oysters, white shrimp, southern flounder, and hard clams.

Predominant fisheries occurring offshore of the study area include the gill net fishery and shrimp trawl fishery. The gill net fishery generally occurs during the fall and winter at sporadic locations between zero to three miles offshore of the study area. The shrimp fishery occurs throughout the study area from about ¼ mile to three to four miles offshore.

Recreational fishing includes fishing from head boats, charter boats, private boats, piers, and the surf. Fishing from head boats is best in the winter months for snapper and grouper. Fishing from charter boats is excellent for king mackerel and bottom fish during the winter. Offshore gulfstream species like yellowfin tuna (*Thunnus albacares*) and wahoo (*Acanthocybium solandri*) are available. Inside fishing has been successful for inshore species such as red drum, speckled trout, and flounder. Private boat anglers can find bluefin tuna, king mackerel, and other bottom fish species in the offshore. Other species such as speckled trout, red drum, and flounder can be found on the inside areas of the sounds, creeks, and the AIWW.

5.11.2 Other Recreation

The mild climate and easy access to the beaches and waterways support a myriad of outdoor recreational activities in the study area including sunbathing, walking along the beach, surfing, picnicking, surf fishing, boating, etc. The sound sides of Bogue Banks support significant marsh communities with excellent bird watching opportunities and offer unique kayaking experiences. Numerous camps, tour guides, and rental companies are located throughout the study area to support the wide array of outdoor recreational interests.

6.0 ENVIRONMENTAL CONSEQUENCES

The Proposed Action Alternative could have both direct and indirect effects on the environment. The qualitative impact assessment of the alternatives presented in this document uses the categories "no impact," "less than significant impact," and "significant impact" to categorize effects.

6.1 Coastal Processes

6.1.1 Borrow Area

Impact-producing factors in dredge operations in the Proposed Action Alternative include the operation of the hopper draghead on the ocean floor, bottom-disturbing activities such as anchoring, the operation of engines on the dredges and supporting vessels, and the movement of vessels in coastal waters. These activities are described in detail in Section 4.2.

The Proposed Action Alternative would potentially alter the bottom topography compared to existing conditions. The dredging operation would reclaim sand from 197 acres of the 6,900 acres USEPA has permitted as the Morehead City ODMDS. The hopper dredge would remove the sand in furrows averaging two - five ft deep. Changes to the ODMDS, caused by dredging, could conceivably alter localized currents, waves, and bottom sediment type. These localized changes could cause minor and temporary changes in the surrounding environment, including food resources available to species (M&N 2009). However, from a period of 1975 to 2005 there have been 24 disposal events in the ODMDS and therefore is subjected to regular changes in bottom topography. Due to ongoing dredge disposal management, the ODMDS will not experience out of the ordinary perturbations as a result of the Proposed Action Alternative.

Comparisons with previous evaluations of physical effects associated with potential OCS borrow areas closer to shore, as well as characterizations of other OCS borrow areas up and down the Atlantic coast, indicate that the effects on coastal processes such as wave energy, currents, and shoreline erosion would be insignificant (Moffatt & Nichol 2008). This conclusion is based on the substantially greater distance the ODMDS is located offshore relative to other potential borrow sites. In addition, the operational mounding of dredged sand resulting in vertical relief is expected to continue as part of the authorized function of the ODMDS.

The Proposed Action Alternative would cause minor changes in the previously disturbed topography of the ocean floor within the ODMDS, but the effect would be less than significant given the operational nature and depth of the site (40 ft in depth on average), and the historic use of this site as a dredged material management area.

The No Action Alternative would have no effect on the topography of the borrow area as there would be no BOEM authorization for use of OCS material.

6.1.2 Beach Fill

The placement of fill would represent a potential source of direct and indirect impacts of the Proposed Action Alternative. Potential sources of disturbance during sand placement and grading activities include heavy equipment operations and associated noise emissions, night-time lighting, and various other supporting activities involving vehicular operations, generator use, and the presence of construction personnel on the beach. Potential effects on recipient beach habitats include the loss of microhabitat features (e.g., microtopographic relief, wrack lines, tidal pools), changes in beach substrate composition, and changes in beach morphology.

The No Action Alternative would not provide for beach fill placement due to the absence of authorization from BOEM for the use of OCS material. The Proposed Action Alternative would authorize placement of fill within a previously authorized renourished oceanfront shoreline, make use of a compatible sand source, and adhere to routine dredging windows; therefore, resulting in less than significant impacts.

6.2 Water Quality

Localized and temporary turbidity increases would be anticipated, but would disperse rapidly considering the low percentages of non-sand fractions, construction techniques, and the natural longshore dispersion affect. Cleary and Knierim (2001) observed that dredging within Nixon Channel and the associated beach nourishment along the northern portion of Figure Eight Island resulted in a temporary increase of turbidity and TSS primarily at the discharge site located on the ocean shoreline. The highest weekly average of turbidity and TSS recorded at the discharge site was 44.0 mg/l and 301.0 mg/l, respectively (Cleary and Knierim, 2001). Turbidity values at control sites located approximately 10,000 feet from the location of the fill operation averages 7.7 NTU while TSS values averaged 47.7. During the Bogue Inlet Channel Erosion Response Project, turbidity levels were shown to remain within ambient conditions (9.7 to 35.2 NTUs) during the dredging operations.

As discussed in Section 5.3, Phase I of the Bogue Banks Renourishment Project indicated that cross-shore turbidity was highest in the surf zone within the project area and quickly declined seaward of the outer bar to <10 NTU on average (CSE, unpublished data, April 2002). Outside the project area, the cross-shore turbidity was similar to the turbidity inside the project area. Higher turbidity was noted in the shallow, turbulent surf zone (70-120 NTU) but quickly diminished within several hundred feet seaward of the outer bar (~500 ft offshore).

Measurements during Phase 1 indicated that turbidity increases associated with dredging and beach construction tend to remain localized at the pump discharge area and remain at or near background levels within several hundred feet of the discharge. During a similar project in 2001-2002, the USACE dredged the lower portion of the Cape Fear River to renourish Bald Head Island, Caswell Beach, Oak Island, and Holden Beach (NC). Versar (2003) considered that turbidity increases associated with beach renourishment tended to remain isolated close to shore.

The State standard for turbidity is 25 NTU while TSS does not have a defined standard. Any increase in turbidity associated with the excavation of the oceanfront shoreline should be of short duration. Natural conditions support fluctuating turbidity levels in the nearshore and offshore water column of the study area. Storm events, hopper dredging, and standard beach nourishment operations are known to increase these levels due to the resuspension of sand and fine materials (CSE 2001). Because ~98 percent of the excavated material is in the sand size class or larger, it will settle almost immediately and not remain in suspension. Silt and clay-sized material will be decanted from the borrow material by virtue of the hopper dredging process. The excess water pumped into the hopper during loading flows overboard. The effect of turbidity levels in the borrow area is expected to fall within the natural range of background conditions.

Beach compatible sand would be mechanically reclaimed for beneficial placement along the Proposed Action Alternative 7.1-mile footprint. During these sand recovery efforts, localized turbidity levels would potentially increase given the borrow source is not 100 percent coarse grain material and any smaller sediment fractions would be re-suspended. Several typical projects have shown sediment settling rates ranging from centimeters/second to meters/second resulting in settlement primarily within the dredge site's immediate area (Bohlen 2002). Larger grain sizes within the plume settle more rapidly and their precipitation is referred to as the dynamic phase. Coarse sands (> 2 millimeters) and gravels settle almost immediately, often within a distance of less than 50 meters from the dredger (Challinor 2000). Table 8 shows 98 percent of the borrow source material is identified as sand [15A NCAC 07H .0312 (Technical Standards for Beach Fill Projects): granular sediment (≥ 2 millimeters and < 4.76 millimeters)]. The potential for indirect turbidity effects are limited by the borrow source's sand percentage and rapid fallout during removal and placement.

As discussed, these localized and temporary plumes would rapidly diffuse given the predominant grain size, offshore flow, and circulation patterns within the borrow source location (USACE 2009). Considering the relative high sand fraction percentages, these reclamation activities would not significantly affect the water column's chemistry, salinity, dissolved oxygen, or temperature. Transport corridors used by the dredging fleet would affect the water column spatially, but would not significantly alter current patterns, salinities, or temperatures.

Shoreline sand placement would be directed by use of diffusion plates and temporary diversion berms. These shoreline construction techniques induce a parallel slurry flow directing the sand slurry down the beach above the swash zone. The sand/water mix would traverse the beach with the heavier coarse sand precipitating. As the slurry ultimately reaches the wave run-up zone, the remaining sediment fractions would be carried into the nearshore water column. Localized and temporary turbidity increases would be anticipated, but would disperse rapidly considering the low percentages of non-sand fractions, construction techniques, and the natural longshore dispersion affect.

The potential indirect effects from the sand reclamation and placement efforts would possibly be seen if a turbidity plume migrated from the active recovery or placement zones. Such a potential could result from a non-compatible pocket of sediment, or if a plumbing-run leaks. Such potentials exist and appropriate responses (e.g. discharge redirection, work zone relocation, valve/gasket replacement) would be planned using preliminary geotechnical data, good engineering and construction techniques, observers, and inspections. Adjacent benthic and water column resources could be indirectly affected from potential temporary turbidity plume migration near the discharge point, but significant adverse effects are not anticipated considering the high sand fraction of the ODMDS material and construction management approaches.

The No Action Alternative would have no effect on water quality, as there would be no BOEM authorization for use of OCS material.

6.3 Air Quality

Criteria air pollutant emissions were estimated for the proposed dredging from the ODMDS and placement along the three reaches within EI and PKS. These emission estimates were developed using approximations of power requirements, duration of operations, and emission factors for the various equipment types. Multiplying horsepower rating, activity rating factor (percent of total power), and operating time yields the energy used. The energy used multiplied by an engine-specific emission factor yields the emission estimate.

Operational data from a similar renourishment/dredging operation in Duval County, Florida, was used to estimate power requirements and duration for each phase of the proposed hopper dredging activity. The horsepower (hp) rating of the dredge plant was assumed for each activity as follows: propulsion (3,500 hp), dredging (2,000 hp), pumping (2,000 hp), and auxiliary (1,165 hp). Different rating or loading factors were used for dredging, propulsion, and pumping. The estimated duration of dredging within the Duval County project was approximately 163 days, which is approximately a month and a half longer than the Proposed Action Alternative timeline. The estimated time to complete each dredge cycle, including idle time, was approximately 12 hours per load. It was assumed that about 3,983 cy of material would be moved in each cycle, requiring about 326 loads to excavate enough material to place 1.048 M cy of sand on the beach. The Proposed Action Alternative would place up to 1 M cy of material.

Emission factors for the diesel engines on the hopper dredge, barge, tugboats were obtained from EPA's *Compilation of Air Pollutant Emissions Factors, AP-42, Volume 1* (2002). Emission factors for tiered equipment used in beach construction were derived from NONROAD model (5a) estimates. Total project emissions of nitrogen oxides (NOx), SO_2, CO, volatile organic compounds (VOC), and particulate matter (PM) are presented in Table 17.

The Proposed Action Alternative may result in small, localized, temporary increases in concentrations of NOx, SO_2, CO, VOC, and PM. Since the Project is located in an attainment area, there is no requirement to prepare a conformity determination. Since the federal waters attainment status is unclassified, there is no provision for any classification in the CAA for waters outside of the boundaries of state waters. Calculating the insignificant and temporary addition in emissions that may occur was conservatively considered by comparing project estimates to 2010 County totals.

Emissions associated with the dredge plant would be the largest contribution to the inventory. However, the total increases are relatively minor in the context of the existing point, nonpoint, and mobile source emissions in Carteret County. Projected emissions from the Proposed Action Alternative would not adversely impact air quality given the relatively low level of emissions. With the Proposed Action Alternative, the criteria pollutant levels from construction-equipment emissions would be temporary and localized, resulting in no long term accumulation of contaminants. In addition, estimated emissions would not jeopardize the County's attainment status therefore, effects would be less than significant.

The No Action Alternative would have no effect on the air quality of area, as there would be no BOEM authorization for use of OCS material.

Table 17. Estimated emissions for the Proposed Action Alternative.

Activity	Emissions (tons)					
	NOx	SO_2	CO	VOC	PM_{25}	PM_{10}
Dredge Plant (Hopper)	64.2	1.1	14.7	1.7	1.0	1.1

**Personal communication, Laura Boothe, NCDENR, Division of Air Quality, February 2012.

6.4 Noise

The small town nature of the project area (i.e., beach communities) does not support significant point source noise pollution concerns such as major highways, large airports, heavy construction, etc. often associated with large cities. No large manufacturing, industrial, or mining-type operations are on Bogue Banks. Bogue Field, also known as Marine Corps Auxiliary Landing Field Bogue, is located off N.C. 24 between Morehead City and Cape Carteret. It is an auxiliary landing strip allowing pilots to train for a variety of flight operations. This airport does provide occasional background noise within the project area; however it is temporal in nature and does not significantly affect noise levels on the community. Ambient noise associated with breaking waves, wind, etc. is a prominent feature of the beach communities. During peak tourism seasons, traffic along the local roadways and local commercial areas facilitates short-term increases in noise pollution. Each community has local sound ordinances and complaints of municipal residents concerning noise are within normal expectations. The towns do not experience a problem to the extent that maximum densities for residential dwellings have been established, nor have noise level reduction standards (outdoor to indoor or indoor to outdoor) been established.

Open-water coastal environments have a number of underwater ambient noise sources such as commercial and recreational vessel traffic, dredges, wharf/dock construction (e.g., pile driving), natural sounds (e.g., storms, biological), etc. To better assess potential species effects (i.e., disturbance of communication among marine mammals) associated with dredge-specific noise from borrow area dredging operations, Clarke et al. (2002) performed underwater field investigations to characterize sounds emitted by bucket, hydraulic cutterhead, and hopper dredge operations. A summary of results from the study for hopper dredge operations are presented below:

The noise generated from a hopper dredge is similar to a cutterhead suction dredge, except there is no rotating cutterhead. The majority of the noise is generated from the drag-arm sliding along the bottom, the pumps filling the hopper, and operation of the ship engine/propeller. Similar to the cutterhead suction dredge, most of the produced sound energy fell within the 70- to 1,000-Hz range; however, peak pressure levels were at 120 to 140 decibels (dB) (Clarke et al. 2002). Assumed noise emissions and receptors would not permanently jeopardize community background levels; therefore, effects would not be significant.

Robinson et al. (2011) investigated underwater noise produced by marine aggregate dredging in the UK. At frequencies below 500 Hz, dredging noise was similar or less than a typical merchant vessel traveling at slow speed (8-16 knots). However, high frequency broadband dredging noise was more similar to the noise produced by a merchant vessel at high speed with a cavitating propeller. The major source of high frequency broadband dredging noise was the impact/abrasion of the mined aggregate passing through draghead, pipe, and pump; with gravel producing higher broad band noise levels than sand. In terms of acoustic energy deposited into marine environment in a given time, dredges were much less noisy than other sources of anthropogenic noise such as pile driving and geophysical surveying with airgun arrays.

Dredging equipment in the ocean and earthmoving equipment on the beach will result in increased noise levels in the vicinity of the equipment during beach nourishment operations. Beach filling and shaping operations will progress down the beach at a rate of about 400-700 ft per day, ensuring that no single location will experience increased noise levels for more than a few days therefore resulting in less than significant noise effects.

The No Action Alternative would have no effect on noise receptors within the area, as there would be no BOEM authorization for use of OCS material.

6.5 Aesthetics

The Proposed Action Alternative would include the use of the ODMDS to accomplish the nourishment project. Presence of the dredging equipment just off shore, as well as at the ODMDS, could temporarily detract from the visual aesthetics of the area. The sand color of the ODMDS may be slightly different from the sand color of the beach and may detract from the aesthetic quality of the beach. This impact, however, would be short-term since the sediments' color and gradation will lighten and sort naturally by sunlight, rain, and wind over time. The so-called sand "bleaching" effect has been observed along the completed portions of the Bogue Banks FEMA emergency beach nourishment projects (Ophelia and Isabel) that were constructed with the currently proposed ODMDS borrow material.

The No Action Alternative would result in no negative impacts from placement of material or dredging operations due to the absence of authorization from BOEM for the use of OCS material. The Proposed Action Alternative would result in temporary adverse visual impact from construction equipment and long-term positive visual effects from a restored beach; therefore, resulting in less than significant impacts.

6.6 Archaeology/Cultural Resources

As a part of investigations related to development of the engineering plan and EIS for the Bogue Banks Master Beach Nourishment Plan, Mid-Atlantic Technology and Environmental Research, Inc. (M-AT) of Castle Hayne, NC, under a subcontract agreement with Moffat & Nichol Engineers, of Raleigh, NC, conducted underwater archaeological investigations of the ODMDS, the proposed sand borrow area (Hall 2011). This work was conducted pursuant to provisions of Section 106 of the National Preservation Act of 1966 (36 CFR 800, Protection of Historic Properties) and the Abandon Shipwreck Act of 1987 (Abandon Shipwreck Guidelines, National Park Service, Federal Register, Vol. 55, No. 3, 4 December 1990, pages 50116-50145).

The first part of the investigation was a marine remote sensing survey of the ODMDS located offshore Atlantic Beach, NC. As described in Section 4.0, the proposed borrow area is approximately 197 acres in size. The second part of the investigation was an underwater archaeological identification and assessment of six (6) remote-sensing targets that were selected after the completion of the remote sensing survey of the ODMDS Borrow Area.

All of the targets identified during this project were found to be associated with modern debris that is related to the present day ODMDS. No submerged cultural resources or historic artifacts were identified during the investigation of the ODMDS. This remote sensing effort also confirmed no hardbottom resources are located within the proposed borrow sand source template (Hall 2011). BOEM will also work with SHPO should shipwreck remains be unexpectedly discovered (30 CFR 250.194 and 30 CFR 250.1010). Therefore, no significant impacts to cultural resources in the project area (borrow, placement or pump-out areas), as result of the proposed action, are anticipated with implementation of the measures to protect existing identified resources, cease of work if an unexpected discovery occurs, and immediate notification to SHPO so they can determine if the resource is significant or not and make the determination of the best means to protect the resource. The Proposed Action Alternative will have no effect on archaeology/cultural resources within the ODMDS or placement reaches.

The No Action Alternative is unlikely to have impacts on cultural resources, as there would be no dredging within the ODMDS.

Pursuant to Section 106 of the National Historic Preservation Act and the Advisory Council on Historic Preservation's Regulations for Compliance with Section 106, consultation with SHPO was preliminarily conducted in 2008 to assess potential impacts of dredging within the ODMDS. It was determined pre-construction cultural resource surveys of ODMDS was not necessary as long as the post-project depth of the ODMDS does not exceed the original bottom contour (Appendix H). Additional consultation has been completed thru the CAMA review process (Completed State CAMA permit application as of 08 May 2011). The DCM staff processed the permit application and coordinated the review process with eleven other state agencies, including SHPO, and the USACE. SHPO's response to the CAMA Major Permit is provided in Appendix H.

6.7 Benthic Resources

Beach nourishment may also reduce the availability of intertidal benthic infaunal prey. Sand placement generally causes temporary mass mortality of the intertidal benthic infaunal community. In addition to mortality associated with direct burial, fine sediments may increase turbidity resulting in the death of suspension-feeding organisms and interfering with larval recruitment (Reilly and Bellis 1983, Lindquist and Manning 2001). A number of researchers have reviewed the effects of beach nourishment on benthic infauna (Nelson 1993, Hackney et al. 1996, Greene 2002, and Defeo et al. 2009). Most studies, as discussed by Peterson et al. (2000 and 2006), have reported short term impacts and rapid recovery rates ranging from two weeks to seven months; however, a number of studies have documented longer recovery periods ranging upwards of eighteen months to two years. According to Peterson et al. (2006), previous reports of limited initial impacts and rapid recovery rates (ranging from days to weeks) were associated with the use of compatible sediments.

In contrast, reports of large initial impacts and lengthy recovery periods were associated with uncharacteristically high levels of fines (silts and clays) in the introduced sediments. Peterson et al. (2006) also noted that limited initial impacts and rapid recovery rates occurred on beaches with high rates of longshore transport; whereas, large impacts and slow recovery rates occurred on beaches with low rates of longshore transport. High rates of longshore transport may dilute and disperse incompatible sediments and increase benthic infauna immigration rates, thus increasing the rate of recovery. Nourishment projects that are implemented during the winter avoid critical recruitment and reproductive periods, thus potentially reducing the initial extent of impacts and the length of the recovery period (Reilly and Bellis 1983, Hackney et al. 1996, Donoghue 1999, Peterson et al. 2000, and Versar 2003).

The Proposed Action Alternative is likely to result in possible mortality for non-motile invertebrates in the immediate area of the dredging and the shoreline placement. However, this alternative will have reduced effects based on the high sediment compatibility and the seasonal window minimizing potential long-term benthic suppression.

The No Action Alternative is unlikely to have impacts on benthic resources, as there would be no dredging within the ODMDS or shoreline placements.

6.8 Fish and Wildlife Resources

6.8.1 Terrestrial

6.8.1.1 Maritime Shrub Thicket

The maritime shrub thicket community occurs sporadically throughout EI and PKS, occurring on the backside of the island, north of the main road, and interspersed with marsh areas, which border the sound. Because the community is landward of the proposed project construction limits, no significant effects would be expected.

The No Action Alternative would have no impacts on shrub thicket resources.

6.8.1.2 Beach and Dune

Under the proposed plan, approximately 37,501 ft of beach berm and dune would be constructed. Constructed dunes would be waterward of the first line of stable vegetation and would tie into existing dunes, where practical. This would result in a seaward movement of the shoreline. Project construction would not be expected to have an adverse effect on wildlife found along the beach or the dune areas. However, short-term transient effects could occur to mammalian species using the dune and fore-dune habitat, but those species are mobile and would be expected to move to other, undisturbed habitat areas during construction.

Nourishment operation at EI and PKS would be expected to directly affect ghost crabs through burial (USACE 2004b, Lindquist and Manning 2001, Peterson et al. 2000, and Reilly and Bellis 1983). Because ghost crabs are vulnerable to changes in sand compaction, short-term effects could occur from changes in sediment compaction and grain size. According to Hackney et al. (1996), management strategies recommended to enhance recovery after beach nourishment include: (1) timing activities so that they occur before recruitment and, (2) providing beach sediment that favors prey species and burrow construction. Ghost crabs are present on the project beach year-round (Hackney et al. 1996); therefore, direct effects from burial could occur during the proposed construction time frame of November 16 to March 31. However, the peak larval recruitment time frame would be avoided and only compatible borrow material would be used. Ghost crab populations are expected to recover within one year of post-construction (USACE 2004b, Lindquist and Manning 2001, Peterson et al. 2000, and Reilly and Bellis 1983). Because ghost crabs recover from short-term effects, and recommended management strategies would avoid long-term effects; no significant long-term impacts to the ghost crab population would be expected with the Proposed Action Alternative. In addition, the Proposed Action Alternative would restore a protective beach berm, creating additional foraging habitat within the dune system.

The No Action Alternative would have significant impacts on the beach and dune habitat as protection of dune and beach habitat will be reduced over time.

6.8.2 Marine

During project construction, there will be an increase in the turbidity of the surf zone in the immediate area of sand deposition. Most of the fine material in the beach fill would be expected to wash seaward into the surf zone during construction. This increase in fine material may cause the temporary displacement of various species of fish, causing a negative impact to surf fishing in the area of deposition. A study done by the NMFS on the effects of beach nourishment on nearshore macro infauna concluded that beach nourishment projects have no harmful effects - provided that the sediments are similar to those where they are placed (Saloman and Naughton 1984). The material that would be used for beach fill is similar in composition to the native beach material; therefore, the amount of fine material expected to wash out of the beach fill should be minimal.

With the expected short-term effects to the benthic communities, temporary and spatially restricted fill effects are anticipated on demersal organisms since benthos organisms are a predominant food source; and, in turn, affect pelagic species that feed on demersal species. These organisms, specifically post-larval, juvenile, and adult red drum, spot, croaker, striped mullet, summer flounder, juvenile and adult bluefish, Florida pompano (*Trachinotus carolinus*), southern kingfish, Atlantic menhaden (*Brevoortia tyrannus*), and shrimp species, represent an important commercial value for the fishing industry. However, these effects are expected to be short-lived due to the fact that the project activities will occur during periods of decreased biological activity and outside the peak periods of larval recruitment and will minimize impacts to fauna of the intertidal and subtidal bottom habitats. Impacts to recreational and commercial fisheries are anticipated to be localized, short-term, and not cumulatively significant.

The No Action Alternative would be unlikely to have impacts within the marine environment, as there would be no dredging within the ODMDS or shoreline placement.

6.8.2.1 Non-ESA-Listed Marine Mammals

This section considers potential impacts on species not managed under the ESA. Some cetacean species occur in the project area year-round [e.g., bottlenose dolphin (*Tursiops truncates*), beaked whales (*Ziphiidae* spp.), and pinnipeds], while others (e.g., right whale, humpback whale, and manatee, as discussed further in 6.9) occur seasonally as they migrate through the area. Some marine mammals in the project area are managed under the ESA [ESA; 50 CFR §402; 16 USC §1536(c)]; potential project impacts on those species are considered in Section 6.9 as well as within the BA (DC&A 2012a).

Under the Proposed Action Alternative, some of the smaller marine mammals (primarily bottlenose dolphins), could be attracted to the dredge site by the disturbance and potential availability of prey, then potentially exposed to increased levels of turbidity, noise, and the possibility of entrainment or entrapment in the dredge apparatus. Turbidity caused by re-suspension of sediments during the dredging could adversely affect feeding to the extent that the organisms rely on vision to locate their prey. Noise from the dredging operation could adversely affect marine mammals, or at a minimum, trigger an evasive response.

The NMFS (2003) has established that a received sound level of 180 dB may result in injury or mortality to cetaceans from pile-driving activities. The level for pinnipeds (which are not expected in the Proposed Action Alternative Area) is set at 190 dB. For both pinnipeds and cetaceans, NMFS has set the level of potential behavioral harassment at 160 dB. Given that project-generated sounds from dredging activities would be substantially less than those levels (Section 6.4), the Proposed Action Alternative would be expected to have no significant adverse effects on marine mammals.

The transport of dredged material by hopper dredge from the ODMDS to the placement site on Bogue Banks could have adverse impacts on animals in the path of the vessels due to vessel strikes. Potential leakage of dredged material could cause minor, localized turbidity that could cause avoidance reactions by dolphins and small whales. Animals could be struck by the hopper dredges and/or support vessels as these vessels transport the dredged material to the placement site and return to the ODMDS. The likelihood of dolphins being struck by project-related vessels is very small. Dolphins are accustomed to vessels, even frequenting the bow waves of large vessels, and can easily avoid the relatively slow-moving project vessels.

On 9 December 2008, NMFS established regulations to implement speed restrictions of no more than 10 knots applying to all vessels 65 ft or greater in overall length in certain locations and at certain times of the year along the United States East Coast. The purpose of the regulations is to reduce the likelihood of deaths and serious injuries to endangered North Atlantic right whales that result from collisions with ships (73 FR 30173), but would also reduce the likelihood of deaths and serious injuries to all marine mammals and sea turtles. Accordingly, the Proposed Action Alternative with the speed restrictions on vessels would not be expected to have significant adverse effects on marine mammals attributable to vessel activities.

The No Action Alternative is unlikely to have impacts on marine mammals, as there would be no dredging within the ODMDS.

6.8.3 Avian

Marine birds visiting the ODMDS could be affected by dredging operations. The foraging habitat would temporarily be altered by the lights, noise, and spatial effects of the dredging equipment. Coastal seabirds [e.g., gulls, brown pelicans (*Pelecanus occidentalis*), and terns], and far-ranging pelagic seabirds [e.g., tropicbirds (*Phaethon* spp.), petrels (Hydrobatinae), jaegers (*Stercorarius* spp.), gannets, and shearwaters (*Puffinus* spp.)] could be attracted to the dredging operations. They might avoid the area instead, because of the noise and light, which would deter them from a normal foraging area. It is not possible to predict which reaction would be more likely, although gulls and pelicans are habituated to human activities and are known to frequent vessels, which they associate with food.

The identified project limits avoid important shorebird habitat in Bogue and Beaufort Inlet complexes. Although the project area is heavily developed and sustains heavy recreational use, migratory shorebirds could still use the project area for foraging and roosting habitat. Tern and shorebird nesting colonies at Shackelford Banks, Fort Macon, and within the Bogue Sound complex would not be expected to be affected by the minor increment in vessel traffic in the nearshore environment associated with the Proposed Action Alternative. As mentioned in Section 6.7 of this report, beach nourishment activities could temporarily affect the roosting and intertidal macro-fauna foraging habitat; however, recovery often occurs within one year if nourishment material is compatible with native sediments. A recent two-year study in Brunswick County, NC, (USACE 2004b) indicated that beach nourishment had no measurable impact to shorebird use. Accordingly, the Proposed Action Alternative would be expected to have less than significant impacts on avian resources at the ODMDS and along the dredge routes to the nourishment sites. The potential effects of beach fill would result in a temporary loss of foraging habitat due to short-term burial of benthic invertebrates in the placement area (approximately 189 acres of intertidal habitat, which is defined here as below MHW). Bogue Banks is approximately 26 mi long; therefore, adjacent foraging areas would be available.

The No Action Alternative is unlikely to have impacts on pelagic bird species, as there would be no dredging within the ODMDS.

6.8.4 Essential Fish Habitat and State Managed Species

Dredge operations at the ODMDS could have direct and indirect effects on fish species. Direct effects would include adverse effects from dredging and indirect effects would include changes to the environment caused by the proposed project. Under the Proposed Action Alternative, resident fish and fish attracted to the dredge site by the disturbance and exposure of benthic prey items could be exposed to elevated levels of turbidity, noise, and the possibility of entrainment or entrapment in the dredge apparatus. Eggs and larvae, especially of demersal fish, as well as less motile shellfish, could also be entrained and lost.

It is unlikely that dredging would result in injury or death of substantial numbers of adult fish. The immediate vicinity of the dragheads (i.e., within a few meters) would be a relatively noisy and a potentially turbid area that fish would tend to avoid. Some individuals are likely; however, to become disoriented and entrained in the dredge intake, and early life stages would be unable to avoid the dredge. Given the limited geographic scope of the dredging (approximately 197 acres within the 6,900-acre ODMDS), this impact is expected to be less than significant.

Under the Proposed Action Alternative, elevated levels of turbidity would be limited to the immediate vicinity of the dredge. Fish subjected to those high turbidity levels could experience adverse effects from having their gills clogged by sediment. Turbidity could also affect feeding by fish dependent on vision to locate prey. As in the case of entrainment, the number of fish that might be affected by elevated levels of turbidity is expected to be relatively small, and the effect is expected to be short-lived as the dredge relocates. Accordingly, the impact on fish resources is anticipated to be less than significant.

Anthropogenic noise has the potential for a wide range of impacts on fish; including behavioral responses, masking, temporary hearing effects, physiological effects, and mortality (Normandeau Associates 2012). Intense underwater noise (greater than 120 dB) is thought to produce a number of behavioral changes among fish, and very intense noise (greater than 150 dB) has been implicated in the injury and death of fish. Fish generally respond only to very low or very high frequency sounds and vessel noise can cause either avoidance or attraction (Vella et al. 2001). Studies of fish reactions to vessel noise indicate that avoidance occurs at 118dB within the frequency range of 60-3,000Hz, whereas sounds in the range of 20-60Hz have no effect (Engas et al. 1995). Changes in schooling behavior have also been noted, such as forming tighter formations, increased swimming speeds and turning away from the noise source (McCauley 1994). Studies reviewed by Normandeau Associates (2012) documented responses to seismic airguns and acoustic deterrent devices ranging from avoidance and startle responses to no response. Noise can cause masking of sound important for intraspecific interactions among fish and shellfish (Vasconcelos et al. 2007, Codarin et al. 2009). NMFS (2003) stated that intense sound could affect hearing in fish, but cited studies suggesting that this would be unlikely at received sound levels less than 200 dB re 1 μPa, and that the hearing loss would likely be temporary. Although fish mortality has been reported at locations very close to pile driving sources and in the vicinity of underwater explosions, mortality has not been documented for exposure to other noise sources such as seismic airguns, dredging, and vessel noise (Normandeau Associates 2012).

Most studies have addressed noise from military sonar and oil exploration activities, which are very intense sounds. Few, if any, studies have investigated the effects of routine commercial navigation and in-water construction on fish. Although there is some data on the noise levels associated with bucket dredging (e.g., USACE 2001c), there appear to be minimal comprehensive studies of the noise associated with hydraulic dredging. That noise would be generated by the diesel generator(s) powering the pump and draghead, the mechanical action of the draghead in the sediment, the sediment slurry moving in the pipes, and, in the case of the hopper dredge, the propulsion system (engine noise and cavitation from the propellers). Tyler-Walters and Jackson (1999) state that a working cutter-suction dredge approximates to a received sound pressure level of 130 dB re 1 μPa over a frequency spectrum of 45 - 7,000 Hz at a distance of 330 ft, and that the passing of a small trawler (which would be similar in noise profile to a typical slow-moving hopper dredge) generates a similar noise level. A hopper dredge would generate both types of noise, so that the combined noise sources would produce a total noise level of between 130 - 140 dB re 1 μPa at 330 ft distance (Talisman Energy 2005). Note that values for generated sound pressure levels are typically expressed as the pressure at a distance of 3.3 ft; since that is not relevant to marine life, Tyler-Waters and Jackson (1999) recommend using the pressure at a distance of 330 ft, where levels are typically about 40 dB less due to the attenuation with distance.

The data summarized above suggests that dredging operations are unlikely to generate noise levels high enough to cause harm to fish. Given that fact and the absence of published evidence of widespread harm from dredging operations, it is concluded that the project effects on fish from underwater noise would be less than significant.

A remote sensing investigation of the proposed ODMDS borrow area did not identify any potential hard bottom sites (Hall 2011); therefore, dredging would not impact hard bottom EFH. Soft bottom habitats and associated benthic invertebrate resources at the ODMDS would be directly impacted by dredging. Indirect effects on benthic-foraging fish would include a temporary reduction in soft bottom foraging habitat and associated benthic prey organisms. Benthic community recovery rates at ocean borrow sites may be influenced by a number of factors; including natural disturbance regime, sediment type, spatial scale of disturbance, depth of the borrow pit, and the timing and frequency of disturbance (Wilber and Clarke 2007). Soft bottom benthic communities are generally dominated by opportunistic taxa that are capable of rapid recovery following storm-related disturbance of the seafloor. Benthic community recovery at borrow sites offshore of Kure Beach, NC, occurred relatively quickly (less than nine months), with observed differences being more related to inter-annual variability than sediment removal (Posey and Alphin 2002). Recovery of infaunal abundance, diversity, and community composition occurred within one year at borrow sites in New Jersey; whereas full recovery of sand dollar biomass required 1.5 to 2.5 years (Burlas et al. 2001). Van Dolah et al. (1992) observed short-term reductions in abundance and diversity, with a return to levels comparable to pre-impact conditions within three to six months; although changes in community composition persisted for at least one year at a deep borrow pit where pre-project fine sand substrate was replaced post project by muddy sediment. According to Burlas et al. (2001), there are two primary benthic community responses to borrow site dredging: 1) rapid recovery (<1 year) at relatively shallow borrow pits that are quickly infilled by natural sand transport and 2) development of a depauperate soft-sediment community in deep borrow pits that accumulate fine sediments. Proposed borrow site dredging at the ODMDS would remove shallow layers of sediment in strips, thus increasing the likelihood of rapid infilling and infaunal recolonization. Based on the temporary nature of the impacts, and considering relatively small size of the affected area and the availability of abundant alternative foraging habitat adjacent to the borrow site, effects on trophic interactions and benthic-foraging fish would be minor.

The Proposed Action Alternative would not be expected to cause any significant adverse effects to EFH or HAPC for those species managed by the SAFMC and MAFMC. Effects would be expected to be minor on an individual and cumulative basis.

The No Action Alternative is unlikely to have impacts on EFH or HAPC species, as there would be no dredging within the ODMDS.

6.8.4.1 State Managed Fish Species

There are no SAVs, shell, or hardbottom habitat located within the proposed sand source location, recipient beach locations, or potential transport corridors. Specific areas such as Cape Lookout, Bogue Sound, NC's tidal inlets, NC-designated nursery areas, SAVs, and oyster/shell bottom are considered HAPCs for several managed species. The Proposed Action Alternative would avoid direct and minimize potential indirect effects to these HAPCs. The closest PNAs, as designated by the NCDMF, are three to four mi from Beaufort and Bogue Inlets and the closest SAVs are approximately 0.5 mi away from the inlet mouths (NCDMF 2011). Potential changes in general current patterns, tidal flow, and salinity regimes are not anticipated as a result of the proposed Project. The marine water column, unvegetated sandy bottoms, other EFHs, and managed/associated species' are not anticipated to experience long term adverse effects resulting from the proposed Post-Irene Renourishment Project.

The No Action Alternative is unlikely to have impacts on state managed fish species, as there would be no dredging within the ODMDS.

6.8.4.2 Hardbottoms

There are no hardbottom habitats within the ODMDS reclamation area, transport corridors, or nearshore waters adjacent recipient beaches; therefore, the Proposed Action Alternative would have no impact on hardbottoms.

The No Action Alternative and the Proposed Action Alternative would have no impacts due to the absence of hardbottom within the ODMDS.

6.9 Threatened and Endangered Species

Impacts to threatened and endangered species could result from the operation of the dredge and the transport of dredged material from the borrow site to the fill site on Bogue Banks [see BA (DC&A 2012a) for more detail]. The below section summarizes potential direct and indirect impacts to managed species based on the Proposed Action Alternative.

6.9.1 North Atlantic Right Whale and Humpback Whale

Dredging operations would coincide with right whale and humpback whale migration periods along the NC coast. Consequently, right whales and humpback whales may be present in the vicinity of the ODMDS during dredging operations. Potential impacts associated with dredging operations include vessel collisions and acoustic disturbance. Dredges routinely operate at speeds of less than five knots during dredging operations. During transit between the borrow area and pump-out sites, dredges would adhere to a speed limit of ten knots or less. Protected species observers with at-sea large whale identification experience would be posted on dredges (during excavation and transit) at all times. Additional federal regulations [50 CFR 224.103(c)] prohibit the approach of any vessel within 500 yards of a right whale. If a right whale is sighted at a distance of less than 500 yards, vessels would be required to alter course and move away from the whale at a slow, safe speed. If a right whale is sighted within 500 yards of the dredge, operations would cease until the observers are confident that the whale has left the area. If a whale is sighted during transit, the crew would reduce speed and alter course as necessary to maintain a distance of 500 yards between the vessel and the whale. All whale sightings would be documented and reported to NMFS. The 24-hour presence of endangered species observers, combined with speed restrictions, should greatly reduce the potential for vessel strikes.

Underwater noise has the potential to disrupt marine mammal communication, navigational ability, feeding, and social patterns. Most observations of marine mammal responses to anthropogenic noise have been limited to short term responses involving cessation of feeding, resting, or social interactions. Although shipping and industrial noise may represent a threat to baleen whales (Mysticeti), the severity of this potential threat is unknown (NMFS 2010a). Observed responses of baleen whales to various types of underwater noise include avoidance of the source area, cessation of feeding, rapid swimming away from the source, altered dive patterns, vocalization changes, and changes in respiration (Fisheries and Oceans Canada 2010). There have been studies of the effects of shipping and industrial noise on right whales and humpback whales. Right whales, in the Bay of Fundy summer foraging area, showed no response to experimental shipping noise; however, whales exposed to synthetic alert signals abandoned their foraging dives and remained at the surface for the duration of the exposure period (Nowacek et al. 2004). Responses of Hawaiian humpback whales to experimental shipping noise included changes in diving/surfacing behavior, swimming speed, and direction of travel (Hemphill et al. 2006, Green and Green 1990). Although the potential impacts of dredging noise on right whales are not known, it is assumed that the presence of the dredge and the associated noise output could cause migrating whales to alter their course. However, since whales are transient within the study area and are not actively engaged in critical feeding or mating behaviors, any potential adverse effects on right whales and humpback whales should be minimal.

The No Action Alternative is unlikely to have impacts on whale species, as there would be no dredging within the ODMDS.

6.9.2 West Indian Manatee

Potential effects include direct physical injury as a result of in-water construction activities (i.e., dredging) and associated vessel traffic. However, the proposed beach nourishment construction window (16 November - 31 March) would avoid periods when manatees are likely to be present. Dredging would be restricted to the ODMDS; and therefore, would not affect seagrasses or other potential foraging habitat. Implementation of the above protective measures for the Proposed Action Alternative would result in less than significant impacts to the West Indian manatee.

The No Action Alternative is unlikely to have impacts on manatees, as there would be no dredging within the ODMDS.

6.9.3 Piping Plover

6.9.3.1 Direct Effects

Potential direct project effects include disturbance, habitat alteration, and losses of benthic invertebrate food resources. Potential sources of disturbance during sand placement and grading activities include heavy equipment operations and associated noise emissions, night-time lighting, and various other supporting activities involving vehicular operations, generator use, and the presence of construction personnel on the beach. Potential effects on recipient beach habitats include the loss of microhabitat features (e.g., microtopographic relief, wrack lines, tidal pools), changes in beach substrate composition, and changes in beach morphology. Renourishment projects generally result in burial and temporary mass mortality of the intertidal benthic infaunal community along the recipient beach. In addition, fine sediments may increase turbidity, resulting in the death of suspension-feeding organisms and interfering with larval recruitment (Reilly and Bellis 1983, Lindquist and Manning 2001). Benthic effects may extend beyond the boundaries of the immediate project area as the finer fill material is transported to adjacent beaches via longshore drift.

Adherence to the proposed construction window (16 November - 31 March) would preclude any direct project effects on breeding activity. Construction would occur during a period when migrating and wintering plovers are expected to be present in the area; however, piping plovers are unlikely to occur on the narrow developed ocean-facing beaches that exist within and adjacent to the project areas. Furthermore, the target beaches are separated from likely areas of occurrence at Bogue Inlet and Beaufort Inlet by distances of two and eight miles, respectively. Based on the very low potential for interactions, construction activities are unlikely to disturb migrating or wintering plovers.

Although the rare occurrence of a piping plover within the project area cannot be entirely ruled out; the project beach is not considered to be suitable nesting, foraging, or roosting habitat. Therefore, any general effects on beach habitats and benthic invertebrates are unlikely to affect piping plovers. Compliance with beach fill standards and adherence to environmental windows should minimize the extent and duration of general habitat and benthic effects. Compliance with NC Technical Standards for Beach Fill Projects (15A

NCAC 07H .0312) would ensure compatibility of the fill material, and adherence to the environmental construction window (16 November - 31 March) would reduce effects on benthic infauna. Furthermore, the relatively short length of the target beaches should allow for rapid recovery of the benthic community via immigration from adjacent beaches.

6.9.3.2 Indirect Effects

Projects that alter natural barrier island and inlet processes can lead to indirect effects on piping plover habitat. The primary concern associated with beach nourishment involves potential effects on natural ocean overwash. Natural ocean-to-sound overwash events contribute to the creation and maintenance of piping plover habitats. Overwash events create open sandy habitats and contribute to the maintenance of soundside habitats through sediment transport. Beach scraping, creation of artificial dunes/berms, and beach nourishment may artificially increase the height of the primary dunes and eliminate interdune gaps; thus, reducing natural overwash and limiting habitat development.

Due to the presence of a natural high-elevation primary dune system, overwash is not an important process on Bogue Banks (USFWS 2002). Although rare, overwash events may occur on the narrow central portion of the island; dense development between the primary dune and the sound severely limits the potential for beneficial effects on habitat.

Implementation of protective measures including compliance with beach fill standards and adherence to environmental windows should minimize the extent and duration of general habitat and benthic effects of the Proposed Action Alternative; therefore, resulting in less than significant impacts to the piping plover.

The No Action Alternative is unlikely to have impacts on the piping plover as there would be no dredging within the ODMDS and placement of material on Bogue Banks.

6.9.4 Sea Turtles

6.9.4.1 Sand Placement and Grading

The placement of sand on project area beaches may affect sea turtle nesting habitat. Potential adverse effects on nesting habitat include alteration of beach substrate characteristics and modification of the natural beach profile. Beach substrate characteristics that may be affected by nourishment include density, compaction, shear resistance, moisture content, slope, sand color, grain size, grain shape, sand mineral content, and gas exchange (Nelson and Dickerson 1988, Crain et al. 1995). Substrate alteration may affect the ability of female turtles to nest, the suitability of the nest incubation environment, and the ability of hatchlings to emerge from the nest. Unnatural beach profiles and escarpments may prevent nesting females from reaching suitable nesting habitat; resulting in the selection of marginal or unsuitable nesting sites in front of escarpments, or in nest exposure as escarpments recede landward. Numerous studies have described the effects of beach nourishment on nesting success (Crain et al.

1995, Steinitz et al. 1998, Ernest and Martin 1999, Herren 1999, Rumbold et al. 2001, Byrd 2004, and Brock et al. 2009). These studies indicate a reduction in nesting success during the first post-nourishment year, followed by a return to normal levels by the second or third year. Declines in nesting success have been attributed to substrate compaction, escarpment formation, and/or modification of the natural beach profile. Beach nourishment also has the potential to improve poor quality nesting habitats associated with chronically eroded beaches (Brock et al. 2009). Davis et al. (1999) and Byrd (2004) documented increases in nesting success immediately following the nourishment of eroded beaches. Increases in nesting success were attributed to the addition of dry beach habitat.

Embryonic development and hatching success are influenced by temperature, gas exchange, and moisture content within the nest environment (Carthy et al. 2003). Changes in substrate characteristics such as grain size, density, compaction, organic content, and color may alter the nest environment; leading to adverse effects on embryonic development and hatching success (Nelson and Dickerson 1988, Nelson 1991, Ackerman et al. 1991, Crain et al. 1995, Ehrhart 1995, and Ackerman 1996). Nourished beaches often retain more water than natural beaches, thus impeding gas exchange within the nest (Mrosovsky 1995, Ackerman 1996). Uncharacteristically dark sediments absorb more solar radiation, thus potentially resulting in warmer nest temperatures (Hays et al. 2001). Dark sediments may produce nest temperatures that are too high for successful embryonic development (Matsuzawa et al. 2002). Higher temperatures may significantly reduce incubation periods and contribute to a higher incidence of late-stage embryonic mortality (Ernest 2001). Nest temperature also influences sex determination in hatchlings, with warmer temperatures producing more females and cooler temperatures producing more males (Wibbels 2003). Consequently, dark sediments may alter hatchling sex ratios. Investigations of beach nourishment effects on hatching success have reported variable results; including positive effects (Broadwell 1991, Ehrhart and Holloway-Adkins 2000, and Ehrhart and Roberts 2001), negative effects (Ehrhart 1995, Ecological Associates Inc. 1999), and no effect (Raymond 1984, Nelson et al. 1987, Broadwell 1991, Ryder 1993, Steinitz et. al. 1998, Herren 1999, and Brock et al. 2009). The variation in findings has been attributed to differences in the physical attributes of individual projects, the extent of erosion on the pre-nourishment beach, and construction techniques (Brock et al. 2009).

Holloman and Godfrey (2008) studied the effects of multiple beach nourishment events on sea turtle nesting and hatching success on Bogue Banks. This five year study (2002-2007) included monitoring of nesting activity, hatching success, substrate compaction, and nest temperature. A total of 167 nests, including two leatherbacks and one green, were laid during the study period. Nourishment had no significant effect on nesting success (i.e., nest/false crawl ratios). There was no indication that nourishment adversely affected egg development or hatching success, with the exception of one nest on Atlantic Beach that apparently failed due to poor gas exchange. Nourishment had no significant effect on compaction; however, nests in nourished areas were on average 1.9°C warmer than nests laid at the same time on undisturbed beaches. Nourishment on the western end of EI had less of an impact on nest temperature, apparently due to better sand compatibility. Although sex ratios were not determined, Holloman and Godfrey concluded that nourishment probably increased the number of females produced.

The proposed beach nourishment construction window (16 November – 31 March) would avoid the sea turtle nesting and hatching season. Therefore, no direct impacts on nesting activity, nests, or hatchlings are anticipated. Measures to minimize adverse effects on habitat and potential indirect effects on nesting/hatching success would include the use of compatible sediments and monitoring for escarpment formation. Based on avoidance of the nesting season, the high sediment compatibility, and considering the proposed conservation measures and the lack of significant effects from past nourishment projects, beach nourishment is not likely to adversely affect listed sea turtles.

6.9.4.2 Dredging

Dredging of the borrow site would include the use of hopper dredges. Hopper dredging has a long history of sea turtle interactions throughout the southeastern United States. Hopper dredges employ a trailing suction draghead to remove sediment from the seafloor. Sea turtles are injured or killed when they are drawn into the hopper dredge intake pipe, a process referred to as "entrainment." The potential for sea turtle entrainment at the ODMDS would be minimized through a number of conservation measures; including adherence to a (16 November – 31) March seasonal dredging window, mandatory use of the rigid deflector draghead, and the use of protected species observers to monitor operations onboard the dredge. Similar measures are currently required for all USACE dredging projects in the South Atlantic Division, having been developed through a series of past Section 7 ESA consultations between USACE and NMFS (NMFS 1991b, 1995, and 1997). The deflecting draghead creates a sand wave in front of the draghead, thus pushing animals out of the way and reducing the potential for entrainment. Sea turtle entrainment rates have been dramatically reduced when the rigid deflectors are used and deployed correctly (Dickerson et al. 2004). However, if these deflectors are not operated so that they maintain constant contact with the ocean bottom, they can actually act as a trap for sea turtles instead of a deflector (Dickerson et al. 2004). To ensure proper use of the draghead, dredging operations at the ODMDS would be monitored via the Silent Inspector automated dredging quality assurance monitoring system. The Silent Inspector system allows draghead operational monitoring in near real time, thereby minimizing the potential for sea turtle interactions due to improper deployment of the draghead. Protected species observers would be responsible for monitoring the draghead and the hopper inflow screening for evidence of sea turtles. Furthermore, during transit, protected species observers would monitor for the presence of protected species in the vicinity of the dredge.
Although the proposed conservation measures would greatly reduce the likelihood of sea turtle impacts during dredging operations, sea turtles have been entrained by hopper dredges using the defector draghead at Morehead City during late November and December. Based on this history, adverse effects on loggerhead, green, Kemp's ridley, and hawksbill sea turtles cannot be entirely ruled out. Potential dredging impacts are further evaluated in the BA and are being addressed through formal Section 7 ESA consultation between BOEM and NMFS. NMFS will issue a Biological Opinion that may include additional conservation measures or alternative actions to minimize impacts.

The No Action Alternative is unlikely to have impacts on sea turtles, as there would be no dredging within the ODMDS.

6.9.5 Shortnose Sturgeon and Atlantic Sturgeon

The proposed project would use a hopper dredge to excavate sediment within the ODMDS. Atlantic and shortnose sturgeon have been taken by hopper, pipeline, and clamshell dredges along the Atlantic coast. Hopper dredges employ a trailing suction draghead to remove sediment from the seafloor. Sturgeon are injured or killed when they are drawn into the hopper dredge intake pipe, a process referred to as "entrainment." The potential for sturgeon entrainment at the ODMDS would be minimized through a number of conservation measures, including the use of rigid deflecting dragheads and monitoring requirements. The deflecting draghead creates a sand wave in front of the draghead, thus pushing animals out of the way and reducing the potential for entrainment (i.e., sea turtles and sturgeon). Monitoring requirements would include the presence of endangered species observers to monitor dragheads and inflow screening for sturgeon. Although the rigid deflecting draghead likely reduces the potential risk of sturgeon entrainment, takes may still occur due to dredge operator error and difficult dredging conditions (uneven bottom contours, currents, slope, etc.). Although few studies have evaluated the risk of entrainment relative to behavior, size class, and life cycle; the effects of entrainment on adult fish are presumed to be low (Dickerson et al. 2004).

Between 1990 and 2007, dredging operations along the North Atlantic Coast and South Atlantic Coast resulted in the take of 11 Atlantic sturgeons and 11 shortnose sturgeons. All of the shortnose sturgeon takes occurred in rivers along the North Atlantic Coast (Delaware River and Kennebec River). Shortnose sturgeon were taken by cutterhead (5), hopper (5) and clamshell (1) dredges. Atlantic sturgeon takes included two along the North Atlantic Coast and nine along the South Atlantic Coast. Atlantic sturgeons were taken by hopper (9) and clamshell (2) dredges. No sturgeons were taken in the vicinity of the Morehead City Harbor during this period (USACE 2009). Approved protective measures during implementation of the Proposed Action Alternative would minimize effects resulting in less than significant impacts on sturgeon.

The No Action Alternative is unlikely to have impacts on sturgeon, as there would be no dredging within the ODMDS.

6.9.6 Seabeach Amaranth

The proposed construction window (16 November – 31 March) would avoid the majority of the seabeach amaranth growing season. Therefore, no direct effects on plant growth or reproduction are anticipated. Potential indirect beach nourishment effects include the burial of seeds and habitat modification. Sand placement may result in the burial of seeds, potentially affecting their ability to germinate. The relationship between nourishment, seed burial, and germination is not known. In general, seabeach amaranth numbers have increased following past nourishment projects on Bogue Banks, possibly due to the creation of new habitat or the redistribution of seeds along with beach fill sediments (Personal communication, Dale Suitor, USFWS Raleigh Ecological Services Field Office, 2011). Prior to beach nourishment in 2000, no plants were observed at PKS. Following nourishment in 2001/2002, 779 plants were recorded in 2002 and 2,690 plants were recorded in 2003 (Nash 2003). The USACE routinely conducts monitoring for seabeach amaranth on Bogue Banks (USACE, unpublished data, 2012). As stated above, observed numbers of plants are highly variable, ranging from zero to 250 plants in a reach for the Fort Macon, Atlantic Beach and Pine Knoll Shores, portions of Bogue Banks.

The Proposed Action Alternative will have no impact on seabeach amaranth due to avoidance and protective measures implemented during the construction period.

The No Action Alternative is unlikely to have impacts on seabeach amaranth, as there would be no dredging within the ODMDS or beach placement within Bogue Banks.

6.10 Recreation and Tourism

The proposed project would produce temporary and localized restrictions on recreation opportunities during the construction time period (16 November 2012 to 31 March 2013). The economic effects of the Proposed Action Alternative during construction are not expected to be significant. Effects on surf fishing would be limited to the area where material is being placed on the beach. Such localized temporary impacts can easily be avoided by anglers in the area. Nearshore fishing boats can operate around the dredging equipment operating in the area. The Proposed Action Alternative is not expected to affect the operation of commercial fishing boats operating in or going through Beaufort or Bogue Inlet. Unless there is extreme weather, the ocean going dredge would operate continuously. Therefore, the economic impact on commercial and recreational fishing is not expected to change with the project construction.

Additional minor effects include limited and localized noise from construction equipment which is discussed in Section 6.4. However, post-construction will provide an improved and wider beach, increasing recreational opportunities. Recreational opportunities and tourism will benefit in the long term due to a larger beach. Tourism and related economic benefits are expected to be augmented by increased public access adjacent to fill areas and storm protection to oceanfront residential and commercial structures; thereby, maintaining the existing tax base.

6.11 Environmental Justice

As mandated by EO 12898, “Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations,” states that “each Federal agency make achieving environmental justice part of its mission by identifying and addressing, as appropriate, disproportionately high adverse human health and environmental effects of its programs, policies, and activities on minority populations and low income populations.”

The alternatives considered in this document would facilitate the remediation of a recreational oceanfront shoreline. Based on the above discussion on the environmental consequences; reclamation, construction and operation of the proposed project would have less than significant impacts related to environmental justice. The Proposed Action

Alternative would create tourist related jobs as well as increase public access to the recreational beach.

Neither alternative would have impacts related to environmental justice. The Proposed Action Alternative would be of short duration, involve relatively few workers, would not have significant impacts, and would not negatively affect onshore communities. Accordingly, the alternatives would not have impacts that would disproportionately affect minority or economically disadvantaged populations.

7.0 SECONDARY AND CUMULATIVE EFFECTS

Secondary and cumulative effects are those effects on the environment that result from the incremental impact of the proposed action when added to other past, present, and reasonably foreseeable future actions regardless of what agency or person undertakes the other actions. Time crowded perturbations, space crowded perturbations, indirect and synergistic effects, and combinations thereof are considered in this analysis. The time bounds for this cumulative effects analysis are from the late-1970s through the proposed implementation of the MBNP. Bogue Banks beaches were nourished as early as 1978. This analysis will focus on potential cumulative effects within the Project area since portions of affected beaches under the current proposal have received fill in the past as well as barrier islands within approximately 50 miles of the Project area.

The cumulative effects assessment focused on dredging effects from the proposed ODMDS, and effects of placing sand material on the ocean shoreline. The cumulative effects analysis included a review of several environmental reports prepared for and published by the USDOI, BOEM. These reports included:

Use of Federal Offshore Sand Resources for Beach and Coastal Restoration in New Jersey, Maryland, Delaware, and Virginia (USDOI 1999);

Collection of Environmental Data Within Sand Resource Areas Offshore North Carolina and the Environmental Implications of Sand Removal for Coastal and Beach Restoration (Byrnes et al. 2003);

USACE Dare County Beaches (Bodie Island Portion) Final Feasibility Report and EIS on Hurricane Protection (USACE 2000);

USACE's Draft Evaluation Report and Environmental Assessment, Morehead City Harbor Section 933 (USACE 2003); and

Final Integrated General Reevaluation Report and Environmental Impact Statement, Shore Protection, West Onslow Beach and New River Inlet (Topsail Beach) (USACE 2009)

Several of the above documents include comprehensive assessments of statewide cumulative effects. In discussing the potential cumulative effects of offshore borrow area dredging and beach nourishment, time- and space-crowded perturbations were considered to be relative to the Proposed Action Alternative.

The State of NC has approximately 320 mi of ocean shoreline. Carteret County, NC is centrally positioned on NC's coast south of Cape Lookout. Bogue Banks is an approximately 26-mile long barrier island located on the low-energy limb of the Cape Lookout foreland with a relatively unique east-west orientation. Beaufort Inlet borders the island to the east, separating Bogue Banks from Shackleford Banks. Bogue Inlet borders Bogue Banks to the west, separating the island from Bear Island. Shackleford Banks is part of the Cape Lookout National Seashore (CLNS), and Bear Island is part of the Hammocks Beach State Park. Bogue Sound, a relatively shallow embayment system encompassing reaches of the Atlantic Intracoastal Waterway (AIWW), separates Bogue Banks from the mainland and Onslow Bay (Atlantic Ocean). There are numerous completed and proposed projects involving beach renourishment, similar to the completed and proposed renourishment activity on Bogue Banks. However, Bogue Banks' south facing orientation and its undeveloped and protected neighboring islands set it apart from many NC shorelines. Most nourishment actions are typically authorized as one-time beach nourishment events as is the case for the Post-Irene effort.

The following are brief summaries of NC shore protection projects or locations whose proximity are the closest to Bogue Banks.

Surf City and North Topsail Beach, NC, Draft Feasibility Study

The USACE – SAW is conducting a federal feasibility study for storm damage reduction and shoreline protection for a 50-year period of analysis along North Topsail Beach and Surf City. The Surf City and North Topsail Beach Shore Protection Project Feasibility Report (USACE 2009) discloses that the most practicable plan of protection is a berm and dune project extending from the southern edge of the Coastal Barrier Resources System (Topsail Unit, L06). Renourishment will occur on a four-year cycle. If protection of this area is found to be in the Federal interest, the project could be implemented as early as 2012.

North Topsail Beach Shoreline Protection Project

The Town of North Topsail Beach has been issued federal and state permits for a beach nourishment/inlet management project. The project involves a proposal to reposition New River Inlet channel, renourish 11.1 mi of oceanfront protecting homes and town infrastructure, and implement an inlet management plan to control the migration of the inlet channel.

West Onslow Beach and New River Inlet, NC, General Revaluation Report and EIS

This approximately five mile federal storm reduction project for the Town of Topsail Beach (designated as the West Onslow Project) consists of a sand dune constructed at 13 ft above mean sea level, fronted (oceanward) by a storm berm constructed at an elevation of nine ft above mean sea level, and a beach berm elevation of seven ft above sea level. The USACE anticipates renourishment will be required every four years. A General Reevaluation Report and EIS have been completed for the project and the project is on hold due to lack of Congressional funding. Funds to initiate detailed engineering and design for the project were not included in the federal budget for 2012; therefore, the construction date for this project is uncertain.

Topsail Beach Interim (Emergency) Beach Fill Project

The Town of Topsail Beach has recently completed an interim beach fill project using material obtained from existing navigation channels and upland dredged material disposal sites located behind the island. The purpose of the one-time project was to protect oceanfront development and infrastructure until such time that the federally authorized West Onslow Project can be implemented. This project covered the oceanfront section of the Town located between Godwin Avenue on the south to a point 2,000 ft northeast of Topsail/Surf City town limits, along a total ocean shoreline length of approximately 4.7 mi.

Shackelford Banks Dredged Material Management

In a 20 August 2010 response to the SAW's proposed DMMP for the Morehead City Harbor, the CLNS clarified the Park Service's position regarding beach nourishment on Shackleford Banks: "sediment disposal and other types of shoreline process interference are permitted in national park units when necessary to restore or mitigate the impacts of human-caused activities." The CLNS further acknowledged the beneficial use of maintenance dredged sediment mitigating the ebb tide delta's deflation. Future uses of Morehead City Harbor's beach quality and non-beach quality maintenance dredged material will be proportionately redistributed based on need, mitigation locations, and material quality. Precise volumes, location rotations, and sediment quality by location have not been finalized.

7.1 General Summary of Beach Nourishment in North Carolina

Many NC communities have either received state or federal permit authorizations to conduct community-wide beach work, or are currently preparing official requests. Carteret County and the SAW, in the past 30+ years, have renourished basically all 26 miles of Bogue Banks, from EI to Atlantic Beach, using material dredged from offshore borrow sites, upland confined disposal facilities, and directly from navigation channels (as described in Section 2).

The following summaries are statewide shoreline efforts related to the SAW's activities (Personal communication, David Timpy, USACE – SAW, November 2011):

Shoreline Sand Placement Activities:

- Average/year is 8.0 mi or 2.5% of total NC ocean beach (320 mi)
- Minimum for any year is 3.5 mi or 1.1 % of total NC ocean beach

Given the small percentage of the total NC shorelines affected, the fact that each project is not conducted on an annual basis, but every two or more years (thereby allowing biological recovery), the dynamic nature of the systems, and the minimal and/or short-term environmental effects associated with each project; the cumulative environmental effects of these combined beach disposal and renourishment projects (including the proposed project) are not considered to be significant.

A relatively small portion, approximately 12% of NC beaches, is presently affected by renourishment activities (USACE 2009). It is unlikely that cumulative impacts from space crowded perturbation are occurring or will occur with the construction of this one-time proposed project. With the Proposed Action Alternative, the affected areas would not increase significantly because the areas proposed for renourishment have previously had sand deposition. The analysis suggests that the potential impact area from the proposed and existing actions is small relative to the area of available similar habitat on a vicinity basis (USACE 2010).

Proposed as a one-time event, assessing potential sea level rise effects on or from the Post-Irene project is temporally and spatially limiting. However, effective coastal planning requires the consideration of climate change and sea level rise. Global mean sea level rose at a rate of approximately 1.7 millimeters per year over the course of the 20th century; however, since 1993, global mean sea level has risen at a rate of approximately three millimeters per year [International Panel on Climate Change (IPCC) 2007). IPCC has predicted an increase in global mean sea level ranging from 0.18 to 0.59 meters by 2100 (IPCC 2007). Based on monthly mean sea level data from 1953 through 2006, mean sea level at Beaufort, North Carolina has risen at a rate of 2.57 millimeters per year (Zervas 2009). An additional study by Zervas (2004) averaged data from the Beaufort station over the period 1973 through 2002, indicating a sea level rise rate of 3.2 millimeters per year or 0.32 meters per century. The NCCRC's Science Panel on Coastal Hazards (2010) used tide gauge data to project sea level rise under varying rates of acceleration. The resulting sea level curves project an increase of 0.4 to 1.4 meters by 2100. An increase of one meter is projected when the linear relationship between temperature and sea level observed during the 20th century is extrapolated through 2100. Based on these projections, the Science Panel on Coastal Hazards has recommended that a rise of one meter by 2100 be adopted as the anticipated increase for policy development and planning purposes. Proposed guidelines are being considered for future land use planning. With a targeted construction date of winter 2012/2013 and the single event nature of the proposed action, sea level rise was not considered a significant factor.

For some species such as sea turtles and seabeach amaranth, beach projects would improve habitat by replacing beach material lost to erosion. Invertebrates in the affected areas would be expected to recover, remaining viable as food resources. The potential that the direct and cumulative effects of the Proposed Action Alternative and other existing similar activities would reach a threshold with high potential for population level effects on important commercial fish stocks and birds is low. The proposed conservation measures limiting work only in time frames when oceanfront and aquatic organisms are least active and by requiring contract mechanisms to further minimize potential effects to the coastal resources; long term cumulative effects are not anticipated. Because of the dynamic nature of the systems, the minimal and/or short-term environmental effects, resource windows, and incorporating special conditions and conservation measures; the cumulative environmental effects are not considered significant.

Both beneficial and adverse cumulative effects may occur when the effects of the Proposed Action Alternative are considered. Considering the relatively small footprint, the short project duration, and the resources' recoverability/reversibility; the Proposed Action Alternative contributes a small incremental effect to potential cumulative effects when considered with other past, present, and reasonably foreseeable actions affecting the project area.

8.0 PROPOSED AVOIDANCE AND MINIMIZATION MEASURES

The following avoidance/minimization measures and reporting requirements are proposed to avoid, reduce, or eliminate environmental effects associated with the Proposed Action Alternative. Avoidance/minimization measures as terms and conditions may be added to BOEM's non-competitive lease and NCDCM Major Permit. Minor modifications to the proposed measures may be made during the negotiated agreement process if comments indicate changes are necessary or if conditions warrant.

The construction timing was specifically scheduled to occur outside the sea turtle nesting season, the West Indian manatee summer occurrence in NC, the piping plover (and other shorebirds) migratory and breeding seasons, and for the most part the seabeach amaranth flowering period. The sand placement and dredge operation would be conducted outside of primary invertebrate production and recruitment periods (spring and fall) limiting effects on amphipods, polychaetes, crabs, and clams. In addition, specific hopper dredging conditions and conservation measures have been incorporated into this proposed project (Appendix I).
Proposed conservation measures resulting in avoidance and minimization of potential effects from dredge activities are bulleted below.

- Dredging quality management will be implemented within the offshore reclamation areas and documented by Global Positioning Systems (GPS) units and Silent Inspectors. These management tools would ensure sand resource removals are within previously surveyed and authorized ODMDS reclamation areas.

- Protected species observers would be a contract stipulation requiring trained and experienced personnel knowledgeable in industrial marine mammal and sea turtle observation and reporting standards.

- Associated dredging vessel speed restrictions (10 knots maximum for transit) would be employed during transiting supplemented by protected species observers to reduce potential collision effects with managed or associated species (northern right whale).

- Hopper dredge operations would require sea turtle deflecting dragheads and inflow screening during all sand reclamation efforts.

- Dredging contract will include a requirement for dredging patterns allowing undisturbed furrows remain within the borrow area. Undisturbed furrows will expedite benthic fauna recovery within the ODMDS.

- Directional, shielding, and intensity managed lighting would be employed minimizing potential nocturnal marine species' effects, while meeting Occupational Safety and Health Administration (OSHA) vessel work standards.

- Contract language would require routine inspection of dredging equipment and transport piping minimizing potential leaks at the dredge plant and along transport corridors.

- Contract language would require spill response capabilities and waste management plans for all dredging fleet equipment.

- In the event that the dredge operators discover any archaeological resource while conducting dredging operations in the ODMDS or in the vicinity of pump-out operations, Carteret County's representative shall require that dredge and/or pump-out operations be halted immediately within 305 m (1000 ft) of the area of discovery. Carteret County representative shall then immediately report the discovery to Mr. James F. Bennett, Chief, Division of Environmental Assessment, BOEM, at (703) 787-1660. If investigations determine that the resource is significant, the parties shall together determine how best to protect it.

Proposed conservation measures resulting in avoidance and minimization of potential effects from recipient beach activities are bulleted below:

- Daily monitoring of beach nourishment activities would be conducted to further ensure the compatibility of the beach fill material. Visual monitoring of the fill material would be conducted at the dredge pipe outfall before it is redistributed along the beach. If any incompatible fill material is detected, the contractor will cease operations and immediately contact the Wilmington District Regulatory Branch and NCDCM to determine the appropriate course of corrective action.

- Immediately after the beach construction operation is complete and prior to 1 May, surveys for escarpments will be conducted within the limits of the construction area. Escarpments that are identified prior to or during the nesting season that interfere with sea turtle nesting (exceed 18 inches in height for a distance of 100 feet) would be leveled to the natural beach profile. If it is determined that escarpment leveling is required during the nesting or hatching season, leveling actions would be coordinated with the USFWS.

- All beach equipment (bulldozers, frontend loaders, pickups, etc) would access current public access areas, no new access cuts would be allowed.

- Existing vegetated dune fields would not be disturbed and equipment/personnel would not be allowed within these dune line buffers.

- Contract language would require equipment refueling locations within designated equipment staging areas away from the active work zone if practicable.

- Contract language would require designated contract spill response capabilities.

- If available, staging areas for construction equipment would be located off the beach.

- Construction equipment not in nighttime use would be stored off the beach if practicable, minimizing potential effects on nocturnally active species.

- Diffusion plates would be a contract stipulation, reducing effluent discharge velocities with directional sand-slurry placement.

- Temporary slurry diversion training walls would be pushed up from existing and received material, extending and directing the sandy effluent's horizontal flow, maximizing sediment retention, and minimizing potential swash zone turbidity effects.

- Visual monitoring would be required during all sand slurry discharging operations with "shut down" and agency notification authorization in the event unsuitable material is encountered.

- Directional, shielding, and intensity managed lighting will be employed minimizing potential nocturnal species' effects, while meeting OSHA work standards.

- Contract language would require routine inspection of slurry transport piping minimizing potential pressurized leaks along the beachfront.

- Heavy equipment would be removed from refurbished shorelines as soon as practicable, restoring unrestricted public access.

The proposed project would use a regularly impacted disposal area (ODMDS) that is EPA designated for use as an ocean disposal area for dredging Beaufort Inlet and the federal navigation channels serving the Port of Morehead City (Figure 1). There are no anticipated effects to the ODMDS area due to the frequent disturbances by the USACE's placement of maintenance dredged material from Beaufort Inlet and the Morehead City Harbor.

9.0 CONSULTATION AND COORDINATION

The USACE and BOEM have integrated NEPA compliance with several other environmental requirements, including the ESA, MSFCMA, Coastal Zone Management Act, and National Historic Preservation Act. The USACE served as the co-lead federal agency for environmental compliance with beach placement and navigation compliance, while BOEM has acted in a co-lead federal agency role for environmental compliance with OCS borrow activities. Pursuant to Section 106 of the National Historic Preservation Act and the Advisory Council on Historic Preservation's Regulations for Compliance with Section 106, consultation with SHPO was conducted via BOEM in which no opposition for the use of the ODMDS was received (Section 5.6). In addition, consultation as part of the State's CAMA review process resulted in SHPO responding with no objection to the deposition of additional sand on the three known archaeological sites within the proposed placement area (Appendix H). In March 2012, a BA and an EFH Assessment (DC&A 2012b) were submitted to BOEM and the USACE SAW for initiating USFWS and NMFS consultations.

A number of ESA Section 7 consultations have been conducted for previous nourishment projects at Bogue Banks (see below). During previous projects, the USACE was been sole lead agency for ESA Section 7 consultations with both NMFS and USFWS. Section 7 lead agency responsibilities for the current Post-Irene Renourishment Project are divided between BOEM and the USACE. BOEM is consulting with NMFS on the ODMDS dredging aspects of the project, whereas the USACE is consulting with USFWS on the sand placement aspects of the project. Although the USACE is subject to applicable terms and conditions arising from previous consultations (including the RBOs for dredging), these consultations are not applicable to BOEM or the dredging aspects of the current project. Although many of the dredging conservation measures proposed in this EA are based on measures developed under previous consultations, any legally binding terms and conditions for the Post-Irene dredging component will be contained within the impending NMFS consultation.

During pre-project agency coordination for the 2004 Post-Isabel Sand Replacement Project, NMFS responded that consultation was not required provided all conditions of the 1997 RBO were implemented during the project. The USFWS responded that the Post-Isabel project was not likely to adversely affect listed species provided the project implemented minimum shell content standards and all conservation measures contained in the original permit for the BBBRP. During pre-project agency coordination for the 2007 Post-Ophelia Sand Replacement Project, NMFS again responded that consultation was not required provided all conditions of the 1997 RBO were implemented. The USFWS recommended conservation measures similar to those adopted for the original Bogue Banks Restoration Project. Examples of conservation measures adopted and included as conditions of the project permit are: compliance with the 1997 RBO, adherence to a (16 November – 30 April) environmental construction window, measures to ensure compatibility of the fill material, escarpment monitoring, sea turtle nest monitoring, and no storage of construction equipment on the beach between 1 May and 15 November. The Post-Irene Renourishment Project's proposed conservation measures reflect specific stipulations found in the 1997 RBO.

SECOND DRAFT REVISED 31 OCTOBER 2000

FINAL REVISED 4 APRIL 2001

[*formerly CSE Baird LLC]

Addendum II to Draft EIS dated 31 October 2000

The present version (4 April 2001) of the EIS for Bogue Banks Beach Restoration Plan includes the following changes and additions.

Correspondence Section (between the main report and Appendix A) — Additional comments and responses from corresponding State Clearinghouse agencies, University of North Carolina Institute of Marine Sciences, and Environmental Defense are provided in chronological order of the original correspondence with a supplementary index.

Addendum I to Draft EIS dated 6 March 2000

The present version (31 October 2000) of the EIS for Bogue Banks Beach Restoration Plan includes the following changes and additions.

Main Report — Changes in the main report (Sections 1-6) are highlighted in **SMALL-CAP BOLD** (text additions) and/or with a ~~strikeout~~ (text deletions).

New Section — "Correspondence" (between the main report and Appendix A). Comments and responses from corresponding agencies are given in chronological order of the original correspondence with a supplementary index.

Revised Appendix C — Final report (revised 11 September 2000) on Bogue Banks beach renourishment project: late fall 1999 assessment of benthic invertebrates and demersal fish resources in the offshore mining sites prior to sand mining by Dr Charles H Peterson and Dr John T Wells, Institute of Marine Sciences, University of North Carolina, Morehead City, NC, 13 pages + appendices.

PREFACE

This Environmental Impact Statement (EIS) is prepared in accordance with North Carolina environmental permitting regulations in the coastal zone. Carteret County has sustained accelerated erosion along Bogue Banks as a result of five hurricanes in quick succession since 1995 (Fig. P1). The county, the municipalities of Emerald Isle, Indian Beach, and Pine Knoll Shores, and the unincorporated area of Salter Path desire to perform beach nourishment at the earliest time for purposes of restoring the recreational beach and reducing the direct threat of erosion to developed property. The most recent hurricane (*Floyd*, September 1999) caused $30 million in damages in the county, most of which occurred along the oceanfront in the municipalities listed above. Beach nourishment is considered to be the only viable alternative among three possible alternatives at this time. Continued erosion will directly threaten the tax base of the entire county if nothing is done because of the effective subsidy of county tax rates provided by Bogue Banks property owners. Property abandonment and relocation would cost much more than the proposed nourishment project in reduced tax revenues and the direct costs of relocation over the next decade.

Time is of the essence, but the county recognizes that projects of this type require careful analysis and design, as well as consideration of the environmental consequences. The county has commissioned a citizens' advisory panel and has reviewed alternatives for the past two years. Drawing on expertise from the local as well as national professional community, beach nourishment has been selected as the interim solution. The panel recognizes that only through site-specific project experience can the true consequences and costs of nourishment be known. It acknowledges that there are risks with projects of this type, and the outcome cannot be predicted with absolute certainty. However, the risks of the other two alternatives are considered to be much greater. Continued damages to property are all but certain if nothing is done. And the timeline for property abandonment and relocation is an exceedingly long process when one factors in the emotional investments of owners and the high probability of legal challenges brought when properties are condemned. Property abandonment and relocation at a large scale would leave the beach degraded for many years because it would necessarily become a piece-meal process. Those opting to abandon would leave derelict structures on the beach, imposing aesthetic, environmental, and financial costs to the county and municipalities.

The proposed plan has been formulated over the past year with preliminary input from many resource agencies. It addresses the specific conditions along Bogue Banks and incorporates best-management practices as recommended by federal and state regulatory agencies. The plan seeks to minimize environmental impacts, provide enhanced beaches for the public, and maintain viable wildlife habitat while reducing future storm damages over the next decade.

TABLE OF CONTENTS

TABLE OF CONTENTS

1.0 INTRODUCTION

1.1 PROJECT SPONSOR

The proposed beach nourishment project is being sponsored by Carteret County in conjunction with the Towns of Pine Knoll Shores, Indian Beach and Emerald Isle. Funding is proposed by a combination of locally generated revenue sources. No state or federal funding assistance is currently included.

1.2 PROJECT SETTING

The project area includes the beaches reaching from the town limits of Pine Knoll Shores and Atlantic Beach to the western end of Emerald Isle, ~1 mile east of Bogue Inlet. Total project length of 16.8 miles of shoreline.

Bogue Banks is a barrier island with a southward facing ocean shoreline stretching some 25 miles between two large tidal inlets, Bogue Inlet to the west and Beaufort Inlet to the east. The Banks are surrounded by Bogue Sound on the north and Onslow Bay of the Atlantic Ocean on the south.

Of over 70 miles of barrier island shoreline located in Carteret County, Bogue Banks is the only developed area. The remainder, made up of Shackleford Banks and Core Banks to Ocracoke Inlet, will remain undeveloped in perpetuity as part of the Cape Lookout National Seashore. Bogue Banks is the only ocean shoreline in Carteret County with convenient vehicle access to all citizens.

1.3 PURPOSE AND NEED

Carteret County and the communities on Bogue Banks recognize the oceanfront beaches and adjacent properties as a valuable public economic and ecological resource. Like any valuable resource, it must be protected. From an economic perspective, the need for the proposed Bogue Banks beach nourishment project is to protect and preserve the largest portion of the county's overall economy. Tourism is, by far, the largest industry in Carteret County. The industry contributes ~$208 million annually to the economy of Carteret County, with a direct payroll of more than $38 million to over 3,400 workers.

Bogue Banks represents less than 1 percent of Carteret County's land area but accounts for ~43 percent (over $2 billion of the county's $5.4 billion tax base) of Carteret County's ad valorem property tax base (1997). Approximately 61 percent of all locally generated revenues in the county derive from property taxes with the remainder from sales taxes, occupancy taxes, and fees. Nearly 80 percent of Carteret County's tax levy funds Carteret County schools. Out of 8,483 students in Carteret County schools, only 537 (6.3 percent) reside on Bogue Banks (1997-98). Thus, property owners on Bogue Banks provide almost half the funds for county schools but make up less than 10 percent of the school population. Any reduction of the effective subsidy derived from Bogue Banks property and economic activity would result in increased property taxes over the remainder of the county. Loss of the first row of oceanfront properties (which alone comprise nearly 10 percent of the county tax base) would result in a county-wide tax increase of ~$0.05/$100 (from $0.50/$100 to $0.55/$100) to make up for the reduced tax base.

Oceanfront properties represent an inordinate share of total property tax revenues to the Bogue Banks municipalities. Emerald Isle has a total tax base of ~$1,000,000,000 with ~$300,000,000 of the tax base deriving from oceanfront property. The loss of the oceanfront row of properties in Emerald Isle would result in a property tax increase of ~$0.09/$100 from $0.195/$100 to $0.285/$100. Pine Knoll Shores has a total tax base of ~$415,000,000 with ~45 percent ($185,000,000) of the tax base deriving from oceanfront property. The loss of the oceanfront row in Pine Knoll Shores would result in a property tax increase of ~$0.13/$100 from $0.16/$100 to $0.29/$100. Indian Beach has a total tax base of ~$100,000,000 with $60,000,000 of the tax base deriving from oceanfront property. The loss of the oceanfront row of properties in Indian Beach would result in a property tax increase of ~$0.26/$100 from $0.17/$100 to $0.43/$100.

The county also recognizes the beaches of Bogue Banks as a valuable ecological resource. Of over 70 miles of barrier island shoreline located in Carteret County, Bogue Banks is the only developed portion. The remainder, made up of Shackleford Banks and Core Banks to Ocracoke Inlet, will remain undeveloped in perpetuity as part of the Cape Lookout National Seashore. Bogue Banks serves to draw human activity away from the pristine beaches and ecosystems of Shackleford and Core Banks. The health of the beach environment is essential to a positive experience for the beach visitor. The damage associated with severe storms results in the loss of high oceanfront dunes, scrub and maritime forests. Easily accessible wide dry beach areas, high dunes and maritime forests harbor a wide range of wildlife resources and, because of the effects of erosion, are becoming increasingly rare along North Carolina's shoreline.

The sportfishing industry in Carteret County is second in size only to Dare County. The health of those activities (including fishing, boat building, and outfitting and supply) is dependent on the health of the marine environment.

Project Planning Objectives – In undertaking the beach nourishment project, Carteret County has several objectives that the project must meet. Those objectives are summarized as follows:

- Preservation of the environmental, cultural and aquatic resources of the county.
- Provide an easily accessible recreational beach available to all citizens of the county.
- Provide protection of oceanfront property as a resource of tax revenues to the municipalities of Bogue Banks and the county.
- Maintain the economic viability of tourism, the county's largest industry.

1.4 PROJECT DESCRIPTION

The proposed beach nourishment project will consist of placing the equivalent of ~4.5 million cubic yards of beach-quality sediment along ~16.8 miles of Bogue Banks from the Atlantic Beach/Pine Knoll Shores town line to ~Shipwreck Lane along western Emerald Isle (Fig. 1.1). Nourishment sand will be excavated from up to ~~four~~ **THREE** borrow areas by hopper dredge or hydraulic dredge and placed along as many as six contiguous reaches. [CSE Baird-Stroud. 1999. Shoreline assessment and preliminary beach restoration plan, Bogue Banks, NC. Executive Summary Report, 38 pp.]

Three potential borrow areas (A, B1, and B2) have been sampled and delineated offshore of the project area, and an alternate borrow area (C) has been identified in Bogue Inlet. **AS A RESULT OF COMMENTS FROM NCDENR, BORROW AREA C IS NO LONGER BEING CONSIDERED AS AN ALTERNATE BORROW AREA FOR THE PROJECT**. Sediment quality in each borrow area was compared with native beach sediment quality to determine compatibility indices (R_A, after the method of James, 1975). Twenty samples from the dune, berm, beach face, and low-tide terrace were used to determine the "native" sediment characteristics. The mean grain size computed from 20 samples was ~0.30 mm [versus 0.17 mm used by USACE (1976) for planning along Atlantic Beach].

Borrow area A (revised) had the lowest R_A value (1.16), meaning that ~85 percent of the deposit would be stable as beach fill. Borrow area B1 yielded an R_A value of 2.19; B2 yielded an R_A value of 1.97; and C yielded an R_A value of 1.57. The R_A factors predict how many cubic yards of nourishment material will be required to perform as 1.0 cy of native beach sediment. Variations in R_A factors were used to adjust the required (base) nourishment volume for a particular borrow area. Borrow areas with higher R_A will require proportionately higher excavation volumes to achieve the same performance as native beach sand.

Final selection of borrow area(s) will be based on several factors, including sediment quality, dredging and transportation economics/environmental impacts, and cultural resource impacts. Borrow area A is tentatively identified as the optimal sand source. It extends from ~0.5 to 2.5 miles offshore, centered near the Emerald Isle/Indian Beach town line. Sediments have been confirmed over an ~4.5 square-mile area to a section thickness averaging ~2.25 ft. This yields potentially 10 million cubic yards of beach quality sediment. Only a portion of borrow area A will be required to satisfy the nourishment volume requirements of the project (~5.1 million cubic yards after factoring in the overfill ratio). The average water depth in borrow area A is ~46 ft. The anticipated optimal equipment for excavations will be ocean-certified, self-contained hopper dredges. Such equipment typically excavates shallow trenches (~2 ft of section) in each pass (leaving narrow undisturbed areas at the margin of each cut), then travels to a buoyed pipeline anchored close to shore. Discharge to the beach is via submerged pipeline across the surf zone, then by way of shore-based pipe positioned along the dry beach.

The project will be built in ~1-2 mile sections, optimizing the disposition of pipeline. Sections will be pumped into place with the aid of temporary dikes pushed up by bulldozer in the surf zone. Daily operations will directly impact ~ 500-1000 ft of shoreline as work progresses in either direction from the submerged pipeline. Upon completion of a section, the submerged pipe and beach-building equipment will be shifted to the next section.

The project will add an average of ~50 cy per linear foot along the recreational beach between the base of the foredune and the outer bar. It will displace the shoreline ~75-100 ft seaward after fill adjustment. The backbeach grade for the project will be set close to the existing grade of the dry beach (~+7 ft NGVD). The fill will be sloped in the seaward direction to maintain proper drainage. Where oceanfront development exists at elevations nearly equaling the native dry beach, a low protective dune will be pushed up along the backbeach to prevent the slurry from draining toward buildings.

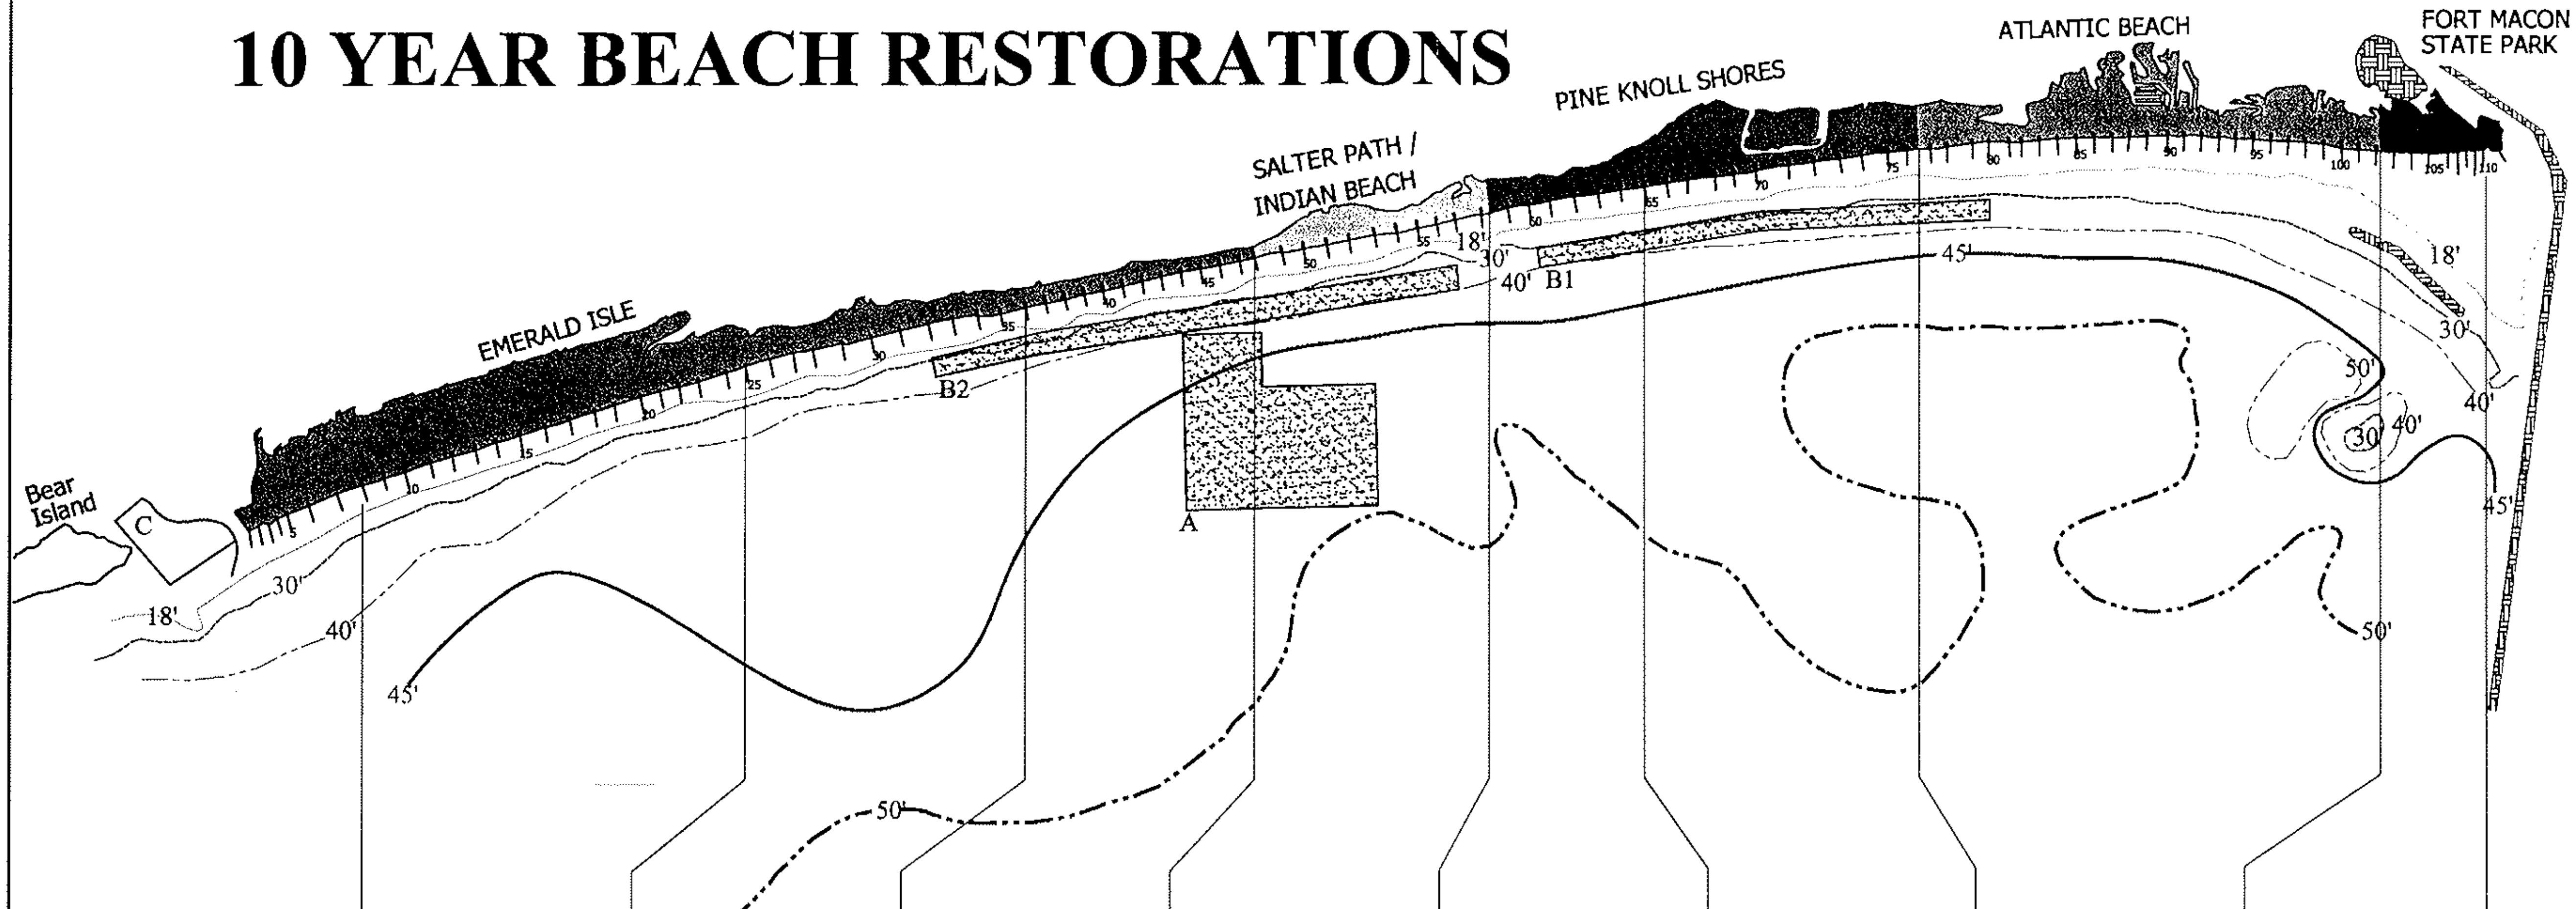
Under normal circumstances, using a single dredge, the project will require 180-300 days to construct (at 15,000-25,000 cy per day average production). The applicant desires to perform construction during winter months to avoid the tourist season, turtle-nesting season, and periods of highest biological productivity. Alternatives involving use of more than one dredge (to shorten the construction period) or splitting construction over two winter seasons are being investigated.

As construction progresses, sections will be graded to final contours, dressed to eliminate low areas, and opened for use by the community. Support equipment will be shifted out of completed sections as soon as practicable, such that construction activities in a given reach will disrupt normal beach use for only a month or so at any locality.

The finished sections will be allowed to adjust to natural processes for several months. Then in applicable areas, dune fencing and/or dune plantings will be installed.

In all likelihood, only portions of the entire project will be constructed under a single mobilization during any particular environmental window. For example, the community of Pine Knoll Shores may secure funding and elect to construct a project within their political boundaries [designated as reaches Pine Knoll Shores East and Pine Knoll Shores West in CSE Baird-Stroud (1999) and this document, Fig. 1.1]. Similarly, the Town of Emerald Isle and the Town of Indian Beach may elect to construct projects for their reaches independent of Pine Knoll Shores. Based on our present understanding of funding availability, it is not likely that the entire 16.8-mile project will be constructed within the same environmental window.

PRELIMINARY PROJECT ALTERNATIVES
10 YEAR BEACH RESTORATIONS



Emerald Isle West 1	Emerald Isle Central 2	Emerald Isle East 3	Indian Beach Salter Path 4	Pine Knoll Shores West 5	Pine Knoll Shores East 6	Atlantic Beach	Fort Macon State Park

Nourishment Volume: 866,000 cy	Nourishment Volume: 844,000 cy	Nourishment Volume: 1,745,000 cy	Nourishment Volume: 990,000cy	Nourishment Volume: 778,000 cy	Nourishment Volume: 1,466,000 cy		
Length: 23,700 ft	Length: 14,545 ft	Length: 12,900 ft	Length: 13,417 ft	Length: 8,760 ft	Length: 15,437 ft		
Borrow Area C: Bogue Inlet Shores via hopper dredge	Borrow Area A: Salter Path Offshore Deposits	Borrow Area A: Salter Path Offshore Deposits	Borrow Area A: Salter Path Offshore Deposits	Borrow Area A: Inshore Deposits	Borrow Area A: Inshore Deposits		

Summary:

Length: ~88,760 ft - 16.8 miles

10-Yr Profile Volume Required: ~4,424,500 cy

Nourishment Required: 10yr volume x R_a

(Ra = Estimated overfill factor for respected borrow areas.)

NOTE: Nourishment volumes are based on a computed profile volume deficit to the outer bar, background volume erosion rate, and overfill ratio for the indicated borrow area. Use of alternative areas will result in revised nourishment volumes and unit construction costs. The low-end cost estimate assumes shared engineering, permitting, and construction mobilization costs. The high-end cost estimate assumes independently formulated and executed projects. Details are given in CSE Baird/Stroud (1999).

2.0 SUMMARY

2.1 MAJOR CONCLUSIONS

Bogue Banks is the only developed, accessible beach in Carteret County, representing ~35 percent of the county shoreline and 1 percent of the county land area. Residential and business properties on Bogue Banks account for ~43 percent of the county tax base but receive a much lower percentage of county services and investments. Chronic erosion, while occurring at low rates compared to many shorelines, has accelerated recently as a result of five landfall hurricanes in quick succession since 1995. Loss of beach area and a general sand deficit have left nearly 17 miles of oceanfront vulnerable to damage during even minor storms. The most recent hurricane (*Floyd*, 1999) caused upward of $30,000,000 damage in the county, largely concentrated along Bogue Banks' oceanfront, where the beach is narrowest. Little or no property damage occurred along Atlantic Beach, which had a much wider beach as a result of nourishment in 1986 and 1994.

Erosion poses an immediate threat to property, infrastructure, and the county tax base. Loss of oceanfront properties to erosion would result in tax increases ranging from $0.05/$100 for all mainland residents to $0.31/$100 for Indian Beach residents, with Pine Knoll Shores properties in between these amounts.

Tourism, the county's primary industry, will decline if the beach continues to erode. Presently, there is less recreational beach area for the public than five years ago. Property owners have increased the frequency of beach scraping to rebuild foredunes and protect imminently threatened homes. Associated with erosion and dune scraping has been a decline in beach habitats for nesting sea turtles and other organisms.

A citizens' Beach Preservation Task Force, meeting frequently over the past two years, has determined that the only viable alternative is to rebuild the beach via nourishment. Over a ten-year period, nourishment results in lower costs compared to the "no-action" alternative or "property abandonment and retreat" alternative.

A ten-year nourishment project is estimated to require a minimum of 4.5 million cubic yards to restore the sand deficit and provide for average yearly losses over a decade or so. This level of effort would add ~50 cubic yard per foot (cy/ft) along 16.8 miles of beach from Pine Knoll Shores to western Emerald Isle and widen the recreational beach 75-100 ft. The project would restore eroded areas to a similar condition as that of Atlantic Beach.

Viable beach-quality sand exists in several strategic offshore areas close to the shoreline. Preliminary estimates indicate that these deposits can be excavated and placed on the beach via hydraulic dredge at a cost of approximately $25 million. Other potential borrow sources (including shoals in Bogue Inlet, Bogue Sound, and Beaufort Inlet, or existing spoil areas controlled by the USACE) are considered less cost effective because of their distance to the project area or their poorer quality material.

The proposed project will require ~6-8 months to construct if only one dredge is available. The county desires to complete the project at the earliest time and will seek ways to complete construction during cold weather months when environmental impacts are lowest. The ~~planned~~ **EARLIEST** period of construction **FOR ANY PARTICULAR REACH IS NOW ESTIMATED TO BE** November ~~2000~~ **2001** through April ~~2001~~ **2002**. Construction activities will directly impact a particular property for only a few days as nourishment proceeds section by section at an average rate of about 300-500 ft per day. The project will be monitored carefully after construction to quantify its longevity and document environmental change. As the first nourishment along most of Bogue Banks, it will necessarily serve as a prototype for future beach maintenance efforts.

2.2 AREAS OF CONTROVERSY

Beach nourishment, in general, involves three primary areas of controversy: (1) funding, (2) physical impacts, and (3) environmental impacts.

2.2.1 Funding – **FUNDING FOR** the proposed project ~~will be funded entirely using county and~~ **IS UNCERTAIN AT THIS TIME BUT WILL LIKELY INVOLVE MOSTLY** local funds. ~~No federal or state funds will be used.~~ Approximately 64 percent of the project will be funded by property owners in special tax districts on Bogue Banks. Analyses have demonstrated that significant economic benefits accrue to the entire county if the beach is maintained and the tax base on Bogue Banks is preserved.

2.2.2 Physical Impacts – Nourishment is the "only engineered shore-protection alternative that directly addresses the problem of a sand budget deficit . . . improves natural protection while also providing additional recreational area." (NAS, 1995, Beach Nourishment & Protection, pp. 1-2). While it has grown in acceptance in recent years, nourishment engenders polarization between proponents who consider it the preferred solution to erosion and opponents who consider it to be a temporary stop-gap measure against an advancing sea (NAS, 1995). Properly viewed, nourishment should be considered as a sacrificial shore-protection technique which provides a first line of defense against the action of storms and chronic erosion at the coast. Its success **will** depend on the frequency of storms, but more importantly, on the background erosion rate and long-term processes controlling shoreline change at the particular site. Nourishment adds to the littoral budget a measure of sediment which will become subject to onshore/offshore as well as longshore transport. Just as a natural beach waxes and wanes between storms, a nourished beach will adjust to daily and seasonal variations in waves and tides.

Most of the controversy and debate regarding the success of nourishment relates to:

- Insufficient postproject documentation of physical changes.
- Wide disparities in background erosion rates and nourishment sediment quality, making extrapolations from one site to another misleading.
- Use of different criteria for evaluating success.

These controversies are anticipated to persist within the community until such time as there is physical proof of the effect of nourishment along Bogue Banks. Presently, 70 percent of Bogue Banks has no experience with nourishment and has little quantitative data on which to define the background erosion rate or project erosion rates after nourishment. Yet, certain factors suggest that Bogue Banks is a better candidate site for nourishment than many other East Coast beaches.

- Nourishment experience at Atlantic Beach (25 percent of Bogue Banks) provides physical evidence of a wider dry beach and reduced storm damage throughout the 1990s compared to similarly exposed beaches in the proposed project area.
- Several independent erosion estimates confirm that 20-year volumetric losses have averaged 1-3 cy/ft/yr, a rate that is relatively low. This is comparable to Myrtle Beach, SC (1.6 cy/ft/yr) but only a fraction of Hunting Island, SC (~25 cy/ft/yr).
- Linear erosion estimates quoted by Pilkey et al. (1998) and most likely based on NC Division of Coastal Management erosion maps are <2 ft/yr for all Bogue Banks localities except Pine Knoll Shores and Indian Beach, which are estimated at 2-3 ft/yr.
- Bogue Banks is a south-facing beach, partially in the lee of Cape Lookout and less exposed to damaging waves which tend to be more frequent from the northeast.
- Rates of net longshore transport are relatively low along Bogue Banks because of its orientation and placement with respect to Cape Lookout and the prevailing direction of ocean waves.
- The proposed project length of 16.8 contiguous miles would make it one of the longest nourishments on the East Coast. Numerous studies have proven that nourishment longevity is proportional to the **square** of the length of the project (NAS, 1995).
- The proposed borrow area (A) contains sediments that are slightly coarser than the native beach and much coarser than the spoil sediments placed by the Corps along Atlantic Beach. Coarser sediment tends to hold a wider dry beach and require less material for the underwater portion of the profile (Dean, 1991; NAS, 1995).

- The proposed quantity of nourishment (~50 cy/ft) incorporates (a) initial volume to replace the sand deficit and (b) advance nourishment equivalent to approximately ten years of background erosion. In addition, plans call for increasing the nourishment volume in proportion to the overfill ratio (R_A) of the borrow area sediments because a certain fraction will be unstable on the beach (~15 percent if borrow area A is used).

- The proposed project will be surveyed yearly from the dune line to beyond the outer bar and compared against the prenourishment conditions using volumetric calculations. Performance will also be evaluated based on persistence of a dry beach. Success will be defined in relation to how closely the postnourishment volume erosion rate compares with the estimated prenourishment volume erosion rate.

Not all physical impacts are predictable prior to construction. It is widely recognized that isolated erosion "hot spots" sometimes develop after nourishment as "packages" of sediment accumulate in one area, leaving deficits nearby. Nearshore bars also evolve, form runnels and outlets, and create related nearshore cell circulation which may locally cause scour of the berm. Such features occur on unnourished as well as nourished beaches. Regardless of the cause of physical changes, the proposed project area is expected to undergo the same transformations as a natural beach, but to do so with the ocean displaced about 100 ft seaward. By artificially increasing the average separation distance between development and the ocean, private property damage will be reduced for any return-period storm, and the tax base of the county will be preserved for another decade or so. After a decade of monitoring, the community will reevaluate the cost and benefits of nourishment and determine at that time based on experience whether continued nourishment is preferable to doing nothing or abandoning property.

2.2.3 Environmental Impacts – The primary environmental impacts of nourishment relate to mortality of in-situ organisms, changes in habitat, mobilization of fine-grained sediments, and pollution due to accidental spills during construction.

2.2.3.1 Mortality of in-situ organisms – The project will result in the excavation of sediments and organisms in the upper ~2 ft of an approximate four-square-mile area offshore of Bogue Banks. This area represents about 5 percent of the ocean bottom between Bogue Banks and the three-mile state jurisdiction limit. Most of the sessile organisms (predominantly polychaete worms) excavated will die. As fill is placed on the beach, some in-situ organisms (e.g., amphipods, *Donax* clams, and *emerita* mole crabs) will be smothered. These are unavoidable impacts. Studies have shown that borrow areas and nourished beaches recolonize eventually. Natural recovery appears to be most rapid under the following conditions (all of which are applicable for the proposed project):

- Excavations by hopper dredge which tends to make shallow cuts and leaves undisturbed furrows from which rapid recruitment of organisms takes place.

- Use of beach-quality sediment comparable to the native beach.

- Construction during cold-weather months when biological populations are a small fraction of their summer densities.

- Minimization of fines in the borrow area and nourishment area, which elevate turbidity levels.

2.2.3.2 Changes in habitat – The project will leave shallow cuts over the borrow area, exposing older sediments to the water column. These sediments will have been less reworked by organisms but contain similar sediment textures and nutrients as the removed sediments. As such, they will leave an unoccupied niche habitat that is expected to become recolonized at time frames comparable to the life cycles of various species. Some studies have demonstrated that recolonization of borrow areas occurs in a few months or less (e.g., Jutte et al., 1999b), while other studies show recolonization occurring over 1-2 year periods. The proposed borrow area and construction method will be similar to sites where recovery occurred rapidly (a few months). However, because the only way of confirming recovery is by systematic monitoring, the county has initiated benthic sampling before construction and plans to continue benthic sampling after construction to document the degree and rate of recovery at this particular site.

The beach fill will displace the shoreline and inshore topography about 100 ft seaward. This will create more beach habitat (expanded turtle nesting sites), reduce the frequency of dune scarping and associated vegetation loss, and eliminate many chronic escarpments in the foredune. It will also lessen demand by property owners for beach scraping and dune restoration. Frequent beach scraping is believed to cause mortalities and population reductions in surf-zone species. It also introduces coarser sediments in the foredune and inhibits revegetation because of the poorer water retention compared to natural dune sands. Existing littoral habitats will be displaced seaward but will be maintained in similar proportion as the native beach. Nutrients introduced with the nourishment sediments will provide a food source to attract benthic organisms to the new foreshore. Recent studies have found that recolonization of the beach in similar settings as Bogue Banks may occur within one month or less (Jutte et al., 1999a). Because it is uncertain to what degree or how rapidly recolonization will occur, the county plans to monitor benthic recovery along the beach after construction.

2.2.3.3 Mobilization of fine-grained sediments – The proposed project will mobilize silts and clays in the borrow area, raising turbidity in the immediate area of construction. Use of hopper dredges will return some of the silt and clay immediately to the borrow area by on-board drainage as the hoppers are loaded. Fine-grained sediments transported to the beach will be unstable and, during placement, will winnow by normal surf-zone mixing. These fines will raise turbidity levels around the point of discharge, then settle seaward of the longshore bar (lower foreshore). The increase in turbidity due to the project is unavoidable. However, turbidity during similar construction at other sites has been shown to be short-lived (hours to days) and below the natural variations in turbidity observed between storms and calm days.

2.2.3.4 Pollution due to accidental spills – Federal and state regulations place a high burden on contractors to prevent accidental spillage of fuel, grease, and related substances used in the operation of hydraulic or mechanical equipment. Zero releases are unattainable, but detectable discharges are rare. The county will monitor construction and insure that all federal and state requirements for discharge of contaminants are met by the contractors.

2.3 UNRESOLVED ISSUES — There are several unresolved issues at this time.

2.3.1 Borrow area(s) – The county desires to obtain bids from as many qualified contractors as possible. Options for using hopper dredges and shallow-cut "dustpan" dredges are being investigated. It will be uncertain until bids are received which combinations of dredge type and borrow area (A, B1, and B2) will yield the most cost-efficient project. Because the sediments in borrow areas B1 and B2 are finer than those in borrow area A, higher volumes will be required to yield the same performance as A. However, closer proximity to the beach for B1 and B2 may yield lower costs compared to A, even after adjustment for the overfill factor. The indicated borrow areas provide more volume than required for the project. During final design, the borrow area(s) will be refined, incorporating recommendations from resource agencies wherever possible.

2.3.2 Fill area(s) – Nearly 17 miles are planned for nourishment. If for some reason, fewer miles are completed, the project's longevity will decline in relation to the **square** of the length of beach that is not nourished. However, considering that the total project length (16.8 miles) is longer than all but a few nourishment projects out of hundreds in the past 20 years, elimination of a portion of the project will still leave a relatively large-scale, long project.

2.3.3 Opportunities for state cost sharing – The county and local communities are investigating opportunities for matching cost shares from the state. This will not alter the basic plan, but it may cause a modification in the schedule.

2.3.4 Community referendum – The county and local communities ~~plan to hold~~ **HELD** a funding referendum ~~in spring~~ **MARCH 21,2000**. ~~If~~ The referendum ~~does~~ **DID** not pass, **AND SO** the project cannot be completed as planned. **IT IS NOW ANTICIPATED THAT INDIVIDUAL COMMUNITIES WILL UNDERTAKE PORTIONS OF THE PROJECT, UP TO THE LEVEL OF EFFORT PRESENTED IN THE TOTAL PLAN OUTLINED HEREIN.**

2.4 RELATIONSHIP OF PLAN

WITH THE EXCEPTION OF ONE SMALL NOURISHMENT IN THE VICINITY OF THE RAMADA INN IN 1990 INVOLVING LESS THAN 278,000 CY OF VERY FINE SAND (M_Z = 3.67Φ, PETERSON ET AL, 2000), no prior nourishments have been performed between Pine Knoll Shores and Emerald Isle. The preliminary design is based on the present condition of adjacent Atlantic Beach and will leave no gap all the way to western Emerald Isle. It is considered an interim "ten-year" plan for the community–one that must be monitored carefully and used as a basis for formulating a long-range solution from among three alternatives: (1) no action, (2) abandonment and relocation, or (3) continued nourishment.

2.5 COMPLIANCE WITH ENVIRONMENTAL REQUIREMENTS

This submittal is of an EIS, but at a later date an application will be made for State and Federal permits. It is anticipated that the permit application will be made prior to completion of EIS review. (Permit application review will run concurrently with EIS review.)

2.5.1 Federal – CAMA submits copies of the EIS to the Army Corps of Engineers for Federal agencies' review. The Corps coordinates federal review of both the EIS and the CAMA Major Development Permit application. Federal review includes Corps review for compliance with section 10 of the Rivers and Harbors Act of 1899 for work within navigable waters. The Corps also reviews for compliance with Section 404 of the Clean Water Act, covering discharge of dredged materials into navigable waters.

The Corps distributes copies of EIS and permit applications to other federal agencies, including the Environmental Protection Agency, National Marine Fisheries Service, and U.S. Fish and Wildlife Service. These agencies review and comment on the EIS, and these comments must be received and considered by the Corps prior to the coordinated Federal response to the EIS. Likewise these agencies' responses must be received and considered prior to issuance of a Federal permit.

2.5.2 State – North Carolina's Division of Coastal Management coordinates the entire review process, both to state agencies and to the Corps. State approvals required include certification of compliance with the Coastal Area Management Act, the Dredge Fill Act, Water Quality Certification (Section 401), and Easement in Public Trust Areas.

For both the EIS review and the permit-application review, DCM distributes copies to state agencies that include the Wildlife Resources Commission, the Department of Administration, the Department of Transportation, and Divisions of Water Quality, Land Quality, Marine Fisheries, Environmental Health, Archives and History, and Community Assistance. DCM receives and reviews comments from these agencies and the coordinated Federal response prior to approval of Finding of No Significant Impact (FONSI) or a requirement for changes in this Plan.

This project requires compliance with NC EPA. This Environmental Impact Statement is the document being submitted to demonstrate such compliance. Based on the review, DCM either issues the FONSI or requires amendments to this Plan.

2.5.3 Local – The Plan outlined in this EIS is in compliance with the local Land Use Plans for Carteret County and the communities of Bogue Banks.

3.0 EXISTING ENVIRONMENT

3.1 LAND USE

3.1.1 Character of Bogue Banks – Bogue Banks is a barrier island with a southward facing ocean shoreline stretching some 25 miles between two large tidal inlets, Bogue Inlet to the west and Beaufort Inlet to the east. The Banks are surrounded by Bogue Sound on the north and Onslow Bay of the Atlantic Ocean on the south. The island is made up of the Fort Macon State Park, the Towns of Atlantic Beach, Pine Knoll Shores, Indian Beach, and Emerald Isle and the unincorporated area of Salter Path.

Of over 70 miles of barrier island shoreline located in Carteret County, Bogue Banks is the only developed area. The remainder, made up of Shackleford Banks and Core Banks to Ocracoke Inlet, will remain undeveloped in perpetuity as part of the Cape Lookout National Seashore. Bogue Banks is the only ocean shoreline in the county with direct vehicle access.

Topography on Bogue Banks varies from the salt marsh flats and flood prone drainage areas along the island's northern shoreline on Bogue Sound to dune ridges on the island interior and along the ocean shoreline. Dune ridge elevations reach 40 feet (ft) above sea level at some locations.

Bogue Banks' soils vary with Newhan sandy soils in the nearshore, beach and dune zones; Duckston, Corrolla and Newhan soils in the scrub zones; Duckston, Corrolla and Fripp soils in the maritime forest zones; and Carteret soils in the salt marsh zones. Corrolla soils are fine sands, moderately to poorly drained that occur behind the frontal dune line. Fripp sands are excessively well drained and make up the interior dune ridge areas. Duckston fine sands are poorly drained and are in the troughs between dune ridges and on flats between dunes and marshes. Newhan fine sands are excessively well drained and make up the dune ridges that parallel the ocean shoreline. Carteret soils are the fine organic muck found in the salt marsh environment.

Vegetation on Bogue Banks reflects elevation and the amount of exposure to salt spray. As distance from the shoreline increases, sparse beach grasses merge with dense scrub vegetation. Maritime forests thrive in areas where the island is wide enough to provide sufficient protection from salt spray for forest growth. Maritime forests generally occur on lands that have been stable for at least 50 years. Vegetation typical of freshwater wetlands and tidal flats populate flood prone areas and natural and manmade drainage ways.

3.1.2 Typical Development – Development of Bogue Banks ranges from the densely developed portions of Atlantic Beach to the Theodore Roosevelt Natural Area in Pine Knoll Shores. Oceanfront development is, for the most part, residential with pockets of commercial hotels and campgrounds, multi-family condominium developments, and high-density mobile home parks. It is estimated that development of oceanfront lots has reached 90 percent build out.

Setbacks for oceanfront construction are established by regulations of the NC Division of Coastal Management (DCM). Residential construction setbacks are 30 times the long term erosion rate as established by maps prepared by DCM. Maps currently in use were updated in 1992. The setback for large commercial or permanent structures in excess of 5000 square feet is 60 times the long-term erosion rate. The minimum setback is 60 ft in areas with long-term erosion rates less than 2 ft. The line for measurement of setbacks is the first line of stable vegetation. In locations where vegetation is sparse, the line is interpolated from adjacent areas where vegetation exist. The measurement line is typically established in the field by DCM personnel as part of the CAMA permitting process.

3.2 WETLANDS — There are no areas of 404 wetlands or coastal wetlands identified in the project area.

3.3 AGRICULTURAL LANDS — No agricultural land is in or adjacent to the project area. Low water retention capacity of the sandy barrier island soils preclude establishment of agricultural crops.

3.4 LITTORAL PROCESSES — Existing data on the littoral processes on the oceanfront side of Bogue Banks include:

- Historical, but not recent tidal statistics.
- Several versions of wave conditions as outputs from wind/wave models, but no wave measurements.

- Estimates of wave and current energy fluxes along the beach as outputs from different wave-shoaling models, but only brief visual measurements of waves and currents.
- Estimates of longshore sediment transport, especially at Atlantic Beach, from (1) wave-shoaling model studies performed by the Corps of Engineers (USACE) and the University of North Carolina (UNC), and (2) qualitative measures of diffusion/advection of the Atlantic Beach nourishment sand from UNC studies.
- Extensive sets of topographic surveys (beach profiles) for Atlantic Beach (only) from both USACE and UNC, with profile sets for the entire island available from 1978 (USACE) and 1999 (CSE Baird-Stroud).

3.4.1 Tides have been measured at Duke Marine Lab in Beaufort on the **sound** side of the islands continuously since 1973. Tidal measurements at other locations were made only during brief studies in 1960 and 1973 and show (USACE, 1999):

Tide Gauge Location	Tide Range in 1960 (ft) Mean	Tide Range in 1960 (ft) Spring	Tide Range in 1973 (ft) Mean
Atlantic Beach (ocean side)	3.6	4.3	3.6
Morehead City	2.8	3.4	2.9
Duke Marine Lab (Beaufort)	2.5	3.0	2.9
Shell Point (Harkers Island)	1.3	1.6	1.6

The more recent 1973-1989 dataset at Duke Marine Lab shows a tide range of 3.0 ft and a spring tide range of 3.5 ft. (http://www.opsd.nos/noaa.gov/cgi-bin/websql/ftp/staqry.pl) The increases in tide range in the sound may be related to the Corps' dredging operations, since the dredged channel was deepened from 30 ft MLW to 35 ft MLW between the 1960 and 1973 studies.

3.4.2 Hurricanes – Tidal surges from storms add to the astronomically produced tides for a total still-water superelevation. Frequency of occurrence of hurricanes is highly variable (Barnes, 1998). One estimate of hurricane frequency made in the 1970s was 1.6 hurricanes per year for Bogue Banks (Sarle, 1977). North Carolina hurricanes increased in frequency in the 1990s. With respect to beaches, the most important effect of hurricanes is the surge. Surge levels do not necessarily correlate with hurricane strength or "category," since categories are determined by wind and pressure, not surge. For example, surge levels at Atlantic Beach were estimated for *Hazel* (1954, Category 4) at 7.0 ft mean sea level (MSL), for *Ione* (1955, Category 3) at 7.2 ft MSL, and *Donna* (1960, Category 3) at 10.6 ft MSL (USACE, 1966). *Donna* may be an appropriate "design" hurricane for Bogue Banks, since it is the only recent hurricane to have breached the island (near the location of a relict inlet in eastern Emerald Isle).

NCSU (Knowles et al., 1973) estimated surge levels for different return periods of storms, along each section of the North Carolina coast. For the section that includes Bogue, stillwater surge levels in feet above MSL are 7.63 ft for a 25-year storm, 9.33 ft for 50-year, and 10.95 ft for 100-year. These surges were then translated into estimates of resulting dune retreat, using empirical data from several storms. Dune retreat is a function of surge, height and massiveness of the dune, and distance between the dune and the mean water line. In the 70s Bogue's average dune reached 16 ft above MSL and had a toe 8.9 ft above MSL that was 158 ft from mean high water. Estimates of dune retreat were 21 ft for a 25-year storm, 162 ft for 50-year, and 220 ft for 100-year. Bogue's beaches are currently much narrower than in this study (the dunes are closer to the water). However, site-specific measurements after *Floyd* (1999) showed that dune retreat averages somewhat less than these model predictions–about 15 ft.

3.4.3 Waves – Wave heights, frequencies, and directions have been estimated for this area by various sources over the years. However, all such studies are based on observations or estimates of offshore winds, which models then convert into the resulting waves. In some studies these waves are then shoaled into breaking-wave depths using wave-refraction models. Estimating waves in this manner results in large errors compared to wave measurements. Early estimates of wave heights include Nummedal et al. (1977) who used Navy shipboard wind observations to determine offshore wave heights for the area of 5.5 ft, with a 7 ft height exceeded 27 percent of the time. The Corps of Engineers' Wave Information Study's 1956-75 data set of waves (Jensen, 1983) modeled from winds shows mean wave height for the area in 10 meters (m) of water (Phase III dataset) of 4.3 ft (USACE, 1992). Summary wave statistics (from USACE CERC's website) for the deeper (20-27m) Phase II stations are:

Station	Dates	Depth (m)	Mean Height (ft)	Mean Period (sec)	Mean Direction (azimuth degrees)
#45 (25 nm south ofEmerald Isle)	1956-75	27	3.9	6.2	112.5
	1976-95	27	3.9	7.4	112.5
#46 (7 nm southeast of Cape Lookout)	1956-75	20	3.6	6.4	112.5
	1976-95	20	3.9	8.2	90.0

Using a 1976-93 version of the Station #46 WIS dataset, a University of North Carolina study (Roessler, 1998, Fig. 25) found wave heights shoaled all the way into the breakpoint varied considerably depending on the direction of approach, but averaged about 3.9 ft, except at the easternmost end of the island where Bogue is sheltered somewhat by Beaufort Inlet's ebb-tidal delta and the Corps' offshore dredging disposal areas.

3.4.4 Dimensions of Littoral Zone (Depth of Closure) – The depth offshore to which there is active interchange of sediment with the beach is of consequence to beach nourishment projects. The goal is to avoid taking sediment from within the active system, since that sediment is already, to some extent, helping to maintain the beach. The depth of closure is defined in standard texts, such as the Shore Protection Manual (CERC, 1984) as the depth beyond which there is active motion of the seabed for an average of only 12 hours per year. Six different methods and sources of information were utilized in determining this depth for Bogue Banks, and the results are detailed in Appendix G2. Those calculations produce the following conclusions:

1) Hindcast data of extreme (12 hr/yr) conditions produce depths of closure between 13 ft and 18 ft MLW.
2) Measured storm conditions produce closure depths between 16 ft and 22 ft.
3) During the few hours that hurricanes are present in the immediate vicinity, closure depth has been computed as 36 ft.
4) The limit of sediment activity was measured at a nearby but more open-coast site at between 3.9 and 6.4 m (13-21 ft).
5) Mapping sediment types by color, texture, and size result in a boundary between beach and shelf sands between 32 and 33 ft depths.
6) The Corps of Engineers' nearshore berm off of Atlantic Beach in 25-30 ft depths has not exhibited significant motion and has not contributed sediment to the beach.

3.4.5 Littoral Transport – Studies of the potential for longshore sediment transport are detailed in Appendix G4. All of the quantitative studies used waves that are part of the USACE Wave Information Study, which is a compilation of wave **predictions** as modeled from the offshore winds that generate waves. Various versions of these databases have been produced over the years, but no measurements have been made of the directional wave field.

Hindcast studies of waves predict different magnitudes and opposite directions of sediment transport along Bogue Banks, depending on which database is used. Early studies (USACE, 1976) predicted net transport eastward. Updated versions of the winds for the same time period (1956-75) produced significantly greater transports, but still to the east. Recent studies (USACE, 1999) show westward transport, using winds from a different time (1976-95). Other studies (Roessler, 1998) also show westward transport. However, our studies detailed in Appendix G4 show that **the magnitudes and direction of transport are solely a function of which wave database is used.** When we used the same databases as the above studies, we confirmed their results, even though our wave-shoaling methods were different. Thus, the qualitative results (net direction and rough magnitude) do not depend on the different wave-shoaling methods and topographic data used by different investigators.

More reliable than computation of transport from waves modeled from winds are geological indicators of net sediment accumulation. These indicators allow some qualitative conclusions to be reached regarding longshore sediment transport along Bogue.

Net longshore **transport rates are low** along Bogue Banks. Evidence includes:

1) Erosion rates measured from aerial photos and beach profiles do not vary dramatically along the island. The change (divergence) of transport rates along the beach is what causes net erosion/accretion.
2) There are no large accumulations of sand at the end of the cell (western end of Emerald Isle). Although that area is currently accreting, it is not doing so rapidly, and over time the area cycles back and forth between erosion and accretion.
3) A study (Reed, 1997) examined the differences in texture and color between the Corps' nourishment sand at Atlantic Beach and the native sand. These differences allowed tracking of nourishment as a "tracer" and determined that the net transport was quite low, much lower than wave hindcast studies suggest.

3.4.6 Erosion Rates – Rates of erosion/accretion were estimated for all sections of Bogue Banks using both volumetric measures of change, where previous data existed, and linear rates of shoreline change from aerial photography. The methods are detailed in Appendix G5 and the results tabulated in Table G5-1. Final classifications of erosion rates are illustrated in Figure G5-2. There is considerable variability in the results between very different methods, but all methods show an overall slow erosion. The bottom line is that most communities on Bogue have slow but continuing erosion rates (on the order of 1 ft/yr shoreline retreat). However, the erosion does not occur at a steady rate, but in episodic events during storms. The net result of storm erosion (average of 15 ft retreat during Hurricane *Floyd*) and the following recovery is a slow retreat of the shoreline.

3.5 PUBLIC LANDS — The "Public Trust Doctrine" and the State Property Sovereignty Rules preserve the rights of all citizens of North Carolina for use of resources located below the mean high water line. Submerged lands, or waters of the state, commence waterward of the mean high waterline.

3.6 RECREATIONAL AND SCENIC AREAS — The beaches of Atlantic Beach, Emerald Isle, Indian Beach, Salter Path and Pine Knoll Shores are known as the Crystal Coast. This designation probably refers to the color of the ocean waters on clear calm days at the beach. The beaches of Bogue Banks provide a variety of excellent scenic and recreational opportunities for the public. Popular activities include, but are not limited to, surf fishing, swimming, surfing, walking, shell hunting, sunbathing, bird watching, and boating. Scenic vistas of the ocean are many. With erosion of the beach there has been significant losses of dry beach areas limiting many beach activities to low tide periods.

3.7 AREAS OF ARCHAEOLOGICAL OR HISTORIC SIGNIFICANCE — The maritime history of Beaufort, Morehead City and the Cape Lookout area goes back to the late 1600s and early 1700s when whalers established bases of operations on Shackleford Banks and Cape Lookout. The stability and depth of Beaufort Inlet offered a safe, deep channel for ship traffic. Not all vessels were successful navigating the inlet. In November 1718, the pirate Blackbeard lost two vessels on or near the sand bar at Beaufort Inlet.

Around 1841, John Motley Morehead, governor of North Carolina, envisioned establishing a port facility at the eastern terminus of the Atlantic and North Carolina Railroad. In 1855, the decision was made to locate the port at Sheppard's Point. By 1858, and much to the chagrin of the people of Beaufort, the Morehead City Port was prospering. Ships called continually, loading cargo directly to and from rail cars.

Development of the Morehead City port was disrupted by the Civil War. In March 1862, Union forces occupied Morehead City, the Newport River and Beaufort. Soon afterwards, Fort Macon fell under Union control. The occupation of Fort Macon provided Union forces with access to a deep water port and a place of rendezvous to support the blockading squadron during the remainder of the war. Beaufort harbor served as a staging area for the fleets under the command of Admiral David Porter for his assault on Fort Fisher in Wilmington, the last major confederate stronghold in North Carolina. During the war, there were a number of vessel losses near Cape Lookout. Not all vessel losses were attributable to military actions. Several vessels ran aground in rough weather near Beaufort Inlet or were lost due to machinery failures.

Six years after the Civil War, the federal government instituted measures to reduce the severity of maritime losses along the coast. In 1874, seven stations were established along the North Carolina coast by the US Lifesaving Service. Stations were established along Core Banks, at Fort Macon and at Cape Lookout.

Growth of the Morehead City Port was slow during the late nineteenth and early twentieth century. In the 1880s, the federal government began work to improve Beaufort Inlet in hopes of increasing maritime trade to the port communities. By 1889, jetties were constructed on Shackleford Banks and on Fort Macon to stabilize the Beaufort Inlet. Between 1905 and 1907, the channel across Beaufort Inlet was deepened to 20 feet at mean low water. Several Corps of Engineers reports between 1907 and 1914 indicated that both Morehead City and Beaufort were growing centers of maritime trade.

Many vessels transiting the North Carolina coast became victims of maritime hazards. Between July 1889 and June 1908, 82 vessels were reported lost off the North Carolina Coast. To prevent vessels from wrecking off of Cape Lookout, a lightship was placed at Lookout Shoals. Mariners had complained that the lighthouse at Cape Lookout was difficult to see.

During World War I, Cape Lookout Bay served as a rendezvous area for convoys headed to Europe. Morehead City was occasionally used as a distribution point for war supplies. From 1926 to 1938, the federal government made considerable improvements to the Port of Morehead City including increasing the Beaufort Inlet channel depth to 30 feet.

Hostilities were evident in the Cape Lookout vicinity during World War II. German submarines sank four tankers in the Cape Lookout Area during March 1942.

Since the war, Morehead City Harbor has undergone continuous improvement to its present day condition as a deep water port with several large vessels calling at the port each month.

The long maritime history of Beaufort Inlet and the areas near Cape Lookout indicate the possibility that shipwrecks or other valuable submerged historic resources could exist on the offshore borrow areas proposed for this project. The National Historic Preservation Act of 1966 and the Archeological and Historic Act of 1979 establish criteria for identification, documentation and assessment of submerged cultural resources. Compliance with submerged cultural resource legislation is administered by the North Carolina Division of Archives and History and the U. S. Department of the Interior.

Tidewater-Atlantic Research, Inc. (TAR) of Washington, North Carolina was contracted to conduct a remote sensing survey of the offshore borrow areas. The scope of the survey was to locate, identify and assess the significance of any underwater cultural material in the project areas. The details of the survey and report of findings are included as part of this document in Appendix B.

3.8 AIR QUALITY — The Air Quality Section of the North Carolina Department of Environment and Natural Resources has jurisdiction over Air Quality in Carteret County. According to the Wilmington District Office, ambient air quality in Carteret County is in compliance with the National Ambient Air Quality Standards.

3.9 WATER RESOURCES — Water quality around Bogue Banks is generally high due to large tidal flows and resultant flushing associated with Bogue Inlet and Beaufort Inlet. Waters of Bogue Sound west of a line from the mouth of Gales Creek to Rock Point in Indian Beach are classified as outstanding resource waters (ORW), which are waters of the state that are unique and of a special state or national recreational or ecological importance that require special protection to maintain existing uses. Waters east of Rock point in Bogue Sound are classified SA. SA waters are suitable for shellfishing for human consumption. Ocean waters of Onslow Bay off of Bogue Banks are of high quality. This quality is due to the fact that no rivers draining large urbanized watersheds discharge directly into Onslow Bay. The White Oak River in the western end of the County and the Newport River in the east have relatively small agricultural, forested, and lightly developed watersheds.

3.10 GROUNDWATER RESOURCES — Groundwater is plentiful throughout Bogue Banks. It is near the surface in many places, especially in the early spring and winter. The underlying limestone deposits of the Castle Hayne formation are the source for water supplies on Bogue Banks. These formations are below the surficial aquifers in the island consisting of a fresh water lens which varies in depth depending on rainfall amounts and has water that is often salty or has high concentrations of dissolved iron and hydrogen sulfide.

3.11 INTRODUCTION OF TOXIC SUBSTANCES — No chemical analysis of the borrow area materials has been done to date. It is unlikely that the borrow area sediments have accumulated any toxic or hazardous substances regulated by CERCLA or RCRA. There have been no known spillage, storage, treatment or disposal of regulated toxic materials within the borrow areas. There are no known discharges to Onslow Bay that could be a source of contaminants. For this reason, it is doubtful that chemical analysis of the borrow area material would contain heavy metals exceeding the EPA standards. The borrow area sediments consist of medium sands with shell fragments and low mud percentage. These types of inert mineral materials do not typically trap contaminants.

3.12 NOISE LEVELS — Noise levels in the project areas are relatively low. No commercial or industrial activities exist in the project areas that create increased ambient noise levels. Generally, noise levels in the project areas are those associated with public use. The residential nature of the ocean shoreline areas generally equates to low ambient noise levels.

3.13 WATER SUPPLY AND WASTEWATER SYSTEMS

3.13.1 Water Supply – Potable water supply on Bogue Banks is provided by municipal water systems and by privately owned public utility companies. Bogue Banks Water Corporation supplies water to the Town of Emerald Isle. Carolina Water Service provides water to Indian Beach and Pine Knoll Shores. The Town of Atlantic Beach operates and maintains the water supply and distribution system for the Town. The water source for all systems is deep wells to aquifers of the Castle Hayne limestone formations which run beneath Bogue Banks. The water is hard but is otherwise of excellent quality.

3.13.2 Wastewater systems – Wastewater treatment and disposal on Bogue Banks is regulated by the Carteret County Environmental Health Department for systems under 2000 gallons per day, and by the North Carolina Department of Environment and Natural Resources, Division of Water Quality for systems larger than 2000 gallons per day. Treatment and disposal of wastewater on Bogue Banks is accomplished in many conventional and innovative ways. Single family residential systems are nearly all conventional septic tanks with subsurface nitrification fields. In some areas, where soils are not suitable for conventional septic systems, septic tanks with on-site low pressure pumped (LPP) subsurface disposal is employed. Multi-family residential developments and hotels utilize collection systems with centralized treatment and disposal facilities. Treatment is generally by package plants employing extended aeration and on-site subsurface LPP disposal. There are no known direct effluent discharges to Bogue Sound or Onslow Bay from wastewater treatment facilities on Bogue Banks.

3.14 MARINE RESOURCES — The first two regions below are commonly divided by the breaker zone. That is, offshore refers to the area between the breakers and the edge of the continental shelf, and nearshore is the region between breakers and the mean low water line that is the lower boundary of the intertidal zone (CERC, 1984). For purposes of examining environmental impacts, it is more sensible and more common to examine "nearshore" resources out to the depth of closure, rather than the moving boundary of a breakpoint. That is, the boundary between nearshore and offshore will be, for the purposes of this EIS, the seaward limit of sediment motion (by waves), termed the "depth of closure" for beach surveys. Exactly what that depth is for this site is examined in detail in Appendix G2 and summarized in the "Depth of Closure" part of Section 3.4 above. Borrow Areas A and B are outside closure depth. Borrow Area C is in Bogue Inlet in shallow water, but sufficiently far within the inlet to be outside of the littoral system (hundreds of feet inland of the inlet throat).

3.14.1 Offshore Resources

Sediment: Offshore areas in North Carolina have been described as more stable than the nearshore zone, because of the lack of sediment motion by waves. USEPA (1983) describes the offshore region as fine sand with low-to-moderate relief, scattered among hard bottom. Our studies characterizing the offshore sediments included grab samples, cores, long vibracores, sidescan sonar survey, and a magnetometer survey. In addition to identification of potential cultural resources in the borrow areas, the sidescan sonar survey was used to identify any large natural features (rocks). None were found in the borrow areas. The offshore sediment conditions are summarized in Section 3.16 below and described in detail in Appendix E. A map of the shelf sediment types and thicknesses in the vicinity of Bogue Banks is reproduced in the appendix as Figure E1.

Biology: Biological resources in the offshore region of the Carolinas have been categorized as having low biomass, high diversity, and large seasonal variability (USEPA, 1983). The latter characteristic of seasonal variability has a significant impact on monitoring plans and is the reason for our plan of sampling on several dates, detailed below.

Vertebrates: Assessment of the significance of the offshore mining of sands for the renourishment involves evaluation of potential impacts on demersal fishes and crustaceans at the borrow site. The fish and crustacean community changes seasonally, so sampling is needed to document presence and relative abundance of demersal fish and crustaceans and to describe their utilization of benthic invertebrate prey. Trawl sampling was conducted in late fall 1999, coincident with the sampling of the benthos. The results of sampling the fish and mobile crustacean community at and around the proposed offshore borrow sites are included here in a report as Appendix C **(REVISED REPORT BY UNIVERSITY OF NORTH CAROLINA INSTITUTE OF MARINE SCIENCE)**. ~~At least one~~ **TWO** additional trawl samplings ~~will be~~ **WERE** completed later ~~this~~ **IN** winter **2000** ~~(targeted for February)~~ to document over-winter use of the borrow sites by fishes. [Trawl results ~~were received on 14 February 2000 and~~ are included ~~here as an addendum to~~ **IN** Appendix C.] Analysis ~~will~~ includes not only the information on fish and crustacean abundances, but also a description of their diet from gut contents in the late fall 1999 **AND WINTER 2000** collections.

Table 4 in Appendix C presents the results of trawling for fishes and crustaceans. The sampling detected relatively large numbers of demersal fish occupying the sea-floor habitat during this period. Offshore areas were dominated by spot, which accounted for more than 50 percent of total catch and was sufficiently abundant there to create a pattern of slightly higher fish densities offshore than inshore. In addition to spot, pinfish, pigfish, and croaker were the most common species offshore. Inshore fishes were dominated by croaker, silver perch, silversides, and sea mullet.

Invertebrates: Because the benthic invertebrate community at the offshore borrow sites changes across the seasons, it is appropriate to sample in multiple seasons (fall and spring) both before and after the renourishment project to assess impacts and recovery. Because renourishment is planned for winter 2000-2001, an initial set of samples was collected in the fall of 1999 to provide fall baseline data to characterize the benthic invertebrate community at the prospective offshore borrow sites and at nearby control sites that will not be mined prior to any disturbance from the renourishment project. ~~A description of results from an analysis of a subset of those initial samples is included here as Appendix C.~~ Also included is an analysis of composition of surface sediment samples in each of the borrow sites and control sites, so as to characterize the sedimentary habitat in which the invertebrates live. Sedimentary habitat is the prime factor that controls abundance and composition of soft-bottom invertebrate communities. The complete invertebrate data set ~~will be analyzed by May 2000~~ **AND SUMMARY STATISTICS ARE GIVEN IN APPENDIX C**.

Results from the fall 1999 sampling are summarized in Table 2 of Appendix C. Results suggest slightly higher macrofaunal abundances in the borrow areas than in their respective control areas. The polychaetes accounted for more than 50 percent of the total macrofauna in these late-fall 1999 samples. Other common phyla in order of abundance were molluscs, nemerteans, crustaceans, and echinoderms. Table 3 of Appendix C shows the analysis of the 40 belt transects for larger benthic invertebrates. The inshore borrow areas revealed higher numbers of these larger invertebrates than the offshore sites. No consistent difference appeared between borrow and control areas in these data. Gastropods were the most common taxon represented in these samples.

3.14.2 Nearshore Resources

Sediment: Sediment sampling of the nearshore (inland of the borrow sites, but subtidal) occurred at several locations along the project area. The appropriate sample numbers to reference in Appendix E from west to east are C21a1, C20a1, C16a1, C12a1, C9a3, and C7a2. C4a1 was taken in Atlantic Beach outside the project area. Sieve analyses, mud content, and carbonate content are detailed in Appendix E.

Biology: Alterations to seabed sediments in the surf zone will be essentially the same as on the dry beach, except that there will be sorting into a finer size. Quantification of submarine organisms inshore of the borrow areas will thus rely on the dry-beach and intertidal sampling program outlined below. A baseline study of benthos in nearshore waters of South Carolina by Van Dolah and Knot (1984) found that infaunal assemblages at nearshore subtidal areas were more complex than those at intertidal areas. Based on their sampling, 243 species representing 24 major taxa were found. Dominant species were polychaetes and amphipods with oligochaetes, pelecypods, and decapods highly represented. Benthos in the area were identified as those that serve as food for commercially important species and were essential in marine food chains. Commercially important species include adult spots which are benthic feeders, primarily eating polychaetes and benthic copepods, and Atlantic croaker that are also bottom feeders preying on polychaetes and bivalves. Pink and white penaeid shrimp also prefer benthos (USFWS, 1992a). The nearshore benthic communities offshore of North Carolina have been characterized by benthic infaunal assemblages with low abundance and high diversity (USEPA, 1983).

3.14.3 Intertidal Resources

Sediment: Six native-beach samples were taken on the low-tide terrace at six different transects along the island. Sieve analyses, mud content, and carbonate content are detailed in Appendix E. A total of 20 samples (2 on the dune, 6 on the berm, 6 on the beach face, and the 6 low-tide terrace) was used to determine a composite native-beach size distribution.

Vertebrates: Because of the very intermittent nature of fish densities in this narrow region, no sampling of fish in the intertidal zone is planned. Offshore tow samples will be used to determine the preproject and postproject fish densities.

Invertebrates: Organisms in the high-energy sandy intertidal environment include mole crabs, coquina clams, amphipods, isopods, and polychaetes. Although none of these species are commercially important, they constitute considerable biomass and serve as important food source for surf-feeding fish and shore birds. No sampling has yet taken place to serve as the before-renourishment monitoring data for the intertidal invertebrates of Bogue Banks beaches. The invertebrate community of the intertidal beaches is so strongly seasonal that sampling to provide baseline information should occur during the warm season, with subsequent sampling to assess potential impacts and recovery repeated at the same season, but after the project has been completed. The initial preproject sampling is ~~scheduled for~~ **ANTICIPATED IN** summer ~~2000~~ **2001**.

~~We already~~ **UNIVERSITY OF NORTH CAROLINA INSTITUTE OF MARINE SCIENCE** possesses a substantial amount of data on abundances of intertidal beach invertebrates from all along Bogue Banks from 1997-1999 from studies conducted by L. Manning **AND OTHERS** (unpubl: see Table 9 of Appendix C for example). **WE ANTICIPATE REFERENCING RESULTS OF THESE STUDIES WHEN THEY BECOME AVAILABLE UPON COMPLETION OF DISSERTATION(S) IN THE NEAR FUTURE. REVIEWING AGENCIES ARE ADVISED TO CONTACT DR CHARLES PETERSON AT UNC (252-726-6841) IF EARLIER RELEASE OF THESE DATA IS REQUIRED. BECAUSE OF THE EXTENT AND FREQUENCY OF THIS SAMPLING BY UNC, THE APPLICANT BELIEVES THAT THIS WILL PROVIDE AN APPROPRIATE BASELINE FOR EVALUATING POSTPROJECT IMPACTS.** This information will be incorporated into an assessment design to evaluate the potential consequences of the renourishment on the beach system, allowing us to make contrasts between the four summers before renourishment and the summer or summers afterwards as one means of assessing impact and rate of recovery.

3.14.4 Beach and Terrestrial Resources

Sediment: The width of the berm at the base of the dune system varies considerably with location along the island and with season. Along most of the project area, the winter berm is nonexistent, because of the continuing erosion. Dune habitat is now also decreasing due to the erosion of the base or toe of the dunes by waves that travel unimpeded over the eroded wet beach to directly attack the dunes. As a result of the nourishment project, the beach is the one resource area that is expected to have beneficial impacts on the species present, primarily due to increased habitat area. Native-beach samples were taken on the berm and on the beach face at six different transects along the island, along with two dune samples. Sieve analyses, mud content, and carbonate content are detailed in Appendix E. A total of 20 samples (2 on the dune, 6 on the berm, 6 on the beach face, and the 6 low-tide terrace) was used to determine a composite native-beach size distribution.

Biology: The dunes along the beach are covered with American beach grass and sea oats. The dominant vegetation along the ocean side of the dune system also includes grassed areas, shrubs, and ornamental trees. Wildlife found along the ocean side of the island is limited as a result of development. Animals present in the project area are primarily those that can customarily tolerate man's presence, such as sea gulls, pigeons, starlings, house sparrows, and small rodents. The beach and dune system serves as an important nesting and food-source area for certain shorebirds (USFWS, 1992a). Baseline sampling of the nourishment sites and control sites will be conducted on the beach itself in summer 2000.

3.15 THREATENED AND ENDANGERED SPECIES

Species to be considered in this environmental impact statement were provided by USFWS and the NMFS and are listed in the table below, followed by a description of these species. (Section 5.15 contains a description of potential impacts to these species as a result of the proposed beach nourishment project.)

Common Name	Scientific Name	Status	Habitat present?	Known observation*
Mammals				
Eastern cougar	*Felis concolor couguar*	E	no	no
Finback whale	*Balaenoptera physalus*	E	no	no
Humpback whale	*Megaptera novaeangliae*	E	yes	yes**
Right whale	*Eubaleana glacialis*	E	yes	yes**
Sei whale	*Baleanoptera borealis*	E	no	no
Sperm whale	*Physeter catodon*	E	no	no
West Indian manatee	*Trichechus manatus*	E	yes	no
Birds				
Piping plover	*Charadrius melodus*	T	yes	no
Red-cockaded woodpecker	*Picoides borealis*	E	no	no
Roseate tern	*Sterna douglallii*	E	no	no
Wilson's plover	*Charadrius wilsonia*	SR	yes	no
Reptiles				
American alligator	*Alligator mississippiensis*	T(S/A)	no	no
Green sea turtle	*Chelonia mydas*	T	yes	yes**
Hawksbill sea turtle	*Eretmochelys imbricata*	E	yes	yes**
Kemp's ridley sea turtle	*Lepidochelys kempi*	E	yes	yes**
Leatherback sea turtle	*Dermochelys coriacea*	E	yes	yes**
Loggerhead sea turtle	*Caretta caretta*	T	yes	yes
Fish				
Shortnose sturgeon	*Acipenser brevirostrum*	E	no	no
Plants				
Rough-leaf loosestrife	*Lysimachia asperulaefolia*	E	no	no
Seabeach amaranth	*Amaranthus pumilus*	T	yes	yes
Moundlily yucca	*Yucca gloriosa*	SR	yes	yes

KEY

Status	Definition
E	A taxon "in danger of extinction throughout all or a significant portion of its range."
T	A taxon "likely to become endangered within the foreseeable future throughout all or a significant portion of its range."
T(S/A)	Threatened due to similarity of appearance - a species that is threatened due to similarity of appearance with other rare species and is listed for its protection. These species are not biologically endangered or threatened and are not subject to Section 7 consultation.
SR	State designation. Species designated as being very rare, generally with 1-20 populations in the state. These species are not subject to Section 7 consultation and are not considered in the biological assessment.

* Observation according to NC Natural Heritage Program data.
** Species is known to migrate along the coast of NC (Wynne, 1999).

The presence of these species in the project area depends on the availability and abundance of appropriate habitat. Since the Bogue Banks project area does not contain any freshwater or forested areas, the eastern cougar, red-cockaded woodpecker, American alligator, shortnose sturgeon, and roughleaf loosestrife are not likely to be found at this site. Listed species that could potentially be located at Bogue Banks are the whale species, West Indian manatee, piping plover, sea turtle species, and seabeach amaranth.

A biological assessment is being prepared and coordinated with the USFWS and the NMFS, pursuant to Section 7 of the Endangered Species Act of 1973, as amended. This assessment has determined that the proposed action may affect the hawksbill sea turtle, leatherback sea turtle, Kemp's ridley sea turtle, green sea turtle, loggerhead sea turtle, and the seabeach amaranth. Other federally listed endangered or threatened species would not be affected. Section 7 coordination will be completed prior to the initiation of the proposed work.

3.15.1 Mammals

- **Right whale, finback whale, humpback whale, sei whale, and sperm whale** – Humpback whales are often found in protected waters over shallow banks and shelf waters for breeding and feeding. They migrate toward the poles in summer and toward the tropics in winter and visit the North Carolina coast during seasonal migrations, especially between December and April (Conant, 1993). They eat schooling fish such as herring and can consume up to 1.5 tons per day of krill. Right whales swim very close to the shoreline and are often noted only a few hundred meters offshore (Schmidly, 1981). They feed primarily on copepods and euphausids. While this whale usually winters in the waters between Georgia and Florida, it can on occasion be found in the waters off North Carolina. Sighting data provided by the Right Whale Program of the New England Aquarium indicates that 93 percent of all North Carolina sightings between 1976 and 1992 occurred between mid-October and mid-April (Chris Slay, 1993). The number of right whales documented in the vicinity of Morehead City during a single season ranges from 2 to 25 (USACOE, 1989).

- **West Indian manatee** – The manatee is an occasional summer resident of the North Carolina coast. The species can be found in shallow (5 feet to usually less than 20 feet), slow-moving rivers, estuaries, saltwater bays, canals, and coastal areas (USFWS, 1991). The West Indian manatee is herbivorous and eats aquatic plants such as hydrilla, eelgrass, and water lettuce (USFWS, 1999). During winter months, the United States' manatee population confines itself to the coastal waters of the southern half of peninsular Florida and to springs and warm water outfalls as far north as southeast Georgia. They are sighted frequently in southeastern North Carolina with most records occurring in July, August, and September, as they migrate up and down the coast (Clark, 1993). However, scattered records of this species in the region span all seasons. Based on this data, the manatee is considered a year-round resident with a maximum population in the late summer months. Manatee population trends are poorly understood, but deaths have increased steadily. A large percent of mortality is due to collisions with water crafts, especially of calves. Another closely related factor in their decline has been the loss of suitable habitat through incompatible coastal development, particularly destruction of sea grass beds by boating facilities.

3.15.2 Birds

- **Piping plover** –The Atlantic Coast piping plover population breeds on coastal beaches from Newfoundland to North Carolina (and occasionally in South Carolina) and winters along the Atlantic Coast from North Carolina south, along the Gulf Coast, and in the Caribbean USFWS, 1996). Since being listed as threatened in 1986, the population has increased from approximately 800 pairs to almost 1350 pairs in 1995, although most of this increase may be attributable to an increase in surveying intensity. Piping plovers nest above the high tide line on coastal beaches, sand flats at the ends of sand spits and barrier islands, gently sloping foredunes, blowout areas behind primary dunes, sparsely vegetated dunes, and washover areas cut into or between dunes (USFWS, 1996). Feeding areas include intertidal portions of ocean beaches, washover areas, mud flats, sand flats, wrack lines, and shorelines of coastal ponds, lagoons, or salt marshes. Loss and degradation of habitat due to development and shoreline stabilization have been major contributors to the species' decline.

  Most piping plovers at Bogue Banks have been observed at the west end of Emerald Isle as predominantly a migratory and winter resident (David Allen, pers. comm.). During a 1991 USFWS International Piping Plover Census (winter), four piping plovers were observed and during a 1996 winter census, one individual was observed. ~~However~~ IN ADDITION, both Bogue and Beaufort inlets contain intertidal flats exposed at low tide that are prime feeding and roosting habitats for a variety of shorebirds and colonial waterbirds including pelicans, cormorants, terns, and black skimmers. These areas may be used by piping plovers as well.

- **Roseate tern** – Roseate terns breed primarily on small offshore islands, rocks, cays, and islets. Rarely do they breed on large islands. They have been reported nesting near vegetation or jagged rock, on open sandy beaches, close to the waterline on narrow ledges of emerging rocks, or among coral rubble (USFWS, 1999). This species is primarily observed south of Cape Hatteras, particularly at Cape Point within Cape Hatteras National Seashore, during the months of July and August.

3.15.3 Reptiles

- **Hawksbill sea turtle** – Hawksbill sea turtles are found mainly in tropical waters of the Atlantic, Pacific and Indian Oceans. Nesting in the United States for this species occurs in spring and is generally restricted to Florida. Although it is not considered common along the North Carolina coast, the hawksbill may be found in North Carolina waters all year and can be present in inshore waters April through December (Epperly et al., 1995). The hawksbill is found along submerged rocky areas, reefs, shallow coastal areas, lagoons of oceanic islands and narrow creeks (USFWS, 1991). It is not often seen in water over 65 feet deep. Its diet includes algae, fish, mangrove, barnacles, clams, sponges, snails, and sea urchins.

- **Leatherback sea turtle** – Leatherback sea turtles are found mainly in tropical waters of the Atlantic, Pacific and Indian Oceans. Nesting in the United States for this species occurs in spring and is generally restricted to Florida. Although it is not considered common along the North Carolina coast, the leatherback may be found in North Carolina waters all year and can be present in inshore waters April through December (Epperly et al., 1995). The leatherback is an open-ocean species that sometimes moves into shallow bays, estuaries, and even river mouths. The preferred diet is jellyfish and may also include sea urchins, squid, shrimp, fish, blue-green algae, and floating seaweed. It is also found along the Atlantic coastline from Massachusetts southward to Brazil.

- **Kemp's ridley sea turtle** – Kemp's ridley sea turtles inhabit shallow coastal and estuarine waters, often in association with subtropical shorelines of red mangrove. The entire population nests on ~15 miles of beach in Mexico between the months of April and June (USFWS, 1991). Outside of nesting, the major habitat for adult Kemp's ridleys is the near-shore and inshore waters of the northern Gulf of Mexico, especially Louisiana waters. However, immatures have been observed along the Atlantic coast as far north as Massachusetts. Although the Kemp's ridley has been documented to nest in North Carolina only once, juveniles of the species are known to migrate in estuarine and oceanic waters off of the North Carolina coast (Schwartz, 1977; Epperly et al., 1995). Overharvesting of both eggs and adults for food and the skin has been a major factor in their decline. Currently the major threat is drowning when inadvertently caught in shrimp nets. The total population is currently estimated to be 1500 to 3000 individuals.

- **Green sea turtle** – With an estimated population of no more than 600,000 adults worldwide, the green turtle exists in both tropical and temperate seas and oceans (USFWS, 1992). The North American distribution ranges from Massachusetts to Mexico, and from British Columbia to Baja California. Green sea turtles generally favor protected waters inside reefs, bays, estuaries, and inlets. Primary habitat appears to be lagoons and shoals supporting an abundance of marine grass and algae. These turtles are predominantly herbivorous, feeding upon marine algae and shallow beds of marine grasses. However, additional food sources may include mollusks, sponges, crustaceans, and jellyfish. The major reasons for the decline in green turtle numbers include over-exploitation of eggs and meat for food, commercial fishing and dredging operations, and nesting habitat destruction associated with outer beach development (USFWS, 1992). Green sea turtle nesting habitat consists of open beaches with a sloping platform and minimal human disturbance. Eastern United States nesting is primarily limited to Florida's east coast (300 to 1000 nests reported annually). Although occasional nesting has been documented as far north as North Carolina and false crawls have been documented at Emerald Isle Beach, no nests have been observed within the project site. However, juvenile green sea turtles are known to migrate in estuarine and oceanic waters off of the North Carolina coast (Schwartz, 1977; Epperly et al., 1995).

- **Loggerhead sea turtle** – The loggerhead turtle utilizes the Bogue Banks upper beach fronts for its seasonal (March-October) nesting events. Off the Carolina coast these turtles commonly occur at the edge of the continental shelf when they forage around coral reefs, artificial reefs, and boat wrecks. They feed on benthic invertebrates including mollusks, crustaceans, and sponges (Morrimen, 1982).

They have also been found to eat fish, clams, oysters, sponges, jellyfish, shrimp, and crabs when near shore. Research has shown that the turtle populations have greatly declined in the last 20 years due to loss of nesting habitat along the beachfront and by incidental drowning in shrimp trawl nets. Dredging activities in the warmer months of the year could impact the sub-adults but this has not been well documented. It appears that the combination of poorly placed nests coupled with unrestrained human use of the beach by auto and foot traffic has impacted this species greatly. Eroding steep beach escarpments, lights, sand fences, and other physical barriers (debris) often cause the mature females to select poor nesting sites at the dune toes which causes higher nestling mortality rates. Loggerhead turtles are known to regularly nest from Bogue Inlet to Beaufort Inlet, including the entire stretch of the project site. Between 1995 and 1999, an average of 28 nests/year were recorded within the project area (Ruth Boettcher, pers. comm.). In addition, juveniles are known to migrate in estuarine and oceanic waters off of the North Carolina coast (Schwartz, 1977; Epperly et al., 1995).

3.15.4 Fish

- **Shortnose sturgeon** – This species ranges along the Atlantic seaboard from southern Canada to northeastern Florida (USFWS, 1999). The shortnose sturgeon feeds on invertebrates and stems and leaves of macrophytes. From historical accounts, it appears that this species was once fairly abundant throughout North Carolina waters, however, many of these early records are unreliable due to confusion between this species and the Atlantic sturgeon (*Acipenser oxyrhynchus*). Because of the lack of suitable freshwater spawning areas in the project area and the requirement of low salinity waters by juveniles, any shortnose sturgeons present would most likely be non-spawning adults.

3.15.5 Plants

- **Seabeach amaranth** – Seabeach amaranth is an annual herb that occurs on beaches, lower foredunes, and overwash flats (Fussell, 1996). Weakley (1986) found that in North Carolina the plant is most common on overwash flats on accreting ends of barrier islands. This species occupies elevations ranging from 0.2 to 1.5 m above mean high tide (Weakley and Bucher, 1992). Historically, seabeach amaranth was found from Massachusetts to South Carolina. But according to recent surveys (USACE, 1992-1995), its distribution is now restricted to North and South Carolina with several populations on Long Island, New York. The decline of this species is caused mainly by development of its habitat, such as inlet areas and barrier islands, and increased ORV and human traffic which tramples individuals (Fussell, 1996).

Between 1992 and 1995, annual surveys of amaranth were conducted all along the North Carolina coast including Bogue Banks (NCNHP, 1995). The results are as follows:

	# Plants Observed at Bogue Banks	# Plants Observed within Project Area
1992	2,556	159
1993	3,762	232
1994	1,181	182
1995	14,776	391

No survey was conducted in 1996 because of early summer hurricanes that washed away or buried most of the plants. In 1997, certain sections of Bogue Banks were surveyed, but were found to support very low numbers of amaranth. ~~Because no survey has been conducted since 1997, the size of recent populations are currently unknown.~~ ~~Several hurricanes that hit the North Carolina coast in 1999 may have buried plants and seeds under sand or heavy winds associated with the storms may have dispersed seeds along the project area and into the ocean.~~ In August of 2000, staff of Land Management Group, Inc., performed an amaranth survey along the beaches of Bogue Banks from Bogue Inlet to Beaufort Inlet. Approximately 40 individuals were found. Most plants were located along Atlantic Beach, in areas that have received nourishment in the last ten years. The individuals were located on the foredune at and above the dune toe. On the remaining beach, including Pine Knoll Shores, Salter Path, Indian Beach, and Emerald Isle, six plants were observed. These individuals were located several feet above the dune toe in an area were extensive beach scraping has occurred.

3.15.6 Other Species – In addition to the federally-listed species, two other species with a state status of significantly rare (SR) have been observed in the proposed project area and are discussed here. The Wilson's plover is a state "watch list" species, categories W1 and W5, indicating that it is known to be declining and that there are threats to its habitat. It has been observed on the east side of Bogue Inlet~~, where a potential borrow area (C) is located~~ (NCNHP data). ~~It is a~~ THIS coastal bird species ~~that~~ breeds along the coast from Maryland southward and winters from the Gulf Coast and Florida southward (Fussell, 1996). In North Carolina, this species breeds primarily from Portsmouth Island southward. Wilson's plovers breed mostly on barrier islands and on dredged material islands within estuaries. This species is often found breeding at sites having similar habitat to those preferred by piping plovers, however Wilson's plovers utilize a broader range of habitat, including habitat with greater vegetative cover. The moundlily yucca plant has also been observed within the proposed project site. It was observed at Indian Beach in 1992 by NC Natural Heritage personnel and is generally found in moist depressions in sand dunes (Radford et al, 1964).

3.16 SEDIMENT CHARACTERISTICS

3.16.1 Summary – Extensive geotechnical surveys were completed in 1999 for purposes of identifying alternate borrow sources for nourishment. Details of the Phase I (June 1999) and Phase II (November 1999) sampling are given in Appendix E of this document.

Four potential borrow areas were identified during Phase I: (A) offshore of Indian Beach, (B1) inshore along Pine Knoll Shores, (B2) inshore from Salter Path to eastern Emerald Isle, and (C) Bogue Inlet intertidal shoals (Fig. 3.16A). Later sampling during Phase II (November 1999) confirmed each borrow area and allowed refinement of the boundaries. Delineation of the borrow areas was based on nearly 90 borings within the designated boundaries (15 borings per square mile). Borrow area A provides the most promising deposits with beach compatibility indices averaging an R_A value of 1.16 [method of James (1975) modified to account for percent mud]. Borrow area A potentially yields ~10 million cubic yards of beach-quality sediment, or roughly twice the required volume.

3.16.2 Prior Studies – Appendix E lists prior geology studies used in planning the 1999 borrow area search. The salient points of these studies with respect to nourishment planning and identification of viable borrow areas include the following:

- Bogue Banks is a relatively stable Holocene barrier island within the less exposed western "limits" of the Cape Lookout cuspate foreland with much more relief compared to the rapidly eroding barriers, Core Banks and Portsmouth Island just north of Cape Lookout (Heron et al, 1984).
- Prior to 4000 years ago, the shoreline off Bogue Banks was transgressive under the influence of deglaciation and rapid sea-level rise across the gently sloping continental shelf of the Carolinas.
- Only a thin sediment cover remains offshore--most of the inner continental shelf consists of outcropping Tertiary hard bottom (Hine and Snyder, 1985).
- Since the rate of sea-level rise slowed and approached its present elevation about 4000 years BP, Bogue Banks has accreted seaward and vertically by the spreading of littoral sediments away from prehistoric inlet deltas (Hine and Snyder, 1985).
- Bogue Banks' positional stability allowed accretion of high dune ridges--in some areas, exceeding 40 feet (ft) above sea level and along most of the shoreline reaching 20 ft.
- Subaerial sediments range from medium to coarse sand along the upper beach to fine sand in the dunes to mixtures of sand, coarse shells, and mud in back-barrier areas. The foreshore sediments coarsen toward the step (inshore breakpoint), then fine to the inner trough and bar. Seaward of a shore-parallel bar situated about 400 ft offshore, sediments fine along the lower shoreface.

3.16.3 Sediment Sampling and Analysis – Despite a limited supply of beach-quality sand offshore of Bogue Banks as inferred from the literature (Appendix E), more detailed confirmation was required before ruling out alternative borrow areas. The study team completed a reconnaissance-level survey during initial planning of the Bogue Banks restoration project based on the following desirable criteria:

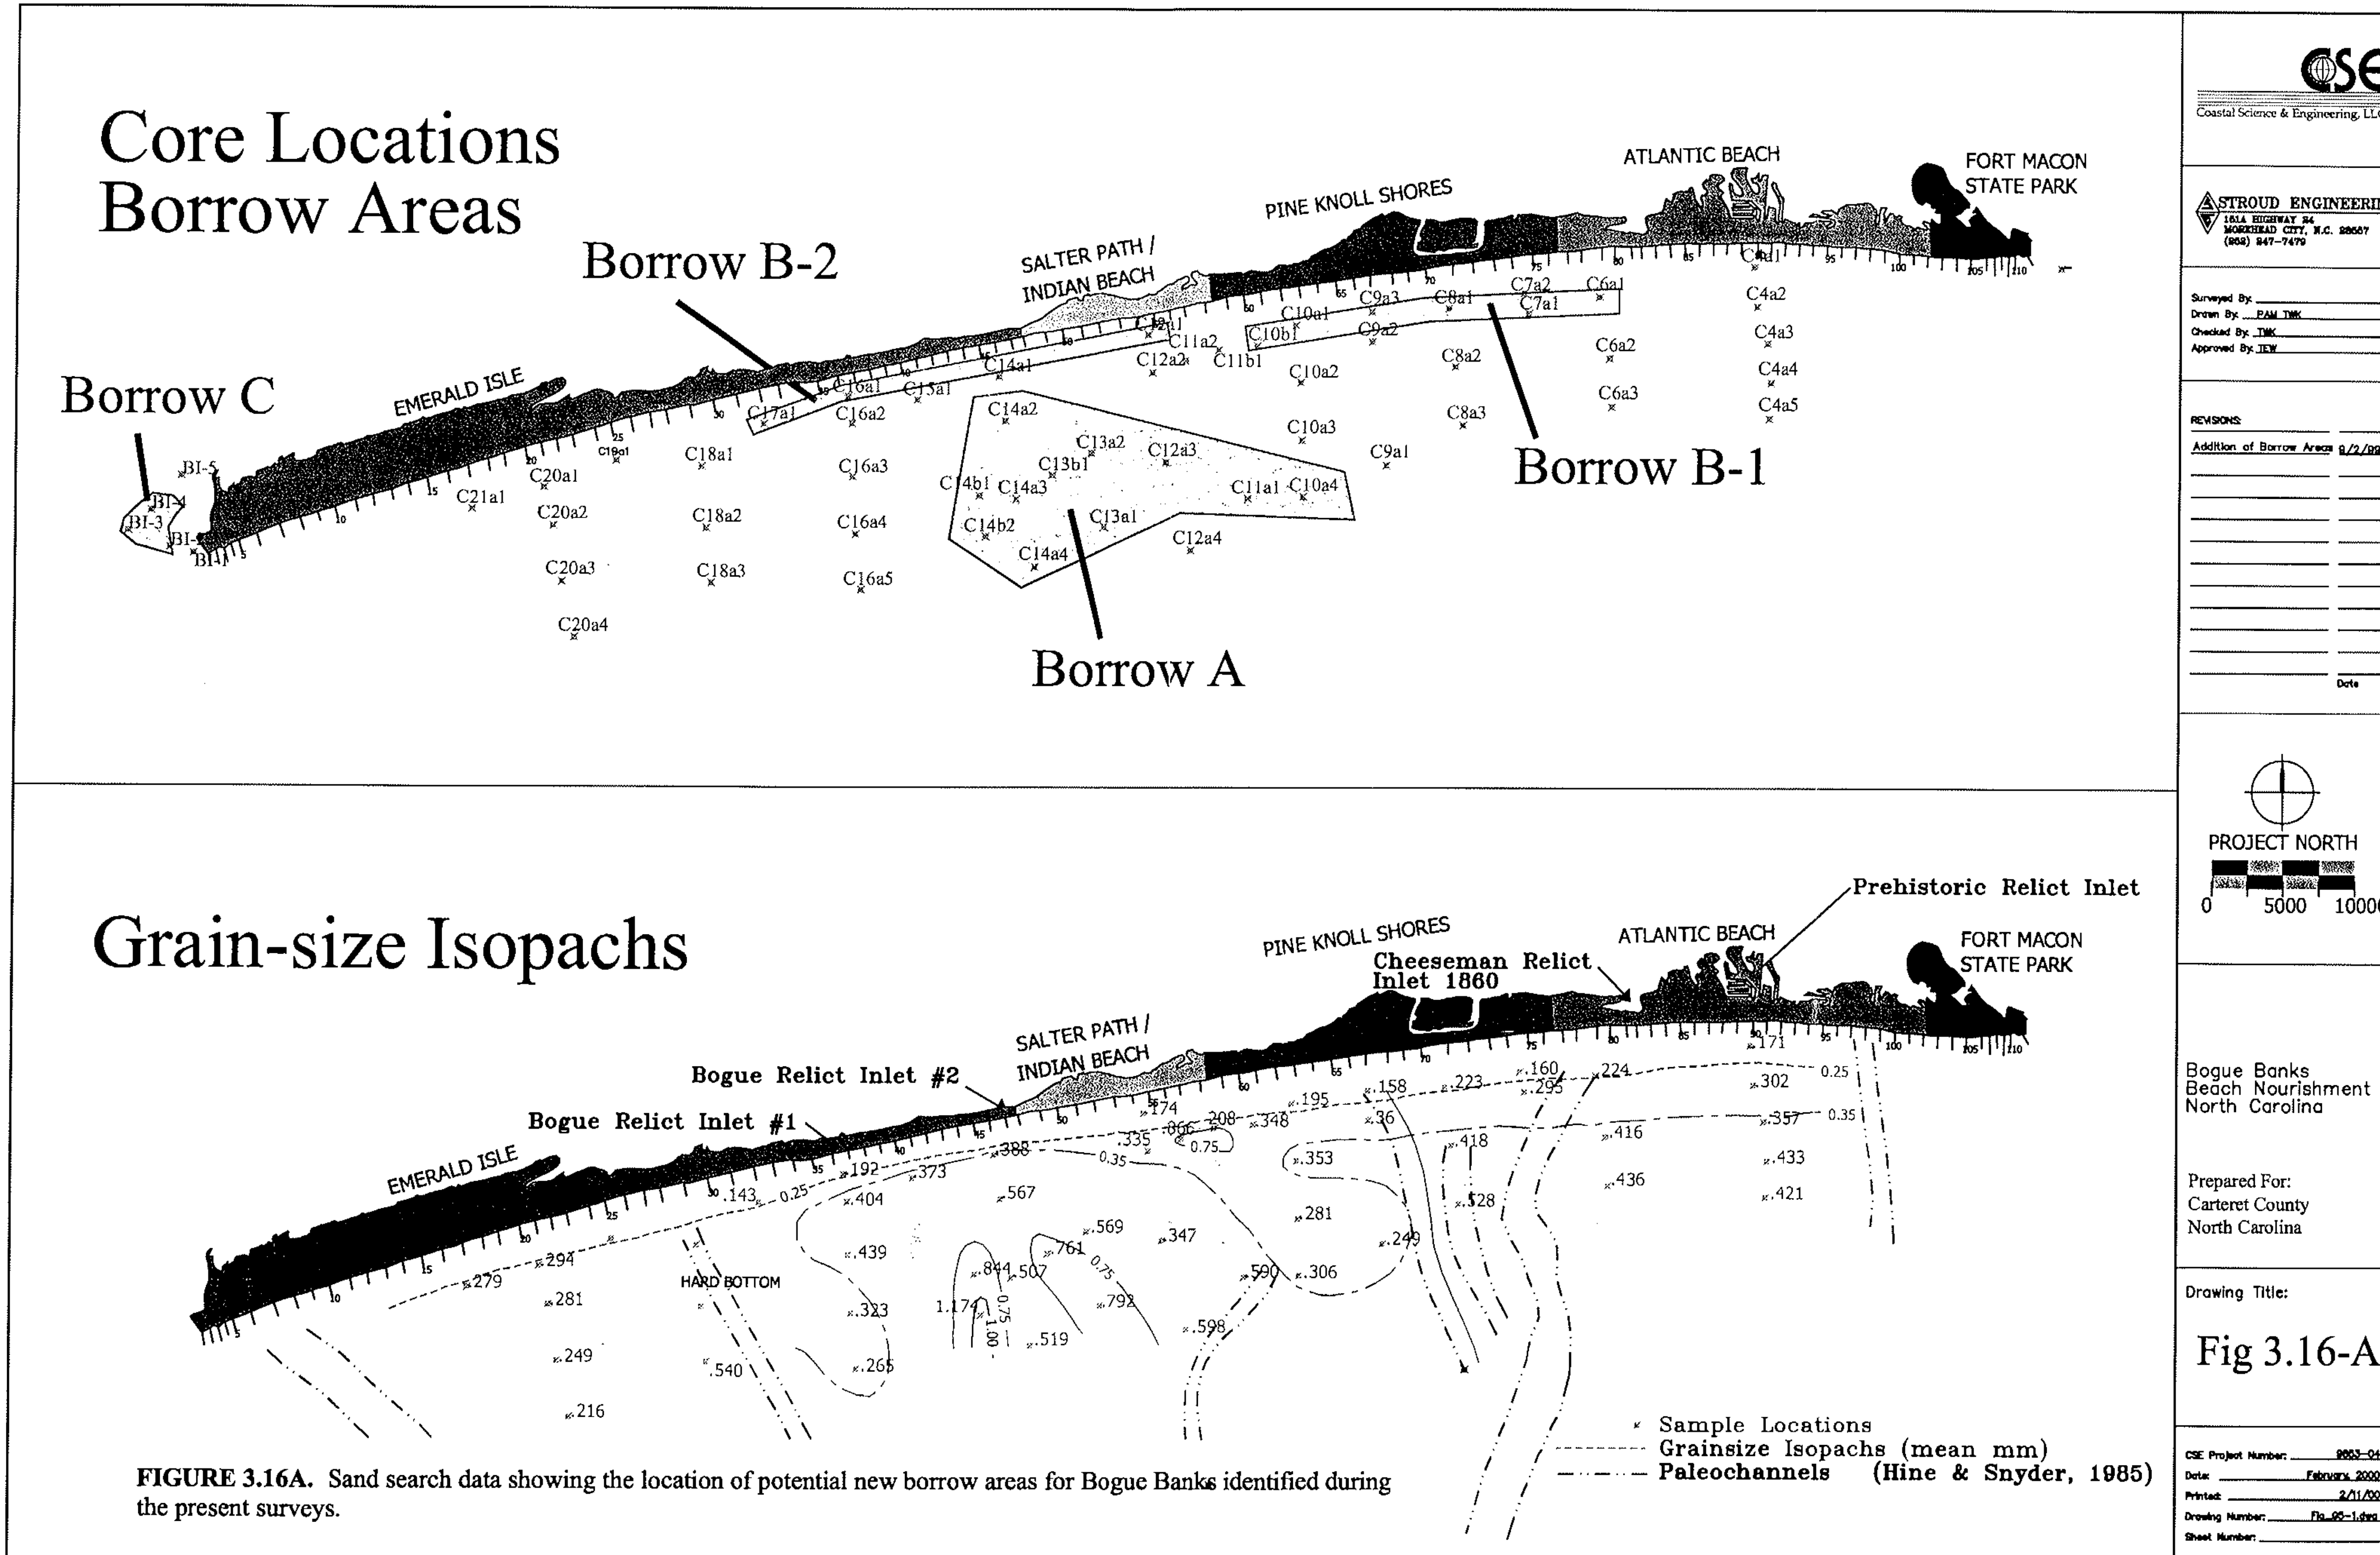

FIGURE 3.16A. Sand search data showing the location of potential new borrow areas for Bogue Banks identified during the present surveys.

- Viable sand deposits closer to the critically eroding areas in the center of the island rather than Beaufort or Bogue Inlets could potentially yield very large cost savings for the project.

- Sediments that are somewhat coarser (on average) than the native beach and coarser than the material typically available from channel maintenance would improve the durability of the nourishment project.

- Deposits with lower mud/fine-sand content than previously used in Corps disposal projects would reduce the rate of fill losses and minimize turbidity in nearshore waters.

- If broad, thin sediment deposits (at least 1-2 ft thick) could be confirmed, efficient hopper dredges or alternate equipment could be used for excavations.

The sediment survey encompassed the following field sampling over two phases between June and November 1999:

- **Beach sampling and textural analysis** (June 1999) to quantify native material — based on 20 samples divided among dune (2), berm (6), beach face (6), and low-tide terrace (6) at six representative transects spanning the length of Bogue Banks.

- **Phase I borrow source sampling** (June 1999)
  - *Offshore reconnaissance* — 53 short cores (~2 ft long) by divers in a regional grid pattern encompassing a 16-mile length of coast from central Atlantic Beach to central Emerald Isle and extending between ~0.25 and 3 miles offshore.
  - *Bogue Inlet* — eight surface grab samples at five stations over intertidal shoals in the middle of Bogue Inlet.

- **Phase II confirmation sampling** (November 1999)
  - *Borrow area A (western half)* — 46 borings (averaging ~2.3 ft) at ~1200-1500 ft spacing; eight vibracores (3-9 ft) at ~3000 ft spacing.
  - *Borrow area B1* — four diver borings (~2.8 ft); three vibracores (7.5-11 ft).
  - *Borrow area B2* — seven diver borings (~2.9 ft); three vibracores (~9-10 ft).
  - *Bogue Inlet intertidal shoals, borrow area "C"* — six short cores (~4 ft).

The only known borings prior to the 1999 survey in the primary offshore region (central Bogue Banks) were those collected in the early 1980s by university researchers (Dr. S.R. Riggs and Dr. A.C. Hine, principal investigators, as reported in Hine and Snyder, 1985). (See Appendix E.)

The present study focused on the uppermost ~2-3 ft layer for three reasons:

1) Preliminary evidence suggested that the "Holocene" section was more likely to contain beach-quality sediments.

2) Hopper dredges reportedly work most efficiently in borrow areas where the depth of cut is of the order 1-2 ft (E. Elefson, Aug. 1999, Weeks Marine, pers. comm.).

3) Environmental recovery of borrow areas appears to be more rapid where hopper dredges are used (Jutte et al., 1999b).

In total, the 1999 sediment surveys accomplished the following:

- Defined a "native" sediment size distribution.
- Characterized the upper 2-3 ft of sediments in an approximate 50 square mile area off Bogue Banks.
- Identified potential offshore borrow areas encompassing six square miles based on ~15 borings per mile.

Appendix E gives the sampling, processing, and analysis techniques. A majority of the samples was analyzed for grain-size distribution, percent mud, percent carbonate, percent coarser than 2 mm, and overfill factor (R_A). Isopach maps were prepared for key parameters to facilitate visualization of sediment quality in potential borrow areas.

Sediment quality and compatibility for beach nourishment relate to the degree of similarity between a particular borrow source and the native beach. Ideally, the nourishment sediment will have the same texture as the existing beach and, after placement, will respond to waves, currents, and winds the same way native sediments do. The most accepted technique for assessing borrow-area compatibility is that of James (1975) (CERC, 1984), whereby a population of potential borrow area samples is compared statistically with the native beach size distribution using a parameter called the overfill factor, R_A. R_As of nearly 1.0 suggest the sample will perform more or less equal to the native population. Higher R_As represent the ratio of non-native "borrow" material required to perform as 1.0 unit of native material. Thus, an R_A equal to 2.0 suggests it will take twice as much material to equal 1.0 unit of native sediment (NAS, 1995).

Experience has shown that borrow sources at least as coarse as the native beach (Dean, 1991; CERC, 1984) or having significant coarse fractions (Kana and Mohan, 1998) perform equal to or better than native sediments (as measured by durability of the dry beach). Borrow sediments that are finer than native or that contain high percentages of fine material perform worse (NAS, 1995).

The resulting R_As using the CERC (1984) nomogram were revised based on the percent mud in each sample and reported as a revised overfill factor. Mud is assumed to winnow out quickly, thus increasing the R_A in direct proportion to the mud percentage. Mud is defined as those sediments testing in the silt-clay range (mean size <0.0625 mm or >4.0ϕ).

3.16.4 Sediment Results – Appendix E contains detailed results.

Native Beach Composites – Native-beach size distributions were established using statistical composites of physical composite results of individual samples. Composite "20" (based on 20 samples: 2 dune, 6 berm, 6 beach face, and 6 low-tide terrace) yielded a mean size of 0.302 mm. Since the proposed nourishment is designed to widen the recreational beach including part of the underwater profile, we elected to use composite "20" as the "native" beach. This weights the composite toward the coarse sizes common along the beach face, berm. and low-tide terrace where the majority of the nourishment sand will be placed. The "native" composite selected for a baseline in the present study is considerably coarser than the native sediment distribution used by the USACE (1976) in planning for potential disposal projects along Atlantic Beach. The Corps sampled at 2 ft intervals from the berm to -30 ft mean low water (MLW) at the eastern end of Bogue Banks. Their statistical composites yielded a mean grain size of 0.17 mm (2.52ϕ). The Corps results confirm the fining of sediments offshore but tend to weight the result toward less stable material. The native composite we chose is more conservative for beach nourishment planning because it eliminates from consideration certain fine deposits that characterize the area seaward of the bar.

Table 3.16A contains sediment compatibility results (R_As) for each borrow area compared against the beach "20" composite. Two R_As were computed during Phase II—the first on washed samples (mud eliminated) and the second factoring in the mud percentage. In the latter, mud adds an incremental volume of nonbeach-compatible material which increases each R_A in direct proportion to the sample mud fraction. This "revised" R_A is given in Table 3.16A and on the summary map in Figure 3.16B.

The potential borrow areas yield revised R_As (factoring in mud percentage) of 1.16 at borrow area A, 1.57 at borrow area C, 1.97 at borrow area B2, and 2.19 at borrow area B1. Overall, borrow area A (revised) provides the deposit likely to perform the best for nourishment because its sediments are slightly coarser than the native beach. Carbonate material (mostly broken or crushed shell) comprises about 44 percent of the sediment in the confirmed section (versus 15-20 percent on the existing beach) and about 20 percent of the deposit is coarser than 2.0 mm (Appendix E). Mud percentage in borrow area A averaged ~4 percent in the upper ~2.3 ft of section.

Borrow area C had the next lowest average R_A at 1.57, meaning ~35 percent more material would have to be placed to yield the same performance as borrow area A. Area B2, while averaging in mean size close to the native beach (composite 20) has areas of poor-quality material. As noted in Table E7, certain samples were omitted from the statistics under the assumption that these areas would not be dredged. Other sections of the EIS for the project provide refined borrow area criteria and suggest revisions in the areas to avoid marginal sections. The confirmed borrow volumes indicate borrow area A alone could potentially provide sufficient quantities for the present project. Similarly, borrow areas B1 and B2 could provide 65 percent of the volume required (after adjustment to account for an overfill factor of ~2.0). Borrow areas B1 and B2 would require much more sand than borrow area A to yield comparable performance as the native beach. Borrow area C is not sufficient by itself to provide the necessary project volume but could serve to supplement borrow areas A, B1, and B2. Further considerations addressed elsewhere in the EIS are the economics of borrowing from multiple areas based on proximity to the project sections.

The revised R_As following Phase II sampling were slightly higher than the preliminary R_As determined for the Phase I samples (area A = 1.16 versus 1.10, area B1 = 2.19 versus 1.62, area B2 = 1.97 versus 1.62, and area C = 1.57 versus 1.15). These differences are due to the much greater number of samples available in Phase II and the incorporation of mud percentages into the analysis. This yields a more accurate representation of sediment quality for each area compared to the preliminary results of Phase I (CSE Baird-Stroud, 1999).

TABLE 3.16A Summary RAs and representative statistics for borrow areas A, B1, B2, and C. Based on Phase II samples plus applicable Phase I samples. See Figure E-7 for Phase II revised borrow area delineations.

Borrow Area	# Samples	Mean Grain Size (mm)	Mean Grain Size (phi)	%mud	RAs revised
A	61	0.51	0.974	4.0	**1.16**
B1	13	0.23	2.105	2.6	**2.19**
B2	17	0.30	1.729	4.1	**1.97**
C	8	0.42	1.255	<1	**1.57**
Native Beach	20	0.302	1.725	<1	1

Borrow Area	Area Acres	%carbonate	% >2mm	Confirmed Thickness (Ft)	Confirmed Borrow Volume (Cubic Yards)
A	2850	~44	~20.5	2.2	10+ million
B1	645	~20	~4.5	2.9	~3 million
B2	760	~22	~7.5	2.8	3+ million
C	370	ND	~5	~5	~3 million
Native Beach		~15-20	~5	NA	

Notes: Phase I & II samples omitted from the above statistics because they are outside the revised borrow area or represent sections below the confirmed thickness.

Area A: C10A4, C11A1, C12A3, C14B2b (lower unit below 1.8 ft), A-11s2 (lower unit below 3.3 ft), A-22s2 (lower unit below 3.0 ft), A-35s2 (lower unit below 2.4 ft), A-58, A-70B (below 1.25 ft).

Area B1: C7A2, ATH 9s2 (lower unit below 3.8 ft).

Area B2: C12A2, C17A1

Area C: Sample BI-4A, BI-4B, BI-3C, C-06

The confirmed borrow volume represents the potential maximum volume of material that could be obtained from the indicated borrow areas. In actuality, shallower cuts over a more select area will be planned during final design, with the idea of optimizing the area for best fill performance and lowest cost of dredging. The final borrow areas will be revised to avoid any cultural artifacts or unique biological habitats identified in other sections of the present EIS.

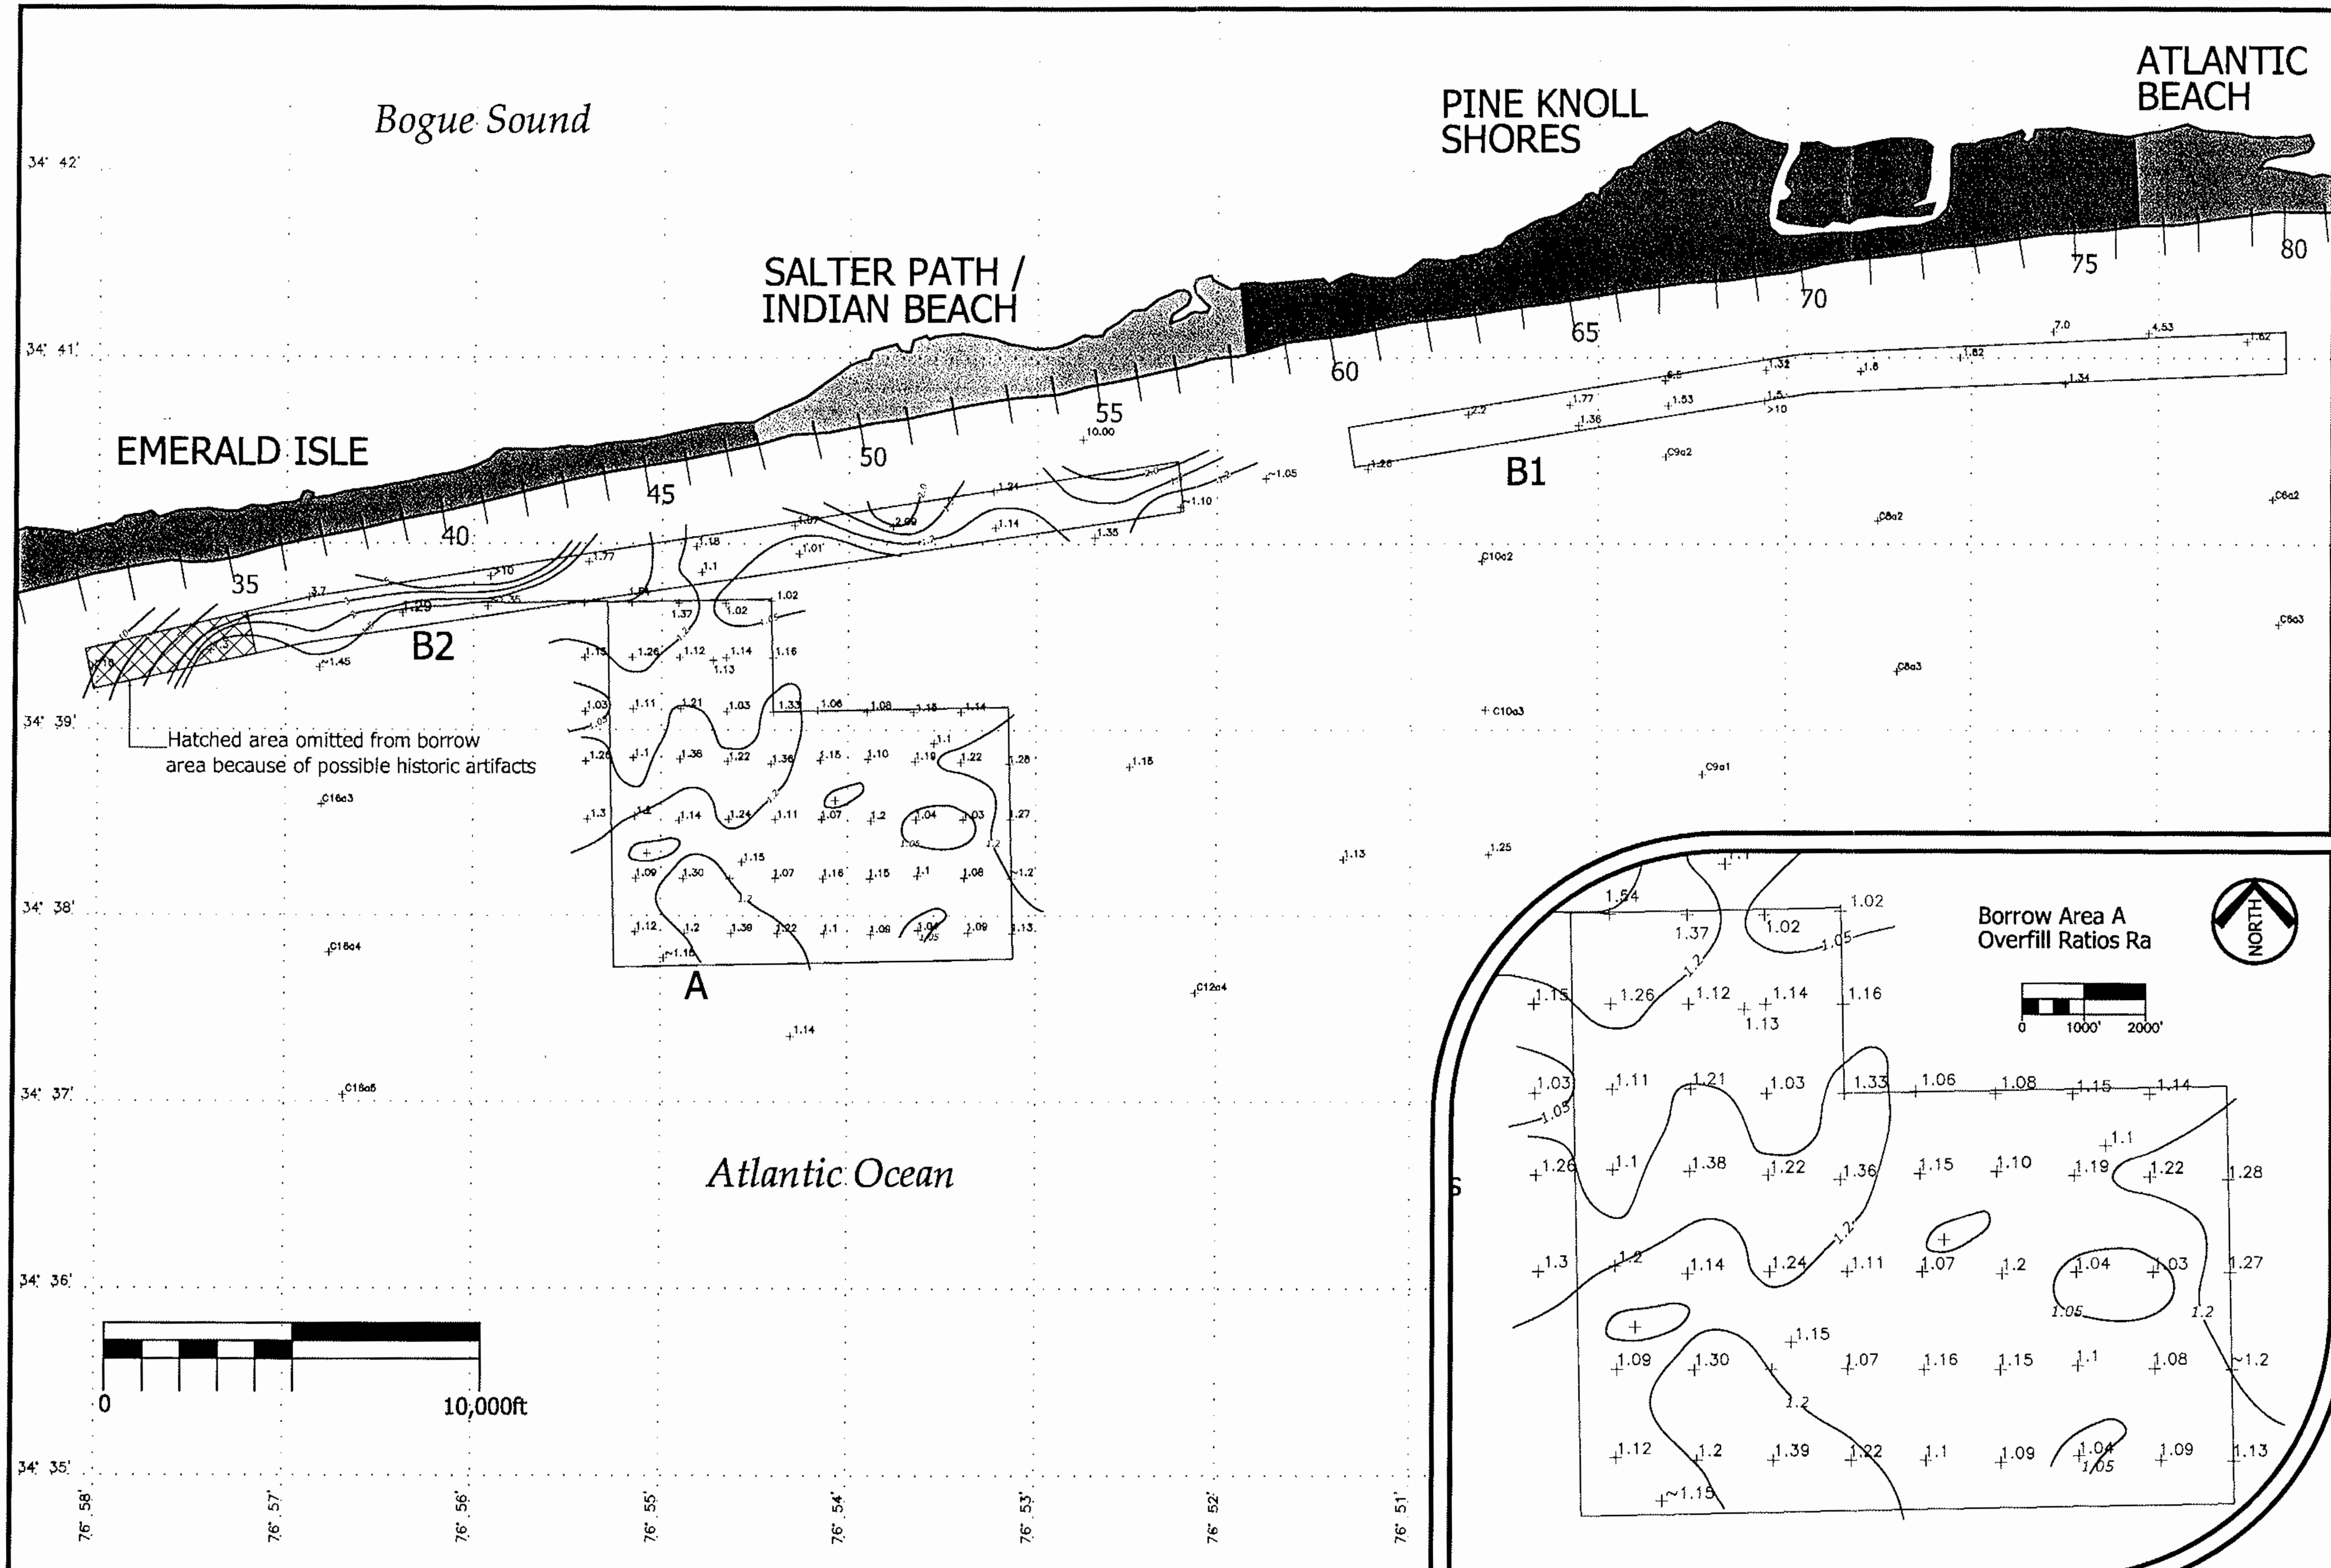

Figure 3.16B
Borrow area sediment capability based on revised overfill factors Ra for potential borrow areas A, B1, B2.

3.17 ECONOMIC AND SOCIAL ENVIRONMENT

3.17.1 Carteret County's Commercial and Tourism Based Economy – The economic environment of Carteret County is shaped by its geography and can be seen in the commercial and tourism related economies of the county. The county's economy, while diverse, is driven primarily by tourism and tourism-related jobs. The commercial and manufacturing segments of the economy are relatively small. The nine largest manufacturers in Carteret County are Atlantic Veneer with 330 employees, Cross Creek Apparel with 185 employees, Bally Refrigerated Boxes with 212 employees, Hankison International with 200 employees, Creative Outlet with 150 employees, Jarrett Bay Boatworks with 125 employees, Parker Marine Enterprises with 125 employees, and Veneer Technologies with 117 employees. Tourism is, by far, the largest industry in Carteret County. The industry contributes approximately $208 million annually to the economy of Carteret County, with a direct payroll of more than $38 million to over 3,400 workers. During 1998, unemployment in the county ranged from 7.8 percent in January to 3.0 percent in June. During 1997 and 1998 retails sales varied from a low of $44,000,000 in February 1998 to a high of $87,300,000 in July 1997, reflecting the seasonal nature of Carteret County's economy and the importance of tourism.

Thirty-nine percent of all tax revenues generated in Carteret County derive from sales taxes, occupancy taxes, fees, etc. Carteret County has a 3 percent occupancy tax. Occupancy taxes in fiscal year 1998-1999 contributed $1,706,788 to the operating budgets of the County and municipal governments. As mandated in the enabling legislation, occupancy tax revenues must be used for tourism related activities. In Carteret County, occupancy tax revenues are used to market the County's tourism attractions, and to operate and maintain the Crystal Coast Civic Center. Approximately 84 percent or $1,432,120 of all occupancy taxes collected in 1998-1999 came from rental of oceanfront properties or hotel occupancy on Bogue Banks.

Carteret County has also become a hub for marine science research. The North Carolina State University, Center for Marine Science and Technology, University of North Carolina at Chapel Hill, Institute of Marine Sciences, Duke University Marine Laboratory, the National Oceanic and Atmospheric Administration and the Division of Marine Fisheries are all located in Carteret County.

3.17.2 Culture of Beach Visitation – The three leading tourist destinations for U.S. travelers (in order) are: beaches, national parks, and historic sites. Beach visitation is an international pastime. Evidence of this trend of man to seek refuge and relaxation at the shorelines of world exist in the ruins and still viable coastal developments developed during the time of the Roman Empire. Carteret County has been a travel destination for centuries. The earliest visitors to the area came in the early 1700s and began to colonize the area with Carteret County officially being formed in 1722. The seasonality of visitation and the economic rewards it brings at peak times has shaped the economy and life of Carteret County residents for hundreds of years.

People visit Carteret County from all over the state, country and world. The Tourism Development Bureau fields over 150,000 inquiries for information on Carteret County each year from people interested in visiting the area. From within North Carolina, the majority of visitors come from Raleigh followed by Greensboro, Highpoint and Charlotte. From within the United States, people travel from Virginia, Pennsylvania, Ohio, New York, New Jersey, and Washington DC, in that order. The majority of international travelers to Carteret County come from Canada, followed by the United Kingdom, Germany, Japan, France, and Brazil.

Many North Carolinians visiting Carteret County own second homes on Bogue Banks and travel to the county on weekends or for the entire summer while still maintaining homes and careers in other cities.

Carteret County has the second largest fleet of sportfishing boats in North Carolina. Sport fishing and construction of sport fishing boats have become a significant economic resource in the County. In addition, the ocean waters off Bogue Banks and Cape Lookout are known to be in the top ten sites in the world for sport diving.

4.0 ALTERNATIVES

4.1 OVERVIEW OF ALTERNATIVES — Under existing federal and state laws, there are only three alternatives for dealing with erosion along Bogue Banks: (1) no action; (2) abandon property, retreat, and relocate; (3) nourish the beach.

Structural shore protection involving seawalls, revetments, and bulkheads is not allowed under present North Carolina coastal zone management (CZM) regulations. Semi-hard solutions involving sand-retaining structures, such as groins and detached breakwaters, plus nourishment are not recommended in areas of low erosion rates away from inlets (NAS, 1995). In general, present CZM policies along ocean coasts favor beach nourishment because it is ". . . the **only** engineered shore protection alternative that directly addresses the problem of sand budget deficit . . ." (NAS, 1995, pg. 1).

Of the three primary alternatives, all have large costs associated with them as described below, and whether nourishment is the lowest cost alternative depends on a combination of four main factors:

- Existing sand deficit with respect to the desired scale of the beach.
- Average, long-term erosion rate at the site.
- Density and value of developed property at risk.
- Proximity of beach-quality borrow sediments and their cost of transportation to the project area.

> *Beach nourishment can provide protection from storm and flooding damage when viewed within human time scales (decades not centuries) in those situations where its use is technically feasible, provided that:*
> - *erosion rates are effectively incorporated into project design . . .*
> - *. . . engineering standards are used for planning design and construction, and*
> - *projects are maintained . . .*
>
> *. . . Beach nourishment may not be technically or economically feasible or justified for some sites, particularly those with high rates of erosion. Government authorities with responsibility for coastal protection should view beach nourishment as a valid alternative for providing natural shore protection and recreational opportunities, restoring dry beach area that has been lost to erosion. (NAS, 1995, p. 3)*

[NOTE: Signatories to this statement include Dr. R.J. Seymour, chair, Scripps; Dr. Robert G. Dean, University of Florida; Dr. Paul Komar, Oregon State University; Dr. Orrin H. Pilkey, Duke University; and Dr. Robert L. Wiegel, University of California Berkeley; among others.]

4.2 DO-NOTHING ALTERNATIVE — The do-nothing or no-action alternative is evaluated based on whether the alternative considered meets the project planning objectives. In terms of those objectives, the no-action alternative is not a viable plan of action for the County. Discussions of each objective are provided below.

Planning Objective: preservation of the environmental, cultural and aquatic resources of the county

The no-action alternative would not meet this objective given the current state of the beach. Continued erosion will increase the frequency of dune scraping. Forty acres of vegetation and its associated habitat will be lost. Turtle nesting habitat will be eliminated because of steep escarpments and unstable back beach areas subject to wave uprush.

Planning Objective: provide an easily accessible recreational beach available to all citizens of the county

The no-action alternative would not meet this objective. Significant recreational beach has been lost due to erosion of the shoreline. In many locations recreational use is limited to low tide periods. When structures are permitted to fail due to erosion of the beach, the costs of demolition and removal are often borne by the municipality. It is estimated, based on expenditures by municipalities and the county over the past four years, that without a substantial berm, costs for cleanup of debris on the beach will be $400,000 per year. Accounting for escalation and normalized to present worth, debris cleanup costs are $3,509,000. The costs associated with rebuilding beach access structures borne by homeowners, municipalities, the county and by homeowners associations is estimated at $2.1 million per year. A

survey of the beach indicated that in excess of 80 percent of access structures either had been repaired or were in need of repair. It was observed that, in areas of Atlantic Beach and west Emerald Isle where a wide berm exists, few access structures were repaired. It is estimated that the average repair costs is $3000. Escalating the costs and normalizing to present value results in costs for access structure repair of $19,161,950.

Planning Objective: provide protection of oceanfront property as a resource for tax revenues to the municipalities of Bogue Banks and to the county

The no-action alternative would not achieve this objective. Based on the number of oceanfront properties that it is estimated will be lost over the ten-year analysis period, the net present value of **property tax revenues lost** for the municipalities and the county is $6,332,889. This is present worth for a ten-year project period.

In addition to loss of revenue to municipalities and the county, there would be a negative economic impact caused by the retarded appreciation of all property on Bogue Banks. The precedent for this trend is Topsail Island in Onslow County. Property on North Topsail Island showed zero appreciation between the last re-evaluation conducted by Onslow County. It is unlikely that Bogue Banks would experience a zero increase over an assessment period. According to assessments conducted in 1989 and 1997, Bogue Banks property appreciated at approximately 4.8 percent annually. Real estate brokers contacted indicate an appreciation over the last five years of 10-15 percent annually. Just a lag of only 2.0 percent in the rate of appreciation would result in an economic loss of some $ 9 to 106 million with escalation over a 10 year period. With escalation and normalized to present worth, that represents over 1.25 billion dollars over a ten-year period. This value manifests itself in lost value to owners, lost revenues to real estate brokers and in reduced appreciation for purposes of tax revenues (estimated ~$8.6 million at the going rate over ten years).

These revenue losses would have to made up by each municipality and the county by increasing ad valorem taxes on non-oceanfront properties and, in the case of the county by additional taxes levied on properties not located on Bogue Banks.

Planning Objective: maintain the economic viability of tourism, the county's largest industry

The no-action alternative would not meet this objective. Healthy beaches providing suitable recreational beach are the main attraction of the tourism industry. Loss or degradation of that attraction would have a significant impact on the tourism industry. Loss of oceanfront properties would eliminate indefinitely the rental income and associated economic activity generated by the income.

In the past five years, there has been an increase in storm frequency, increase in dune scraping frequency, apparent decline in the rate of property value appreciation compared to other beach communities, and increased public perception of erosion. All of these factors contribute to significant economic impacts which can not be quantified precisely. However, it is possible to estimate a range of potential costs based on recent experience in Bogue Banks. Following are potential costs that will accrue over a **ten-year period** to the entire community and property owners on Bogue Banks if the no action is taken in response to continued erosion.

A) Impacts to community (Carteret County) economy – government losses:	
- Reduced Property tax revenues (see above)	$6.3 million
- Loss in Occupancy Tax due to lower beach use	$1.1 - $2.8 million
- Loss in Sales Tax due to lower beach use	$13.1 - $32.8 million
- Debris removal after storms (walkovers, decks, etc.)	$3.5 million
- Reduced property tax revenues (due to lower Bogue Banks property value appreciation)	$8.6 million
Subtotal	$32.5 to $55.9 million
B) Environmental Impacts to Carteret County:	
- Loss of 40 acres of vegetated dunes	not quantifiable
- Reduced turtle nesting area	not quantifiable
- Chronic impacts to beach fauna	not quantifiable
- Loss of recreational beach (computations in Appendix F)	$0.8 - $2.1 million

C) Impacts to Owners in Special Tax Districts on Bogue Banks

- Beach scraping after storms		$2.2 million
- Reconstruction of walkovers and beach access		$19.1 million
	Subtotal	$21.3 million

Poststorm repairs (foundations, sheathing, windows, etc.) — not calculated

D) Other Potential Private Losses:

- Reduction in payroll in tourism industry due to lower beach use	$32.1 - $80.2 million
- Reduction in other (nontax, nonpayroll) tourist expenditures	$90 - $226 million

Total Economic Costs for No-Action Alternative (10 Years)

Community/Governmental (A & B above)	**~$53.8 million – $77.2 million**
Private [C & D above]	**~$143 million – $327 million**

Estimates are present worth of escalated annual costs. Details of determination of costs are presented in Appendix F.

The above estimates have been determined for the 10 year project life. Given the marginal condition of the beach today, it is likely that the cost of repairs will increase faster than the rate of inflation and faster than the above estimates because shoreline damage increases geometrically with decreasing distance to the waterline. In the analysis of Appendix F, we assume that cost occur equally in each of the 10 years for each cost category. Additionally, escalation rates for real estate used in the analyses is 4.8 percent annually compared to a historic appreciation in market value of 10 to 15 percent annually. Therefore estimates are considered conservative.

4.3 RETREAT/RELOCATION ALTERNATIVE — The relocation/retreat alternative involves moving oceanfront structures that are threatened by erosion of the shoreline. As of the date of this EIS, the town building Inspectors of Emerald Isle and Pine Knoll Shores have identified 173 oceanfront properties in Emerald Isle and 36 properties in Pine Knoll Shores that are threatened or, in many cases, condemned due to beach erosion.

Study of the retreat/relocation alternative for this EIS involved identification of oceanfront properties that would be threatened over the 10-year study period. A survey was conducted to locate the toe of the naturally occurring dune along the project area. Using the long-term erosion rates developed in the Shoreline Assessment and Preliminary Beach Restoration Plan Report, a 10-year setback zone was determined for reaches of the beach that fall into one of the six erosion rate zones. Beach erosion rates for each of the six areas are shown in Table 4.1. Note: These erosion rates are considered conservative with respect to the property relocation alternative. Higher erosion rates would impact more properties and result in substantially higher costs.

TABLE 4.1. Erosion rates and 10 year retreat distances for project areas.

Location	Long-Term Erosion Rate (ft/yr)	10-Year Retreat Distance (ft)
West Emerald Isle	2.0	20
Central Emerald Isle	2.0	20
East Emerald Isle	2.0	20
Indian Beach/Salter Path	2.0	20
West Pine Knoll Shores	3.0	30
Central Pine Knoll Shores	2.0	20
East Pine Knoll Shores	3.0	30

A visual survey was made of the oceanfront properties to identify structures that fall into the 10-year setback zones for each reach. This included single family residential structures and condominium units.

Using tax maps, a count of properties was determined in each of two categories: (1) the properties with sufficient land area to allow relocation of the structure on site, and (2) those properties where erosion of the property and street setback requirements will require that the structure be relocated to another lot. Estimates of moving costs are based on discussions with house movers, on costs from R.S. Means Cost database, and on the project cost experience of Stroud Engineering in Carteret County. Detailed breakdowns of the costs for relocation on site, relocation to new lot, and total present day costs for each municipality are provided in Appendix F.

The retreat/relocation alternative is evaluated based on whether the alternative plan meets the project planning objectives. In terms of those objectives, the retreat/ relocation alternative is not a viable plan of action for the County. Discussions of each objective are provided below.

Planning Objective: preservation of the environmental, cultural and aquatic resources of the county
The retreat/relocation alternative would not meet this objective given the current condition of the beach. Continued erosion will increase the frequency of scarping. Forty acres of vegetation and its associated habitat will be lost. Turtle nesting will be eliminated because of steep escarpment and unstable backbeach areas subject to wave uprush.

Planning Objective: provide an easily accessible recreational beach available to all citizens of the county
The retreat/relocation alternative would not meet this objective. Significant recreational beach has been lost due to erosion of the shoreline. In many locations recreational use is limited to low-tide periods. Additionally, with the loss of oceanfront properties, there is loss of beach access areas. In Emerald Isle and Indian Beach, beach access is provided at locations where public street rights-of-way dead end at the back of the dunes. Loss of the oceanfront property will include loss of these beach access areas.

Planning Objective: provide protection of oceanfront property as a resource for tax revenues to the municipalities of Bogue Banks and to the county
The retreat/relocation alternative would not achieve this objective. The total economic loss associated with this alternative is evaluated. Details of the evaluation are provided in Appendix F. The total losses are evaluated and expressed here in terms of the net present worth in year 2000. The evaluation includes annual escalation of construction costs and land values. The losses include the costs of property lost, costs of property that must be purchased in order to relocate a structure, and the costs of relocation. It is assumed in the analysis the condominiums located in the setback zone will have to demolished and reconstructed at another location on the development site. Costs are distributed equally over the 20-year study period with escalations included for real estate value and construction costs.

The present worth of retreat/relocation is shown in Table 4.2. The present worth of the retreat/relocation alternative is $110,940,556 compared to the project costs for beach nourishment of $30,000,000. Both represent year 2000 costs. [Note: This does **not** count the costs associated with the no-action alternative, many of which will also apply under the retreat/relocation alternative.]

Planning Objective: maintain the economic viability of tourism, the county's largest industry
The retreat/relocation alternative will not meet this objective. Healthy beaches providing suitable recreational beach are the main attraction of the tourism industry. Loss or degradation of that attraction would have a significant impact on the tourism industry. As with the no-action alternative, loss of vacation rental revenues is not quantified in this EIS. Loss of oceanfront properties would eliminate indefinitely some rental properties and reduce the remaining number of viable the rental properties thereby reducing rental incomes and associated economic activity generated in the County and municipalities.

TABLE 4.2 Net present worth of retreat/relocation alternative.

[Discount rate = 6.125%. Discount rate is yield on 30-yr treasury bond, latest auction reported in Wall Street Journal, 02/24/2000.]

	ANNUAL COSTS OF RELOCATION / RECONSTRUCTION			
Cash Flow Year	**Single Family Relocate On Site**	**Relocate Off Site**	**Condominiums Rebuild On Site**	**Rebuild MH Sites**
1	$1,076,400	$ 8,991,000	$2,180,250	$156,000
2	$1,108,692	$ 9,393,930	$2,245,658	$160,680
3	$1,141,953	$ 9,796,860	$2,313,027	$165,500
4	$1,176,211	$10,199,790	$2,382,418	$170,465
5	$1,211,498	$10,602,720	$2,453,891	$175,579
6	$1,247,843	$11,005,650	$2,527,507	$180,847
7	$1,285,278	$11,408,580	$2,603,333	$186,272
8	$1,323,836	$11,811,510	$2,681,432	$191,860
9	$1,363,551	$12,214,440	$2,761,875	$197,616
10	$1,404,458	$12,617,370	$2,844,732	$203,545
Present Value	**$9,444,103**	**$82,357,407**	**$19,129,046**	**$1,368,711**
TOTAL NPV	**$110,940,556**			

4.4 PREFERRED ALTERNATIVES — The preferred alternative is beach nourishment at a level which fully restores the profile deficit with respect to a "healthy" beach and provides advance nourishment for approximately ten years to accommodate the background erosion rate. Nourishment is the only practical solution that will offset the sand deficit, maintain the recreational beach, and protect developed property and community infrastructure. There are many ways beach nourishment can be accomplished. This section of the EIS outlines the main implementation alternatives with respect to sand sources, beach fill design, methods of construction, construction schedule, and maintenance.

4.4.1 Alternate Borrow Areas – Based on previous practice along the U.S. East Coast, the following classes of borrow sources have been used for beach nourishment (CERC, 1984):

- – Lagoon sediments
- – Inlet shoals (inshore)
- – Inlet shoals (offshore)
- – Nearshore bars
- – Offshore deposits
- – Recycled spoil sediments
- – Accreting spits/beach deposits
- – Attached bar deposits
- – Inland deposits
- – Freshwater pond deposits
- – Fillets at jetties
- – Imported material

In general, economics favor the borrow source(s) that matches the native beach quality, involves the shortest transportation distance, and minimizes environmental impacts. Large-scale projects such as the present Bogue Banks restoration plan require large volumes of material which may not be available in only one deposit.

4.4.1.1 Unacceptable Sources – The following sediment sources are considered unacceptable for the project.

- *Lagoon deposits in Bogue Sound* – generally much too fine compared to native beach sand and would not provide sufficient quantities of beach-compatible sediment.

- *Nearshore bar(s) along the project area* – part of the active profile and important for wave energy dissipation, therefore inappropriate as a borrow source; sediments too fine for the dry beach in this setting.

- *Accreting spits/beach deposits* – Bogue Banks has insufficient quantities of sand in accreting spits or accreting beach zones (e.g., western Emerald Isle) for the project. At least 20 times more sand is required than resides onshore as "surplus" near the ends of the island.

- *Attached bar deposits* – only very limited reaches near the inlets have any "surplus" sands in attached bars. This would provide only a tiny fraction (of the order 1-2 percent) of the material required for the project.

- *Inland deposits* – most of Bogue Banks is developed or privately owned. Even if a large tract were available and suitable for sand mining, costs of land acquisition in this setting would increase the cost of the project well beyond other alternatives. Other inland deposits on the mainland may be beach quality, but transportation distances make them much more expensive than other alternatives.

- *Freshwater pond deposits* – there are no known freshwater ponds nearby that require maintenance excavations or could provide the quantities of beach compatible sediment required for the project.

- *Fillets at jetties* – there is insufficient excess littoral sand trapped in fillets along the jetties/groins at the inlets adjacent to Bogue Banks.

- *Imported material* – imported beach-quality sediment from sources more than 15 miles from Bogue Banks will be significantly more expensive because of transportation costs than the acceptable sources (listed below).

4.4.1.2 Acceptable Sources – The following sediment sources were evaluated in more detail because of their likelihood of providing acceptable material (Appendix E).

- *Offshore deposits* – a sand search over a 50-square-mile area off Bogue Banks revealed about six square miles of beach-quality sand in close proximity to the project area.

- *Inlet shoals (inshore)* – review of aerial photos and ground-truth sampling confirmed the presence of extensive inlet shoals at Bogue Inlet which contain beach-quality sediment. In a 10 February 2000 letter, the Wilmington District outlined the costs and methods to open a new inlet channel. In this EIS, we are only proposing mining the inshore shoal (borrow area C). Studies by the USACE confirm that beach-quality material exists in some inshore areas of Beaufort Inlet.

- *Inlet shoals (offshore)* – studies by the USACE confirm that beach-quality material exists in offshore shoals of Beaufort and Bogue Inlets.

- *Recycled spoil sediments* – studies by the USACE confirm that beach-quality material resides in certain spoil areas, such as Brandt Island, which can be "recycled" to the beach.

The results of sediment sampling and review of published reports (Section 3.16 and Appendix E) yield the following ranking of acceptable borrow areas with respect to quality (as measured by composite overfill factors, R_A):

1) Offshore, area A
2) Bogue Inlet shoals (inshore)
3) Offshore, area B2
4) Offshore, area B1
5) Beaufort Inlet, outer shoals (inferred)
6) Brandt Island spoil area
7) Beaufort Inlet, offshore disposal mound (inferred)

With respect to transportation distances, the above-listed resources are ranked as follows (best to worst):

1) Offshore, areas B1 and B2, average distance <2 miles
2) Offshore area A, average distance ~5 miles
3) Bogue Inlet shoals, average distance ~10 miles
4) Brandt Island, average distance ~12 miles
5) Beaufort Inlet, average distance ~14 miles

The preferred borrow area is A based on sediment quality and transportation distance.

4.4.2 Alternate Fill Profile — Beach nourishment may be performed at a continuum of scales, depending on the goals of the project, availability of borrow sediment, method of construction, and budget. Since the proposed project area has never been nourished, there are no site-specific data to use as a guide other than the existing natural profile and available erosion rate estimates. Nearby Atlantic Beach has been nourished twice, but its sediment characteristics (after nourishment) differ from those in the proposed project area.

CSE Baird-Stroud (1999) evaluated the condition of the beach and inshore zone along Bogue Banks, using the profile volume method (Kana, 1993; Kana and Mohan, 1996). This method establishes site-specific criteria by which volume deficits can be determined against an ideal or desirable profile volume (i.e., one which contains sufficient dimensions to sustain daily, seasonal, and storm fluctuations of the beach without significant damage to the backshore). The profile volume method, if performed to the estimated depth of closure, integrates all cross-shore variations in profile geometry and is therefore insensitive to the timing of surveys.

Our analyses (CSE Baird-Stroud, 1999) demonstrated that there is a profile deficit averaging ~40 cy/ft along the 16.8-mile reach from western Emerald Isle to Pine Knoll Shores (profiles 8-76), compared to the existing profile volume along Atlantic Beach. Considering the fact that Atlantic Beach sustained Hurricanes *Dennis* and *Floyd* (1999) as well as *Fran* (1996) with only minor damage compared to other sections of Bogue Banks, its profile volume yields a rational minimum value. During final design, the profile volume will be analyzed quantitatively to estimate the level of protection provided.

The desired fill volume is one that restores the deficit (with respect to the criteria and goals of the project) plus adds "advance nourishment" to increase longevity. Advance nourishment is generally related to the anticipated average annual losses from the project area (i.e., the background erosion rate). The Bogue Banks Beach Preservation Task Force evaluated projects which factored in 5-year, 10-year, and 20-year advance nourishment requirements based on best-available background erosion rates. It was the decision of the task force to formulate the project around the 10-year nourishment project (i.e., initial deficit averaging 40 cy/ft plus 10-year advance nourishment averaging 10 cy/ft). This provides a reasonable time period over which the first project can be evaluated and provides a project scale that is practical for dredging. Small-scale projects do not afford economies of scale during construction and result in more frequent nourishments and the associated disruption to normal beach use by people and animals.

The proposed fill will be placed by hydraulic dredge between the base of the foredune and the outer bar. Only the profile above high water is controllable in nourishment construction. Intertidal and underwater portions of the profile will be subject to natural adjustment by waves. Given the relatively high backbeach elevations along most of Bogue Banks and the issue of easements for construction, the majority of the fill will be placed no higher than +7 ft NGVD (the natural elevation of the berm) and seaward of the existing toe of the foredune and all development. Along portions of eastern Emerald Isle, a low dune (elevations <+12 ft NGVD) will be constructed as part of the project to prevent the dredge slurry from flowing landward across developed property (where the foredune is missing).

Other fill profiles considered included:

- **Nourishment entirely below low water** – not the preferred alternative because it is more difficult to control sand placement, does not provide a safe working platform during construction, and does not provide immediate restoration of the dry beach and associated backbeach habitats.

- **Nourishment largely contained in a protective foredune** – not the preferred alternative because (1) a dry beach and healthy underwater profile are necessary prerequisites for a stable foredune; (2) nourishment sediments should be subject to wave action so material will sort naturally, bleach to a natural color, and winnow out fines; and (3) the project's primary goal is to restore a viable recreational beach for broad benefit to the community.

- **Smaller fill sections** – not the preferred alternative because they become more expensive per unit volume to construct due to economies of scale, they will not restore the minimum profile deficit, and they will leave more reaches vulnerable to storm damage.

4.4.3 Alternate Methods of Construction — There are two basic methods for nourishing beaches—via land-based equipment and mechanical placement or via hydraulic equipment (i.e., dredges). In either method, mechanical equipment such as dozers, graders, etc., are used to spread the material in a controlled manner. Some projects involve combinations of hydraulic and mechanical transfer. The preferred method depends on the scale of the project, proximity of the borrow area, and type of borrow area. Hydraulic dredges involve high initial costs to cover the setup of discharge pipeline, etc. Land-based equipment such as trucks or scraper pans can be mobilized at low cost. After mobilization, the unit costs of sand placement depend on transportation distance. In general, unit costs of hydraulic fills are lower because of efficiencies in production and placement. Therefore, large-scale nourishments such as the proposed project tend to be more cost effective if constructed by hydraulic dredge.

4.4.3.1 Methods Considered Unsuitable – The following excavation and sand transfer methods are considered unsuitable for the present project.

- *Over-road trucks* – none of the designated borrow areas are situated inland, and none are directly accessible by road.
- *Mechanical conveyor belt* – none of the designated borrow areas are situated close enough to the project area for this technique to be economic.
- *Dragline* – none of the designated borrow areas are situated close enough to the project area for this technique to be economic.
- *SeadozerÔ* (c/o Cape Fear International, Beaufort, NC) – None of the designated borrow areas are situated close enough to the project area for this technique to be economic. The method would result in more ocean bottom being impacted because it involves "pushing" material by jets/prop wash from borrow areas to the beach, a minimum distance of 0.5 miles. Portions of the project area are situated >>0.5 miles from the nearest borrow source. It is uncertain whether the SeadozerÔ is certified by the U.S. Coast Guard to work seaward of the open-ocean jurisdiction (COLREGS) line, a primary requirement for excavations in the offshore borrow areas (A, B1, and B2).
- *Traditional cutterhead suction dredges* – ocean-certified dredges are required by the U.S. Coast Guard for any excavations seaward of the COLREGS line. Generally, ocean-certified cutterhead suction dredges are the largest of their kind due to the certification requirements. Curtterheads are of the order 5-10 ft in diameter. Such dredges require a minimum operational depth of ~20 ft and work most efficiently if excavations remove at least 4-6 ft of section. Because the designated offshore borrow areas have on the order ~2 ft of beach-quality sediment in the section, cutterhead suction dredges will not be efficient. They would result in deeper cuts and mixing of less compatible material with the beach-quality material. Cutterhead suction dredges are only considered feasible for borrow area C (Bogue Inlet shoals) or Corps maintenance dredging in and around Beaufort Inlet.
- *Miscellaneous methods* – bucket dredging and transfer by barge are not cost effective for areas A, B1, or B2 and are generally not allowed seaward of the COLREGS line. This technique may be feasible for borrow area C where the equipment can work a thicker shoal section. Split-hull barges are not considered feasible because they require a minimum water depth of the order 20 ft for discharge. This depth would place the material too far seaward to achieve the project goals.

4.4.3.2 Methods Considered Suitable

- *Ocean-certified hopper dredge* – Self-propelled hopper dredges with built-in pumpout capability are feasible for borrow areas A, B1, and B2. Ocean-certified equipment typically requires ~25 ft minimum operational depth and is efficient for excavating shallow cuts of the order 1-2 ft. During excavation and loading, the slurry drains via scuppers discharging some fines in situ and leaving coarser material in the hopper compared to the excavated material. When loaded, the dredge travels to a temporary mooring and submerged pipeline near

the project site. It hooks up to the pipeline and pumps the material from the hopper to the beach where it is spread mechanically by dozers.

- *Ocean-certified suction dredge equipped for shallow cuts* – one such dredge exists among U.S. companies which has been specially designed for shallow cuts. This "dustpan" dredge (so nicknamed) is presently owned by Weeks Marine, Inc. (NJ) and is used primarily for beach nourishment involving thin borrow areas offshore (P. Lamourie, Aug'99, pers. comm.). The dredge works most efficiently if the borrow area is close to the project area (e.g., excavations paralleling the beach less than one mile offshore). The slurry is pumped directly to the beach via submerged pipeline and distributed with the aid of dozers and other land-based equipment. In contrast to self-contained hopper dredges, the excavations are pumped only once and therefore transfer more fines to the beach according to the quality of the sediment in the borrow area. Unit costs may be substantially lower than all other methods if the pumping distances are short. This method is considered most feasible for borrow areas B1 and B2.

- *Combined dredge and offroad trucks* – borrow area C and certain Corps spoil and navigation channels may be excavated by hydraulic dredge, transferred to a temporary stockpile area, dewatered, then loaded mechanically into offroad vehicles for distribution along the beach. This alternative is considered most feasible for borrow area C because Bogue Inlet is too shallow for a hopper dredge to exit when fully loaded. Noncertified dredges may legally work in sheltered waters in the inlet and pump a short distance from shoal areas to temporary stockpile areas at the western end of Bogue Banks. From there, offroad dump trucks could transfer material to the project area. Because of the double handling and distances involved, this method is only considered cost effective for the western Emerald Isle reach.

4.4.4 Alternate Construction Schedule — The proposed project involves a substantial volume of sand (>4.5 million cubic yards). Based on project experience elsewhere, one ocean-certified dredge can excavate and place on the order of 15,000-40,000 cy in a 24-hour period. The average production per day varies widely according to transportation distance and specifications of the project. In any case, a substantial period of time will be required to complete the project. For example, if production averages 20,000 cy/day, at least 225 calendar days (~7.5 months) will be required.

Preliminary discussions with environmental agencies indicate construction during colder months is favored because biological productivity tends to be lowest then. Construction during winter also avoids disruption of the peak tourism season.

The following general construction schedules were considered (including advantages and disadvantages).

4.4.4.1 Construction anytime based on dredge availability and lowest bid

- *Advantages* – Likely results in lowest construction cost and substantial financial savings to the community because the contractor controls the schedule around other workload and weather and only mobilizes once. Yields the earliest project completion and initiation of improved storm protection and recreational benefits.

- *Disadvantages* – Likely encroaches on high biological productivity periods, nesting seasons, and tourist season.

4.4.4.2 Construction during limited "environmental" windows between ~November and ~April

- *Advantages* – Direct environmental impacts occur during periods of lowest biological productivity. Avoids prime tourist season. Yields early benefits if the project can be initiated in fall 2000.

- *Disadvantages* – A five-to-six month construction window is insufficient to complete the entire project unless more than one dredge is used. Each dredge introduces large mobilization costs, increasing the total cost of the project. The narrower the dredging window, the fewer contractors will be willing to bid the project, further raising the cost of construction. Down time for weather is more likely during winter than summer. Delays project benefits for at least one year if the winter 2001 construction window is missed.

5.0 ENVIRONMENTAL CONSEQUENCES

5.1 LAND USE — Nourishment of the Bogue Banks beach will not change the land use patterns. Development of shoreline is governed by zoning regulations of the municipalities and County and by the CAMA Land Use Plans approved for each governmental entity. Ocean front development will remain primarily single family residences with patches of multi-family and hotel development. The beach nourishment project is consistent with the approved CAMA Land Use plans for Carteret County, and the Towns of Pine Knoll Shores, Indian Beach and Emerald Isle.

5.2 WETLANDS — No impacts to existing coastal wetlands or 404 wetlands will result from this project. No fill will be placed in 404 or coastal wetlands as part of this project.

5.3 UNIQUE AGRICULTURAL LANDS — The beach nourishment project will result in no impacts to agricultural lands, unique or otherwise.

5.4 LITTORAL PROCESSES

5.4.1 Tides – For borrow areas A and B, the dredging and nourishment operations will take place in the open ocean, so no changes in tidal conditions can occur. Dredging operations only affect tides in closed systems, such as inlets and bays. For borrow area C in Bogue Inlet, tides can be affected only if there is a change in the throat's cross-sectional area of flow. For example, it is thought that the change in tidal range in Beaufort Inlet may be related to the substantially increased cross-sectional flow area caused by dredging the navigation channel. Dredging borrow area C will not impact Bogue Inlet's cross-sectional flow area. Note on the drawing showing borrow area limits (see Fig. 3.16A) that the minimum (controlling) cross-section of Bogue Inlet's throat is well seaward of the borrow area limits. (When we passed along the navigation channel in our boat with a depthsounder, we noticed the ocean-bar minimum cross-section occurred a few hundred feet seaward of the last sample we took, labeled B-1 in Figure 3.16A.)

5.4.2 Hurricanes – Dredging the borrow areas will not change hurricane surge levels, since surges are changes in water-surface elevations. Changes in seabed depths affect surge levels only if enormous changes occur in seabed locations. The main hurricane-related impact of this project is the substantial increase in protection from hurricanes that will occur because of the greatly expanded beach. The biggest improvement will be in protection of the dunes from erosion by waves generated by hurricanes. Currently there is very little distance between the base of the dunes and the water. During the 1999 hurricanes, the dunes on Bogue Banks retreated an average of about 15 ft, with some areas retreating more than 30 ft. In a few low-lying areas there was washover of the dunes during hurricanes. Since the toe of the dune is now so close to the water, hurricane surge raises the water level sufficiently for waves to directly impact the dune toe and erode it away. Most areas of Bogue Banks have sufficiently high dunes to withstand surges. The problem is narrow beaches allowing waves to erode the toe, thus causing the entire dune to retreat.

5.4.3 Waves – Possible changes to waves caused by altering topography in the borrow areas was examined by use of wave shoaling models. The Wave Information Study database of waves from wind-wave models was used as a data source for the shoaling studies over borrow areas A and B. (Borrow area C is well inland of wave barriers, including both the outer protective subaerial shoals and submarine ebb-tidal delta at Bogue Inlet.) Waves were shoaled over A and B for both existing and dredged conditions, with all results shown in Appendix G3. The conclusions are: (1) there will be a temporary increase in wave heights for the sections of the island along the borrow areas of less than 1 percent or 0.1ft; and (2) error bars in the wave directional component of the database are very large. (The error can easily be seen in very contradictory predictions of energy flux, depending on which versions of the WIS database are used.) Thus error in the longshore energy flux predictions (used in estimating potential for longshore sediment transport) is many times larger than the model's predicted 8-9 percent increase in longshore energy flux caused by dredging the borrow areas.

5.4.4 Dimensions of Littoral Zone (Depth of Closure) – Conclusions were presented in Section 3.4 regarding the depth to which there is active motion of sediment. Different methods produced results varying between 13 and 30 ft (methods 1, 2, 4, and 6). Methods 3 and 5 were used to gauge the most extreme condition possible, the time of only a few hours duration when a hurricane was in the immediate vicinity and produces depth-limited waves of 7 meters. Methods 3 and 5 indicated seabed activity between 32 and 36 ft. Only during these extreme hurricane conditions does sediment move in the closest inshore borrow area B, and even then only in the landwardmost portion of the borrow area. The conclusion is that sand in the borrow areas is not within the littoral system, but a relict of past events, such as lowered sea level and relict inlets.

5.4.5 Littoral Transport – Effects of the dredging operation and the beach nourishment on longshore transport of sediment should be considered, since alterations in the transport patterns result in changes to the beach. The usual method for evaluating transport-pattern effects of topographic changes is to include the changes in a model which

uses accurate measures of directional waves. Unfortunately, the usual data for computing the potential for longshore sediment transport, measured directional waves, do not exist for this area.

As detailed in the Appendix G3 on waves, the particular dataset that we used for examining the effects of **borrow-area dredging** resulted in a 8-9 percent increase in longshore energy flux. However, comparisons of the different databases and their effects on littoral transport in Appendix G4 show that both direction and magnitude of transport are solely a function of which database is used. Thus error in the databases far exceed the numerical values of any predictions to the change in longshore energy flux.

The best indicator of effects of the **nourishment** on longshore transport is the behavior of the Corps' nourishment project at Atlantic Beach. When only one stretch of beach is nourished, there are often effects on the neighboring unnourished beaches. Usually the neighboring beaches receive benefits of nourishment sand moving out of the nourishment-project areas, regardless of whether they are on the net updrift or downdrift sides. The reason that updrift beaches also receive sand is that longshore transport occurs in both directions, at different times, and the beach is only updrift in a net-transport sense. Problems can occur, however, if the current patterns are so drastically altered that an already eroding neighboring beach suffers. There is some evidence (Roessler, 1998) from detailed modeling of the current patterns at Atlantic Beach and Pine Knoll Shores that this has, in fact, happened. The obvious solution to such a problem is to not allow such drastic longshore variation in nourishment volumes, especially when a neighboring eroding beach receives no sand at all. The plan for the project proposed in this EIS is to nourish all of the eroding unnourished parts of Bogue Banks, so this problem does not occur. The beach to the east of our proposed project (Atlantic Beach) is already nourished, and the beach to the west (Emerald Isle near Bogue Inlet) is slowly accreting (about 3 ft/yr).

5.4.6 Erosion Rates – Uses of erosion rates in examining environmental impacts include:

- Erosion is one of the factors used in computing nourishment volumes, so the total impact to the borrow areas and nourishment areas depends on erosion rates.
- Erosion rates indicate how rapidly detrimental impacts of the "no action" alternative will affect the oceanfront properties, infrastructure, and tax base.
- After nourishment, erosion rates help to determine how long beneficial impacts will last, both for people and fauna (e.g., increased dry beach width for turtle nesting).

The erosion rates summarized in Appendix G5 were one of the factors used to compute nourishment volumes for this project. The three components of the total nourishment volume are:

- *"Volume deficit"* is the sand needed to increase the beach volume up to some desirable level. The selected level for Bogue is 175 cy/ft, which was the average volume in profiles of Atlantic Beach prior to 1999 hurricanes. The details of computing this volume goal are described in the last section of Appendix G5 entitled "Beach Erosion Analysis used to determine Nourishment Requirement." This component is the largest volume of the three components.
- *"Advance nourishment"* is the volume determined from the erosion rates that is necessary to advance the beach enough to counteract the anticipated future erosion. Various scenarios were computed, and for this project the 10-year protection was selected. This does not mean that in 10 years the nourishment sand will be gone. Rather in 10 years the "advance nourishment" component of the project will be gone. That is, 10 years after the project construction the beach will have eroded back to the still healthy Atlantic Beach-type volume of 175 cy/ft. Of course, if erosion is currently higher than the historical average, as some have argued, then the beach will erode back to the 175 cy/ft Atlantic Beach profile sooner than in 10 years.
- *"Overfill ratio"* is a ratio of how many cubic yards from a borrow area will be needed to produce one cubic yard of material that matches the native beach sand. These ratios have been computed for the different borrow areas, so the total amount of material placed on a section of beach will depend on which borrow areas are used. Final matching of permitted borrow areas with nourishment areas will not be made until construction bids have been received for the project.

Duration of **beneficial impacts** of the project (protecting oceanfront properties, providing a recreational beach, increasing habitat for beach fauna) depend on erosion rates. The erosion rates and selected nourishment volumes show beneficial impacts **well in excess of 10 years**, since the "volume deficit" component of the project is the largest component. As an example, the central reach of Emerald Isle has erosion rates that are roughly average for the island. Duration of the project using a safety factor of two (to account for 100 percent uncertainty in computed erosion rates) is (10 yrs/2)(766,958cy nourishment)/ (226,902cy advance nourishment) = 17 years.

5.5 PUBLIC LANDS — The project will not reduce the existing public rights and use of the beach resources. The "Public Trust Doctrine" and the State Property Sovereignty Rules preserve the rights of all citizens of North Carolina for use of resources located below the mean high water line. Additionally, the County will obtain permanent easements from oceanfront property owners within the project limits. The easements will grant access for construction and measurement and establish permanent rights for the public to cross lands above the mean high water line if those lands are created by filling operations financed with public funds.

5.5.1 Public Access to Beach Resources -- Public access to the beach strand has been developed extensively by the Towns of Emerald Isle, Indian Beach and by Carteret County for the unincorporated area of Salter Path. As part of implementation of this project, the Town of Pine Knoll Shores is developing public access that will meet the USACE guidelines for public access to federally maintained beaches. Before construction begins, the County will require that all municipalities within the project limits meet the Corps of Engineer's guidelines for public access.

5.6 RECREATIONAL AND SCENIC AREAS — Construction of a 100-ft-wide berm, dry beach area will enhance the beach by providing areas on the beach for activities during all tidal conditions. This is a tremendous benefit to Bogue Banks' communities which rely on the beaches and opportunities for beach activities to attract visitors.

The fall season is the peak period for surf fishing on Bogue Banks with activities tapering off during November and December. The beach restoration operations are scheduled to occur between the months of November and April. Surf fishing will not be limited along the beach except in the immediate vicinity of the discharge pipe and earthmoving equipment.

5.7 CULTURAL RESOURCES — To determine the impact of the proposed dredging and beach fill operation on potentially significant submerged cultural resources, a remote sensing survey of the proposed borrow areas was conducted by Tidewater Atlantic Research, Inc. (TAR) of Washington, North Carolina. The survey report prepared by TAR is provided in Appendix B. The survey was designed to locate and identify submerged cultural resources in the study areas, generate sufficient data to make an initial assessment of each target's significance, and provide insight into the necessity for avoidance or additional investigation. The survey was carried out between 7 and 13 December 1999. No magnetic or acoustic anomalies were identified in either borrow area A or borrow area B-1. In borrow area B-2, ten magnetic anomalies were identified near the western end of survey area. Seven of those targets contained signature characteristics indicative of submerged cultural resources. Because they could be associated with an historic shipwreck, either avoidance or additional investigation to positively identify the nature and significance of the material generating the seven anomalies was recommended. To avoid the areas of the seven anomalies identified by the survey, the western portion of borrow area B-2 will be eliminated as a potential source of sand for the project.

5.8 AIR QUALITY — Discharges of pollutants into the air will occur as a result of the operation of dredging equipment offshore and earth moving equipment on the beach. The discharges will be temporary and localized and will not result in any significant impact to ambient air quality standards along Bogue Banks or in Carteret County.

5.9 WATER RESOURCES – Temporary increases in turbidity are associated with both dredging operations and the washing of fine sediments by waves on the nourished beach. The applicable standard required for Section 401 Water Quality Certification quoted here from WQC#2949 issued for a Corps dredging and disposal operation for the nearshore berm off of Atlantic Beach is "that the activity be conducted in such a manner as to prevent significant increase in turbidity outside the area of construction or construction related discharge . . . 25 NTUs in all saltwater classes . . .".

Published measurements of turbidity during beach nourishments are rare. Reference (USACE, 1993, p. 6) is made to turbidity measurements for pipeline discharge of nourishment sediment on Atlantic Beach. Turbidity was a function of distance from the discharge pipe. Measurements ranged up to 250 NTUs in the vicinity of the pipe, but decreased rapidly with distance. That sediment pumped from Brandt Island had a much higher overfill ratio and mud percentage than the borrow areas proposed for this project, so turbidity must necessarily be lower for this project. A fairly comprehensive set of measurements was made for another project with mud percentages more similar to the one proposed here by Hanes (1994). Table 5 in that publication lists measured turbidities for times during and after nourishment and for both the project area and a control site uninfluenced by the nourishment. Turbidities were not measured in the immediate vicinity of the discharge pipe, but rather seaward of the breakers along the nourished stretch of beach. Values are listed for surface, mid-depth, and near bottom in the water column. The control site must have had slightly different conditions, because the after-nourishment numbers showed an average ratio of 0.6 of nourishment site to control site. (The nourished area had less turbidity than the control site well after construction.) But the numerical values were low for this post-construction period: 2.8 to 4.4 NTUs for the nourished area and 4.4 to 9.2 for the control site.

Natural turbidities are usually lower in Florida, where this study occurred, than they are in North Carolina. During construction the nourishment area showed turbidities averaging 50 percent higher than the control site, but again the numerical values were low, ranging between 4.6 and 7.5 NTUs in the nourishment area. These studies show that for turbidities associated with nourishment:

- Turbidities may be quite high in the immediate vicinity of discharge. However, the WQC standard pertains to "outside the area of construction or construction related discharge."

- Neither of the two studies showed turbidities exceeding 25 NTUs outside the discharge area.

- Outside the discharge area, but in the the ocean along the same stretch of beach, **turbidities increased about 50 percent, but the reported increases are less than 10 NTUs.**

- Natural variation in turbidities associated with storms is larger than these increases outside of the discharge area.

Increases in sedimentation associated with nourishment are of concern because of possible impacts on benthic fauna. In the Hanes (1994) study sedimentation rates of fine sediments were compared between the nourished and control sites. The ratio of sedimentation rates between nourished and control was 0.8 before nourishment, 1.3 during, and 1.1 after. Numerical values were in the 15-25 $mg/cm^2/day$ range for all sites. Statistical computations (the Binomial Sign test) which test for the probability that the observed differences were the result of random chance resulted in the conclusion (p. 3029) that **"there were no significant differences in fines sedimentation rates."** Significant differences were observed in sand sedimentation rates, but the wave heights were one-third higher at the nourishment sites with 75 percent higher energies. That increased energy between the sites "is probably the reason for the relatively higher sand sedimentation rates."

5.10 GROUNDWATER QUALITY — No action proposed as part of this project will have an impact on surficial or deep aquifer groundwater.

5.11 INTRODUCTION OF TOXIC SUBSTANCES — No action proposed as part of this project will cause an intentional discharge of hazardous materials into the environment. Insignificant discharges of hazardous substances could possibly occur as a result of operation of mechanical equipment on the dredging platform or by earth moving equipment operating on the beach. State and federal regulations place a high burden of responsibility on the owner and operator of such equipment to prevent hazardous discharges. Regulations for reporting and dealing with discharges are administered by the U.S. Coast Guard. As part of their normal operations, Coast Guard personnel will conduct safety inspections of vessels and equipment operating in the coastal waters. Those inspections include identification of possible discharges of hazardous substances.

5.12 NOISE LEVELS — Dredging equipment in the ocean and earthmoving equipment on the beach will result in increased noise levels in the vicinity of the equipment during beach building operations. Beach filling and shaping operations will progress down the beach at a rate of about 500 ft per day ensuring that no single location will experience increased noise levels for more than several days.

5.13 WATER SUPPLY AND WASTEWATER SYSTEMS — There are no activities associated with this project that will impact existing wastewater collection, treatment, or disposal systems. No activities of this project will impact potable water well sources or distribution systems on Bogue Banks or in Carteret County.

5.14 MARINE RESOURCES

5.14.1 Offshore Resources – Monitoring studies of post-construction borrow areas in the southeast indicate that borrow areas fill in and return to near predredging conditions when there is adequate transport of sediment under the influence of strong currents in the area (Bowen and Marsh, 1988). This project's offshore borrow areas are in depths between 30 and 40 ft MLW (borrow area B) and 40 and 50 ft (borrow area A). Divers at these sites have not observed currents of sufficient magnitude to move sediment. However, most coastal areas in these depths have some rare events (e.g., hurricanes) that generate sufficient flows to move sediment. Thus the conclusion is that sediment levels in borrow areas will return to predredging conditions only during such rare events.

Sediment: The sediment types and areal extents in the offshore region are shown on the map of Figure E1 (Appendix E). Sandy areas are limited in extent, with substantial regions of hard bottom, although none of the borrow areas contain hard bottom. This project's primary expected environmental impact on the substrate in the offshore region is uncovering of buried nutrients in the dredged furrows, resulting in an increase in biological activity.

Biology: There are several environmental issues relating to the benthic habitat and resources that arise in considering a beach renourishment project. The most significant include: (1) impacts to and recovery of the benthic invertebrate community at the borrow sites; (2) potential impacts to commercially or recreationally important demersal fishes and crustaceans in part because of these effects on their benthic invertebrate prey; (3) impacts to and recovery of the benthic invertebrate community on the intertidal and shallow subtidal beach; and (4) potential impacts to commercially and recreationally important fishes in the surf zone and/or shorebirds in large part because of these effects on their benthic invertebrate prey and because of enhanced turbidity along the shoreline. The biological monitoring program summarized here and outlined in Appendix B are intended to address each of these issues.

Vertebrates: Fish, plankton, and other motile animals in the vicinity of the borrow area during dredging are least likely to be affected during dredging, because of their ability to avoid the disturbed areas. Fish species have been observed to leave the area temporarily during dredging operations and return when dredging ceases (Pullen and Naqvi, 1983). A study of nearshore borrow areas after dredging offshore of South Carolina revealed no long-term impacts to fisheries, both fish and planktonic organisms, as a result of the dredging (Van Dolah et al., 1992). Creation of new habitat and the uncovering and suspension of food that attract fish during dredging have been attributed to dredging offshore borrow areas (Naqvi and Pullen, 1982). Dredging of the bottom sediments in the borrow areas can be expected to attract fish (after the dredge leaves) as a result of suspension of bottom material. Impacts to anadromous fish and other estuarine-dependent organisms are not expected to be significant, since construction-related activities in the offshore borrow areas would be localized.

Invertebrates: Benthic organisms in the immediate area being dredged will be largely eliminated during dredging. However, initial recolonization of the dredged areas by opportunistic species is expected to occur soon after cessation of any dredging activities. Further recovery is expected from recolonization from migration of benthic organisms from adjacent areas and by larval transport. Monitoring studies of post-dredging effects and recovery rates of borrow areas indicate that most borrow sites show significant recovery by benthic organisms approximately one year after dredging (Naqvi and Pullen, 1982; Bowen and Marsh, 1988; Van Dolah et al., 1992). To encourage recolonization by organisms from undisturbed substrates, the borrow areas will not be "swept clean." Furrows of undredged materials will remain.

Samples from impact (borrow) areas will be compared with those from control (undisturbed) areas both before and after the sand is removed. [Control areas would have no sand removed, but would otherwise be affected by all other impacts (i.e., storms, shrimping, etc., that affect the impact area).] These samples taken before the removal of the sand will be compared with identical samplings made after the nourishment to evaluate impacts. In addition, the design also calls for spring sampling both before and after the removal of sand to assess the seasonal component, for a total of four sampling periods to complete the assessment of impacts.

5.14.2 Nearshore Resources

Sediment: Nourishment sediment will be placed on the upper part of the beach, but flow down into the surf-zone region. The placed sediments are a close match in size to the sandy beach sediments, but with higher carbonate content, and a few percent mud (Appendix E).

Biology: There are three direct impacts from nourishment projects:

- Very short-lived substantial increases in turbidity during the placement operation (a few days at each location) alter the water column conditions sufficiently that it causes mobile species to leave the area. Return is rapid. Studies have found that speed of return of mobile species is more dependent on the return rate of their prey than on the rapid return of normal turbidity levels.

- Burial of bottom-dwelling organisms essentially destroys the community present, but Reilly and Bellis (1983) found that larval recruitment is rapid, and recovery occurs in one or two seasons.

- Alteration of sediment type necessarily results in changes in type and densities of species. Numerous monitoring studies recommend that the key to minimizing impact is to match the sediment types as closely as possible.

5.14.3 Intertidal Resources

Sediment: During project construction there will be an increase in the turbidity of the surf zone in the immediate area of sand deposition. Most of the fine material in the beach fill is expected to be washed seaward into the surf during construction. This increase in fine material may cause the temporary displacement of various species of sport fish, causing a negative impact to surf and pier fishing in the area of deposition. A study done by the National Marine Fisheries Service on the effects of beach nourishment on nearshore macroinfauna concluded that beach nourishment projects using offshore dredged material have no harmful effects, provided that the sediments are similar to those where they are placed (Saloman and Naughton, 1984).

Vertebrates: In view of the high mobility of fish, it is expected that fish will leave the areas under active construction. Impact on fishing resources in the intertidal zone will be minimized simply by the fact that sand-placement operations will take place at any one location for only a few days and then move further along the beach. Quantitative impacts on fish will be judged from offshore tow counts.

Invertebrates: Impacts on intertidal microfauna in the immediate vicinity of the nourishment project are expected as a result of discharges of nourishment sediment on the beach. A study by Reilly and Bellis (1983) was conducted on Bogue Banks and is used as a seminal study on beach projects throughout the Southeast U.S. "The Ecological Impact of Beach Nourishment with Dredged Materials on the Intertidal Zone at Bogue Banks, North Carolina"

concluded that beach nourishment virtually destroys existing intertidal macrofauna, but that recovery is rapid once the pumping operation ceases. In most cases, recovery occurs within one or two seasons following the sediment placement. "...a speedy recovery largely depended on recruitment from pelagic larval stocks." Most species fell into this category. The few that did not, and recruited instead from neighboring beaches, were slower to recover.

5.14.4 Beach and Terrestrial Resources

Sediment: After construction the beach sediment will be sampled and analyzed. The primary purpose will be to determine how much of the mud in the nourishment sediment still remains and did not decant off during the construction process.

Biology: Since the project is being constructed with offshore sediments, there will be little impact on the upper (dune) portion of the beach. Project construction will result in disturbance and removal of some of the existing vegetation along the seaward side of the existing dune. Dune stabilization with vegetative planting will take place only in the isolated sections of the project where new dunes are built. Most of the project has vegetated dunes. The project is intended to widen the base of the dunes and the beach face, not build up the dune itself. Thus replanting makes sense only for those areas where new dune will be built. The Reilly and Bellis (1983) study that focused on the intertidal zone also encompassed dry-beach sampling. Most species, including all of the larger organisms such as crabs, recruited from pelagic larvae and thus recovered rapidly (one or two seasons). A monitoring program is in place to determine effects of the nourishment on beach species. The pre-project sampling is scheduled for summer 2000. The standard deviations in previous infauna samplings suggest that there will be sufficient statistical power to detect about a 20 percent change in total infaunal density. Analyses of densities of individual families will be less powerful, but an ordination analysis on the entire community data set will have power similar to that of the test of total infaunal density.

5.15 THREATENED AND ENDANGERED SPECIES

5.15.1 Mammals

- **Right whale, finback whale, humpback whale, sei whale, and sperm whale** – Of the five species of whales being considered, only the right whale and the humpback whale would normally be expected to occur within the project area during the construction period. Therefore, the other species of whales are not likely to be affected. Since sections of this beach area have received fill material in the past, this project will not significantly alter nearshore physical conditions. While some food resources may be initially affected by either dredging activities or burial associated with the beach nourishment, most invertebrates will quickly reestablish from adjacent unaffected areas or through recruitment processes. Furthermore, the presence of a hopper dredge in this area should pose no more of a collision threat to migrating whales than normal commercial ship traffic. However, in order to reduce the potential for accidental collision, a whale observer with at-sea large whale identification experience will be present on the hopper dredge from the beginning of hopper dredge use through March 31 to conduct daytime observations. Since habitat conditions and food supplies will be maintained in their current states and the potential for accidental collisions with hopper dredges will be minimized, it has been determined that the proposed project is not likely to adversely affect these whale species.

- **West Indian manatee** – Since the proposed dredging work is currently scheduled to occur during the time of year when manatee populations are expected to be minimal, it is unlikely that there will be any manatees in the project area during the proposed project. Therefore, it has been determined that the dredging of the borrow areas and the subsequent beach nourishment are not likely to adversely affect the West Indian manatee.

5.15.2 Birds

- **Piping plover** – Within Bogue Banks, only the west end of Emerald Isle has been documented to support piping plovers. IN ADDITION, BOTH BOGUE AND BEAUFORT INLETS CONTAIN INTERTIDAL FLATS THAT PROVIDE FEEDING AND ROOSTING HABITAT TO A VARIETY OF COLONIAL WATERBIRD SHOREBIRD SPECIES (DAVID ALLEN, PERS. COMM.). ~~This~~ THESE areas ~~is~~ ARE not located within the project boundaries and will not be affected by beach nourishment or dredging activities. ~~However, one proposed borrow area is located within Bogue Inlet, which contains feeding and roosting habitat for a variety of colonial waterbirds and shorebirds. If this area is chosen for dredging, potential plover feeding habitat may be lost. However, there is sufficient intertidal flat habitat elsewhere in the area to compensate for this potential loss.~~ Therefore, the proposed project will not adversely affect the piping plover.

  HOWEVER, THERE IS CONCERN THAT MOVING SAND TO RENOURISH THE SHORELINE MAY BURY INTERTIDAL MACROFAUNA AND SUBSTANTIALLY REDUCE THE AVAILABLE FOOD RESOURCE TO SHOREBIRDS THAT FORAGE WITHIN THIS AREA. SHOREBIRDS FEED ON WORMS, FLY LARVAE, BEETLES, CRUSTACEANS, MOLLUSCS, AND OTHER INVERTEBRATES PLUCKED FROM THE SAND. THESE POTENTIAL IMPACTS WILL BE REDUCED FOR SEVERAL REASONS. DREDGING AND FILLING ACTIVITIES WILL OCCUR LARGELY DURING WINTER MONTHS, AVOIDING THE LARVAL RECRUITMENT PERIOD OF BOTH MOLE CRABS (EARLY OCTOBER) AND COQUINA CLAMS (SPRING AND SUMMER) (DONAGHUE, 1999). ADDITIONALLY, STUDIES HAVE SHOWN THAT INTERTIDAL MACROFAUNA CAN RECOLONIZE A NOURISHED AREA WITHIN ONE OR TWO SEA-

SONS (ROSS AND LANCASTER, 1996; NATIONAL RESEARCH COUNCIL, 1995; REILLY AND BELLIS, 1978); THEREFORE, IMPACTS WILL BE TEMPORARY. DIRECTLY AFTER IMPACTS TO MACROFAUNA HAVE OCCURRED AND NUMBERS OF THESE SPECIES ARE DEPRESSED, BIRDS THAT PREY UPON THESE INVERTEBRATES WOULD LIKELY MOVE TO ADJACENT UNDISTURBED BEACH AREAS AND OTHER SUITABLE FEEDING AREAS FOR THE TEMPORARY PERIOD OF POPULATION RE-ESTABLISHMENT. LASTLY, SAND OF SIMILAR GRAIN SIZE TO THE EXISTING BEACH WILL BE USED TO REDUCE ANY CHANGES IN PHYSICAL CHARACTERISTICS OF THE BEACH THAT MAY AFFECT NOURISHMENT IMPACTS ON INVERTEBRATES (DONAGHUE, 1999; PETERSON ET AL, 1999; HACKNEY ET AL, 1996). BECAUSE MACRO INVERTEBRATES RECOLONIZE RAPIDLY, NO LONG TERM IMPACTS TO THESE ORGANISMS OR THE SHOREBIRDS THAT PREY UPON THEM ARE ANTICIPATED WITH THIS PROJECT.

- **Roseate tern** – The roseate tern has never been observed within the project site. Bogue Banks is most likely too large and too developed an island to provide appropriate habitat for the roseate tern. Additionally, when the tern is observed in North Carolina, it is mostly during summer months, when this project is not scheduled to occur. Therefore, the project is not likely to affect the roseate tern.

5.15.3 Reptiles

- **Hawksbill, leatherback, Kemp's ridley, and green sea turtles** – The hawksbill, leatherback, and Kemp's ridley sea turtles do not regularly nest along North Carolina coasts. The green sea turtle nests sporadically in North Carolina but has not been observed nesting in the project area. Therefore, beach nourishment activities will not affect any of these sea turtle species. However, all of these species migrate within North Carolina waters throughout the year, mostly between April and December. Hopper dredges will be used to dredge material from borrow areas located within these migratory waters and transport it to the shore. Although the majority of construction activities is planned to occur between November and April to avoid nesting and migrating turtles, dredging activities may begin as early as October and may continue into the spring months in order to complete the project in one season. Therefore, dredging activities may occur during moderate levels of sea turtle migration.

  Hopper dredges move rapidly over the bottom sediments and can injure or kill juvenile turtles lying on the sea bottom. In order to reduce these impacts, certain precautions will be taken. The proposed project will follow NMFS and ACOE hopper dredging protocol (see Appendix). An observer will be present on the hopper dredge (except when water temperatures are cold enough to ensure that turtles will not be present; January and February) to document any takes of turtle species and to ensure that turtle deflector dragheads are used properly. If two sea turtle takes occur within 24 hours, work will cease upon a subsequent take, and will only resume if concurred in by the ACOE. If three takes occur, a risk assessment and appropriate risk management plan will be developed and submitted to the ACOE. Should a total take of five sea turtles occur, all work will be terminated. If a total of two endangered species of sea turtles are taken during a project, work will be suspended until further guidance from the ACOE has been given. Despite these precautions, the chance of impacting migrating sea turtles with a hopper dredge still exists. Therefore, it has been determined that the proposed project may adversely affect the hawksbill, leatherback, Kemp's ridley, and green sea turtles.

- **Loggerhead sea turtle** – The proposed project could potentially affect loggerhead sea turtles in two ways. First, dredging activities proposed to occur offshore may occur in areas used by migrating juveniles. The act of dredging material with a hopper dredge may adversely affect juvenile turtles. However, NMFS and ACOE hopper dredge protocol will be followed to reduce these impacts. Second, nourishing the beach with fill material may affect nesting activities by altering nesting habitat. If the beach becomes too hard through the compaction of deposited nourishment sediments by construction equipment, it could present a physical barrier to turtle nest digging. Furthermore, beach nourishment may influence physical characteristics of beaches (such as sand-grain size and shape, silt-clay content, sand compaction, moisture content, porosity/water retention, gas diffusion rates, and color of sand grains) which could alter the temperature of the beach. These factors could reduce reproductive success of nests laid in nourished areas (Crain et al., 1995; Ackerman, 1996).

  TO MINIMIZE IMPACTS TO NESTING SEA TURTLES IN THE PROJECT AREA, STANDARD PROTOCOL ADOPTED BY THE USFWS AND USED IN PREVIOUS BEACH NOURISHMENT PROJECTS IN NORTH CAROLINA WILL BE FOLLOWED. THIS PROTOCOL INCLUDES THE FOLLOWING GUIDELINES:

  1. ONLY BEACH QUALITY SAND SUITABLE FOR SEA TURTLE NESTING, SUCCESSFUL INCUBATION, AND HATCHLING EMERGENCE SHALL BE USED FOR BEACH NOURISHMENT ON THE PROJECT SITE. FURTHERMORE, SAND OF SIMILAR GRAIN SIZE TO THE EXISTING BEACH WILL BE USED TO REDUCE ANY CHANGES IN PHYSICAL CHARACTERISTICS OF THE BEACH THAT MAY AFFECT NEST SURVIVAL.

  2. IMMEDIATELY AFTER COMPLETION OF THE BEACH NOURISHMENT PROJECT AND PRIOR TO THE NEXT THREE NESTING SEASONS, BEACH COMPACTION SHALL BE MONITORED AND TILLING SHALL BE CONDUCTED AS REQUIRED TO REDUCE THE LIKELIHOOD OF IMPACTING SEA TURTLE NESTING AND HATCHING ACTIVITIES.

3. IMMEDIATELY AFTER COMPLETION OF THIS PROJECT AND PRIOR TO THE NEXT THREE NESTING SEASONS, MONITORING SHALL BE CONDUCTED TO DETERMINE IF ESCARPMENTS ARE PRESENT AND ESCARPMENTS SHALL BE LEVELED AS REQUIRED TO REDUCE THE LIKELIHOOD OF IMPACTING SEA TURTLE NESTING AND HATCHING ACTIVITIES.

4. CARTERET COUNTY WILL ENSURE THAT CONTRACTORS DOING THE BEACH NOURISHMENT AND DREDGING WORK FULLY UNDERSTAND SEA TURTLE PROTECTION MEASURES.

5. BEACH NOURISHMENT AND DREDGING ACTIVITIES ARE PLANNED TO BEGIN AFTER NOVEMBER 1 AND BE COMPLETED BEFORE MAY 1. IF ANY FILLING OCCURS AFTER MAY 1, THE PIPELINE WILL BE PLACED ALONG THE LANDWARD EDGE OF THE BERM.

6. IF ANY BEACH NOURISHMENT OR DREDGING ACTIVITIES TAKE PLACE DURING THE PERIOD FROM MAY 1 THROUGH NOVEMBER 15, A STANDARDIZED NEST MONITORING AND RELOCATION PLAN WILL BE IMPLEMENTED IN ADDITION TO THE MONITORING THAT ALREADY OCCURS. THE PLAN INCORPORATES MONITORING OF THE BEACH DISPOSAL AREA EACH MORNING FROM THE BEGINNING OF THE NESTING SEASON UNTIL ALL EQUIPMENT IS REMOVED FROM THE BEACH AND THE RELOCATION OF ANY NESTS LAID WITHIN THE PROJECT AREA. USING STANDARD NEST RELOCATION TECHNIQUES, ALL NESTS WILL BE LOCATED TO A SUITABLE NURSERY BEACH, AGREED TO PRIOR TO THE START OF RELOCATION EFFORT BY THE U.S. FISH AND WILDLIFE SERVICE AND THE NORTH CAROLINA WILDLIFE RESOURCES COMMISSION. HATCHING SUCCESS OF RELOCATED NESTS WILL BE MONITORED AND REPORTED.

7. IMMEDIATELY AFTER COMPLETION OF THIS PROJECT AND PRIOR TO MAY 1 FOR THREE SUBSEQUENT YEARS, SAND COMPACTION WILL BE MONITORED IN THE AREA OF RESTORATION IN ACCORDANCE WITH A PROTOCOL AGREED TO BY THE SERVICE, THE STATE REGULATORY AGENCY, AND CARTERET COUNTY. AT A MINIMUM, THE PROTOCOL PROVIDED UNDER 7A AND 7B BELOW WILL BE FOLLOWED. IF REQUIRED, THE AREA WILL BE TILLED TO A DEPTH OF 36 INCHES. ALL TILLING ACTIVITY MUST BE COMPLETED PRIOR TO MAY 1. A REPORT ON THE RESULTS OF COMPACTION MONITORING WILL BE SUBMITTED TO THE SERVICE PRIOR TO ANY TILLING ACTIONS BEING TAKEN. AN ANNUAL SUMMARY OF COMPACTION SURVEYS AND THE ACTIONS TAKEN WILL BE SUBMITTED TO THE SERVICE. THIS CONDITION WILL BE EVALUATED ANNUALLY AND MAY BE MODIFIED IF NECESSARY TO ADDRESS SAND COMPACTION PROBLEMS IDENTIFIED DURING THE PREVIOUS YEAR.

7A. COMPACTION SAMPLING STATIONS SHALL BE LOCATED AT 500-FOOT INTERVALS ALONG THE PROJECT AREA. ONE STATION WILL BE AT THE SEAWARD EDGE OF THE DUNE/BERM LINE (WHEN MATERIAL IS PLACE IN THIS AREA); ONE STATION WILL BE MIDWAY BETWEEN THE DUNE LINE AND THE HIGH WATER LINE; AND ONE STATION WILL BE LOCATED JUST LANDWARD OF THE HIGH WATER LINE. AT EACH STATION, THE CONE PENETROMETER SHALL BE PUSHED TO A DEPTH OF 6, 12, AND 18 INCHES THREE TIMES (THREE REPLICATES). MATERIAL MAY BE REMOVED FROM THE HOLE IF NECESSARY TO ENSURE ACCURATE READINGS OF SUCCESSIVE LEVELS OF SEDIMENT. REPLICATES WILL BE LOCATED AS CLOSE TO EACH OTHER AS POSSIBLE, WITHOUT INTERACTING WITH THE PREVIOUS HOLE AND/OR DISTURBED SEDIMENTS. THE THREE REPLICATE COMPACTION VALUES FOR EACH DEPTH WILL BE AVERAGED TO PRODUCE FINAL VALUES FOR EACH DEPTH AT EACH STATION. REPORTS WILL INCLUDE ALL 27 VALUES FOR EACH TRANSECT LINE, AND THE FINAL 9 AVERAGED COMPACTION VALUES.

7B. IF THE AVERAGE VALUE FOR ANY DEPTH EXCEEDS 500 PSI FOR ANY TWO OR MORE ADJACENT STATIONS, THEN THAT AREA WILL BE TILLED PRIOR TO MAY 1 OF THE FOLLOWING YEAR. IF VALUES EXCEEDING 500 PSI ARE DISTRIBUTED THROUGHOUT THE PROJECT AREA BUT IN NO CASE DO THOSE VALUES EXIST AT TWO ADJACENT STATIONS AT THE SAME DEPTH, THEN CONSULTATION WITH THE FISH AND WILDLIFE SERVICE WILL BE SOUGHT TO DETERMINE IF TILLING IS REQUIRED. IF A FEW VALUES EXCEEDING 500 PSI ARE PRESENT RANDOMLY WITHIN THE PROJECT AREA, TILLING WILL NOT OCCUR.

8. VISUAL SURVEYS FOR ESCARPMENTS ALONG THE PROJECT AREA SHALL BE MADE IMMEDIATELY AFTER COMPLETION OF THE BEACH NOURISHMENT PROJECT AND PRIOR TO MAY 1 FOR THREE SUBSEQUENT YEARS. RESULTS OF THE SURVEYS WILL BE SUBMITTED TO THE SERVICE PRIOR TO ANY ACTION BEING TAKEN. ESCARPMENTS THAT INTERFERE WITH SEA TURTLE NESTING OR THAT EXCEED 18 INCHES IN HEIGHT FOR A DISTANCE OF 100 FEET WILL BE LEVELED TO THE NATURAL BEACH CONTOUR BY MAY 1. THE SERVICE WILL BE CONTACTED IMMEDIATELY IF SUBSEQUENT REFORMATION OF ESCARPMENTS THAT INTERFERE WITH SEA TURTLE NESTING OR THAT EXCEED 18 INCHES IN HEIGHT FOR A DISTANCE OF 100 FEET OCCURS DURING THE NESTING AND HATCHING SEASON TO DETERMINE THE APPROPRIATE ACTION TO BE TAKEN. IF IT IS DETERMINED THAT ESCARPMENT LEVELING IS REQUIRED DURING THE NESTING OR HATCHING SEASON, THE SERVICE WILL PROVIDE A BRIEF WRITTEN AUTHORIZATION THAT DESCRIBES METHODS TO BE USED TO REDUCE THE LIKELIHOOD OF IMPACTING EXISTING NESTS. AN ANNUAL SUMMARY OF ESCARPMENT SURVEYS AND ACTIONS TAKEN WILL BE SUBMITTED TO THE SERVICE.

9. FROM MARCH 1 THROUGH APRIL 30 AND NOVEMBER 1 THROUGH NOVEMBER 15, STAGING AREAS FOR CONSTRUCTION EQUIPMENT WILL BE LOCATED OFF THE BEACH TO THE MAXIMUM EXTENT PRACTICABLE. NIGHTTIME STORAGE OF CONSTRUCTION EQUIPMENT NOT IN USE WILL BE OFF THE BEACH TO MINIMIZE DISTURBANCE TO SEA TURTLE NESTING AND HATCHING ACTIVITIES. IN ADDITION, ALL CONSTRUCTION PIPES THAT ARE PLACED ON THE BEACH WILL BE LOCATED AS FAR LANDWARD AS POSSIBLE WITHOUT COMPROMISING THE INTEGRITY OF THE DUNE SYSTEM.

TEMPORARY STORAGE OF PIPES ON THE BEACH WILL BE IN SUCH A MANNER SO AS TO IMPACT THE LEAST AMOUNT OF NESTING HABITAT AND SHALL LIKEWISE NOT COMPROMISE THE INTEGRITY OF THE DUNE SYSTEMS.

By planning to perform the majority of the project during off-season months, monitoring beach hardness, and relocating nests found in unsuitable habitat if project completion delays occur, impacts to nesting loggerhead sea turtles will be minimized. In addition, NMFS and ACOE hopper dredge protocol will be followed to minimize impacts to migrating loggerheads caused by dredges. However, because of the possibility of missing a sea turtle nest during the nest monitoring program, inadvertently breaking eggs during relocation, or injuring a migrating loggerhead with a hopper dredge, it has been determined that the project may affect the loggerhead sea turtle.

5.15.4 Fish

- **Shortnose sturgeon** – It is unlikely that the shortnose sturgeon occurs in the project area (Fritz Rohde, pers. comm.). However, should it occur, its habitat would be only minimally altered by the proposed project. This species feeds on a wide variety of invertebrates and while some food resources may be initially affected by either burial associated with beach nourishment or from dredging activities, most invertebrates will quickly reestablish from adjacent unaffected areas or through recruitment processes. Although hopper dredges can impact shortnose sturgeons, this species is not likely to be present in the project area and, therefore, impacts from dredges are not anticipated to occur. Because of the unlikelihood of shortnose sturgeon being present in the project area and because of the precautions being taken with the hopper dredges, it has been determined that the actions of the proposed project are not likely to affect the shortnose sturgeon.

5.15.5 Plants

- **Seabeach amaranth** – Since dredging of the borrow areas will be done offshore, no impacts to amaranth plants will occur from this action. Furthermore, because beach nourishment will occur in winter months (during seed dormancy) immediate impacts to the amaranth population along the project site will be reduced. However, deeply burying existing seeds could negatively affect the amaranth population in later seasons. Assuming that seeds are located in the general position of former parent plants observed in past surveys, they may be covered by beach nourishment activities. Yet it is not certain whether this deposition will have negative or positive consequences to the seeds since past research is inconclusive. The USACE (1995) found that amaranth at Masonboro Inlet was more abundant in areas that recently received dredged material. In addition, 1995 survey data from the NC Natural Heritage Program found a section of Bogue Banks that was used as a disposal zone in 1994 had an increase in population from 100 to 7300 plants. Dredging activities could uncover buried seeds and allow them to germinate in deposited areas. (This benefit is unlikely to occur during this project if dredged material is supplied from areas offshore that do not contain amaranth seeds.) In contrast, Hancock (1995) concluded that amaranth seedlings generally do not emerge from depths of sand greater than 1 cm. Therefore the added sand may be detrimental if placed on top of seeds already present at Bogue Banks. However, the beach nourishment that is to take place along the coast of Bogue Banks will occur on areas suffering from erosion and should ultimately expand potential habitat for the plant species. AN AMARANTH SURVEY AT BOGUE BANKS IN AUGUST OF 2000 LOCATED INDIVIDUALS IN AREAS THAT HAD RECEIVED NOURISHMENT AND EXTENSIVE BEACH SCRAPING IN THE PAST. YET because known amaranth habitat will be filled, it has been determined that the proposed project may affect seabeach amaranth.

  The USACE has instituted a long-term seabeach amaranth monitoring program at every beach in North Carolina which routinely receives dredged material from federally funded projects. The program is to be conducted until such a time that enough data are available to allow a reasonable prediction of the actual impacts of each planned disposal action on the species in the future. After this beach nourishment project is complete, the project area will be monitored by the applicant to see if and where seeds survived. Within a few monitoring seasons, these data will help predict ultimate impacts of beach nourishment on amaranth at Bogue Banks and will be made available to the Corps' monitoring program.

5.16 SEDIMENT CHARACTERISTICS

5.16.1 **Beach** – Bogue Banks presently contains admixtures of fine, medium, and coarse sands as well as sizable fractions of carbonate material (15-20 percent), and granule-sized material (~3-5 percent). Mean sediment size across undisturbed profiles, which represent less than 5 percent of the shoreline, vary systematically from fine sand in the foredune (elevations >7 ft NGVD) to medium-coarse sand on the berm and beach face (elevations ~+5 to -2 ft NGVD), then fining seaward across the longshore bar (fine sand) and lower shoreface (fine to very fine sand and silt). Shell material spans the widest size range from very fine crushed shell to whole shells in the gravel size range.

The preferred borrow area (A) contains similar admixtures of sediment with the primary difference being the percentage of carbonate material (~40 percent) and mud (~4 percent). Higher carbonate fractions account for the slightly coarser mean grain size in borrow area A compared to the native beach (0.36 mm versus 0.30 mm). Shell material is not considered as suitable for nourishment as quartz sand because it abrades more rapidly (CERC, 1984). At decadal time scales, this is not considered significant. However, over time, shell material introduced via

nourishment will abrade and shift mean grain sizes closer to that of the native beach. Crushed shell material is sometimes preferred by beach goers because it is softer than quartz (hardness of 3 versus 7).

The preferred construction method of hopper dredges will have the effect of eliminating much of the silt/ clay-sized material before transfer to the beach. Remaining fine-grained material will be discharged with the slurry across the beach face during construction and settle offshore beyond the outer bar.

The proposed borrow sediment is expected to yield a slightly more stable dry beach after winnowing of fines and an incrementally steeper equilibrium beach face slope because of its slightly coarser sediment texture compared to the native beach. Because of the presence of the outer bar along Bogue Banks, the nourishment will infill part of the inshore runnel and provide greater wave energy dissipation across the surf zone. It will displace the inshore runnel seaward, but not eliminate it. The process of dredging will eliminate most of the muddy sediments and yield a lighter color-"washed" sediment on the beach. With exposure to sunlight and reworking in the surf, nourished sediments will bleach and abrade to similar color as the native beach. The nourished beach will initially contain twice as much shell material as the existing beach.

5.16.2 Offshore – The preferred borrow area (A) consists of mixed sand and broken shell material with ~4 percent mud in the upper 2-2.5 ft. Medium-scale, symmetric ripples (having a relief of ~0.25-0.5 ft and a crest spacing of ~1-2 ft) occur over ~50 percent of the bottom in borrow area A. Below the confirmed layer, sediments are more variable with some areas containing semilithified limestone and other areas containing thick mud lenses or muddy shell zones. The proposed project will remove a portion of the upper layer (typically ~1.5 ft of section), leaving unconsolidated sediments similar to the dredged sediments exposed in each cut. Hopper dredges are expected to excavate parallel swaths (leaving some undisturbed "furrows" in between) within the borrow area. The undisturbed areas will serve as a "recruitment" area for replacement of organisms in adjacent dredged areas.

Turbidity at the bottom at present is highly variable with about 30 percent of the core sites having high concentrations of silt in the water column (zero visibility in June and November 1999 under relatively calm conditions). Best visibility at the bottom during coring was about 5 ft at ~10 percent of the stations. Typical visibility was about 1 ft in June and November 1999. During dredging, mud will be mobilized, pumped into the hopper, and partially decanted via scuppers back to the water column over the borrow site. Turbidity will be elevated during construction by an uncertain quantity. Prior studies as discussed in Section 5.9 have demonstrated high turbidities in the construction-related discharge, but increases in the area outside the discharge were typically less than 10 NTUs. The area of high turbidity is expected to be restricted to a radius of ~1000-1500 ft from the dredge. Suspended sediment concentrations are expected to return to background levels within a day or so except at the bottom. Newly exposed sediments are expected to produce higher turbidity levels at the bed for several weeks until the new substrate adjusts to ambient flows near the bed.

Inshore waters immediately seaward of the beach will sustain temporarily elevated turbidity levels near the point of discharge. Empirical evidence from other projects suggests temporary sediment plumes will extend in a radius of the order 1000-1500 ft from the point of discharge during construction. All but the finest clays will settle to the bottom beyond the surf zone within hours. Assuming that 2 percent of the nourishment volume delivered to the beach is unstable silt and clay, and that it is dispersed over the project area within 1000 ft seaward of the outer bar, it will incrementally add a layer ~0.025 ft (~0.3 inch) thick to the existing substrate. Presently, the inshore zone seaward of the bar (water depths between 15-30 ft) is very turbid near the bottom with zero visibility (based on scuba surveys in June and November 1999). Isolated patches of soft clay upward of 0.5 ft thick occur across the lower foreshore and inshore zones. These appear to mobilize and migrate over sandy substrate as evidenced by the distinct break in texture at the interface and persistence of small-scale bedforms in the underlying sandy sediment (diver observations in June and November 1999).

The closest outcropping of hard bottom is ~6500 ft from borrow areas A and B2. This distance is ~four times greater than from the expected maximum radius of sediment plumes around the dredge or around the discharge point. The nearest outcrop of hard bottom off the project area occurs about 1600 ft seaward of the bar near transect 11 (Emerald Isle, west reach) and transect 25 (Emerald Isle, central reach). There are no inlets or channelized discharges between the preferred borrow area and adjacent hard bottom areas that could direct a concentrated plume of fine-grained sediments into these habitats.

5.17 **ECONOMIC AND SOCIAL ENVIRONMENT** — The consequences of the beach nourishment project on the economic and social environment of Carteret County are reflected in the project planning objectives, preservation of the county's and towns' tax bases, the health of the tourism industry, and the protection of the oceanfront resource during severe storms. Carteret County's economy is indubitably linked to Bogue Banks. A beach nourishment project on the eroding areas of Bogue Banks would provide protection to the millions of dollars of tax base on Bogue Banks.

In addition, the health of the tourism industry in Carteret County would be impacted positively by the beach nourishment project. As stated previously, the beach is the number one reason tourists visit Carteret County. Tourism

generates over $208 million dollars annually for the Carteret County economy and is the leading North Carolina industry, generating over $2 billion in revenues for the state treasury. A nourishment project would maintain the health of Bogue Banks as an economic resource, and in so doing would maintain the health of the tourism industry in Carteret County.

Finally, the beach nourishment project would provide additional storm protection. By building a wider beach and a protective dune, the nourishment project would provide protection to residential and commercial properties, state and local roads, sidewalks, electric and water utilities, phone and cable facilities, and public beach accesses. The public and private sectors would be saved millions of dollars in repairs. The costs of Hurricane *Floyd* in Carteret County alone were $26,000,000 in residential damage, $2,225,000 in commercial damage and $1,800,000 in governmental damage for a total of $30,025,000. The vast majority of these damage figures were generated from damage sustained on Bogue Banks because of the lack of a wide beach and a protective dune. By comparison, Atlantic Beach, which is located on the eastern end of Bogue Banks, was nourished in 1986 and 1994. The oceanfront of Atlantic Beach faired much better in Hurricane *Floyd* than the sections of Bogue Banks which had not been nourished.

Oak Island, North Carolina, which sustained a direct hit from Hurricane *Floyd* sustained $25 million of damage to private property, $6 million to public infrastructure and beach accesses, lost 70 properties which cannot be replaced, and had clean up costs that have exceeded $2 million. As a result of the damage, Oak Island did not have a fall tourist season which cost them millions of dollars in lost revenue and over 200 oceanfront homes need to be repaired in order to habitable by summer 2000. In total, the economic loss caused by Hurricane *Floyd* will be close to $100 million. A beach nourishment project for Oak Island would cost approximately $5 million and would have saved Oak Island millions of dollars, even after factoring in clean up expenses, in economic losses. During Hurricane *Floyd*, the nourished beaches of Kure Beach, Wrightsville Beach and Carolina Beach, which also experienced direct hits by the storm, had significantly less storm damage when compared to non-nourished beaches of the state.

5.18 MITIGATIVE MEASURES — To minimize potential impacts to threatened and endangered species, several mitigative measures will be taken. The proposed project will follow NMFS and ACOE hopper dredging protocol (see Appendix) to reduce the impacts that hopper dredges may have on wildlife. Although hopper dredging has no seasonal restrictions (NMFS protocol), the majority of construction activities is planned to occur between November and April to avoid nesting and migrating sea turtles, fish, and whales. Furthermore, an observer will be present on the hopper dredge to document any takes of sea turtle species, except when water temperatures are cold enough to ensure that sea turtles will not be present (during January and February), to watch for and alert the dredge operator of whales in the area (from the beginning of hopper dredge use through March 31 for daytime observations), and to ensure that turtle deflector dragheads are used properly. If two sea turtle takes occur within 24 hours, work will cease upon a subsequent take, and will only resume if concurred in by the ACOE. If three takes occur, a risk assessment and appropriate risk management plan will be developed and submitted to the ACOE. Should a total take of five sea turtles occur, all work will be terminated. If a total of two endangered species of sea turtles are taken during a project, work will be suspended until further guidance from the ACOE has been given.

To minimize impacts of beach nourishment on nesting sea turtles and vegetative-stage seabeach amaranth, beach nourishment and dredging activities are planned to begin after November 1 and be completed before May 1, when nesting and germination activities are low. If any beach nourishment or dredging activities take place between March 1 and November 15, a standardized nest monitoring and relocation plan will be implemented. This program will include daily patrols of disposal areas at sunrise, relocation of any nests laid in areas to be impacted by fill placement, and monitoring of hatching success of the relocated nests. Sea turtle nests will be relocated to an area suitable to both the USFWS and the NC Wildlife Resources Commission's Sea Turtle Coordinator. In addition, sand of similar grain size to the existing beach will be used to reduce any changes in physical characteristics of the beach that may affect turtle nest survival. Furthermore, beach compaction shall be monitored and tilling shall be conducted in areas where the post-disposal beach is harder than 500 CPU's to reduce the likelihood of impacting sea turtle nesting and hatching activities.

To minimize impacts to seabeach amaranth populations, the project area will be monitored by the applicant to see if and where seeds survived, after this beach nourishment project is complete. Within a few monitoring seasons, these data will help predict ultimate impacts of beach nourishment on amaranth at Bogue Banks and will be made available to the Corps' seabeach amaranth monitoring program. The beach nourishment that is to take place along the coast of Bogue Banks will occur on areas suffering from erosion and should ultimately expand potential habitat for the amaranth.

PROJECT ENGINEER

EDUCATION

1976 B.S. Civil Engineering
North Carolina State University

1978 M.S. Civil Engineering and Marine Sciences
North Carolina State University

REGISTRATION

Professional Engineer Registered in North Carolina, Florida, and Virginia

PROFESSIONAL ORGANIZATIONS

American Society of Civil Engineers
Chi Epsilon Civil Engineering Honor Society

WORK EXPERIENCE

20 Years Civil and Coastal Engineering Experience

SPECIALTIES

- Site Planning and Design
- Coastal and Waterfront Structures
- Construction Administration
- Stormwater Management
- Dredging and Dredged Material Disposal
- Small Boat Harbor and Marina Planning, Engineering and Permitting
- Environmental Permitting
- Urban Waterfront Redevelopment Planning and Engineering

SPECIFIC PROJECT EXPERIENCE

Mr. Forman brings 20 years of project experience on a broad range of project and client types including military, municipal, state and private clients. Mr. Forman's marina and waterfront project experience includes marina projects with a cumulative total of over 5000 boat slips. He has successfully permitted waterfront structures, marinas, dredging and coastal engineering projects in Florida, Virginia, Maryland and North Carolina and South Carolina. Some representative projects successfully completed under Mr. Forman's direction include:

- Town of Atlantic Beach, Boating Channel Dredging
- Blackbeard Sailing Club, Fixed Breakwater Project
- City of Washington, Downtown Waterfront Redevelopment, Washington, North Carolina
- City of New Bern, Union Point Park Redevelopment, Bulkhead and Promenade
- William's Wharf Landing, Waterfront Redevelopment, Mathews, Virginia
- Moss Planing Mill Redevelopment Study, Washington, North Carolina
- OMC Marina at Gulf Harbors, New Port Richey, Florida
- Oriental Yacht Harbor Marina, Oriental, North Carolina
- Inner Harbor East Marina, Lady Baltimore Marina, Baltimore, Maryland
- Captains Point Marina, Ocean City, Maryland
- Lockwood Marina, City of Charleston, Charleston, South Carolina

ADRIENNE HINER COLE

EXPERIENCE

ASSISTANT DIRECTOR, CARTERET COUNTY ECONOMIC DEVELOPMENT COUNCIL, INC.
Morehead City, North Carolina. February 1, 1999 – Present. Responsibilities: Assisting the Executive Director on all matters within the jurisdiction of the EDC. Specifically, I assist the Executive Director in the following six categories: (i) business retention, expansion and recruitment, (ii) membership services and recruitment, (iii) infrastructure and regulatory issues, (iv) workforce development and coordination, (v) grant writing, (vi) public advocacy, public relations and (vii) special projects as needed.

COUNTY PLANNER AND ECONOMIC DEVELOPMENT DIRECTOR
Pamlico County, North Carolina. March 1997 – January 29, 1999. Responsibilities: As head of the Planning, Economic Development, Building Inspections and Emergency Management Department, I was responsible for the operation and administration of the department including formulating and managing the budget and supervising four employees. Other responsibilities included subdivision and land use administration, land use planning, strategic planning, economic development, infrastructure development, grant writing and special projects.

MARKETING AND PUBLIC RELATIONS VOLUNTEER
THE NATIONAL CAMPAIGN FOR THE ARTS – London, England. October 1996 – December 1996. Responsibilities: Marketing, promoting and advertising the National Campaign for the Arts and arts programs in the United Kingdom. I also served as a liaison between the organization and its sponsors.

INTERIM MEMBERSHIP DIRECTOR, BOONE AREA CHAMBER OF COMMERCE
Boone, North Carolina. January 1996 – April 1996. Responsibilities: Coordinating the Chamber of Commerce membership recruitment and retention activities. Specifically this included organizing volunteers to solicit businesses and establishing incentives for businesses to join the Chamber of Commerce.

INTERN, SOUTHERN APPALACHIAN FOREST COALITION
Asheville, North Carolina. June 1995 – August 1995. Responsibilities: As a graduate school intern, I was responsible for creating a media directory of scientists, politicians, lobbyists, government officials, environmentalists, and others involved in forest issues for the purpose of providing the press with relevant contacts when covering forest issues. In addition, I designed press releases for print and radio and participated in strategic planning and public outreach programs.

EDUCATION

MASTER OF PUBLIC ADMINISTRATION
Appalachian State University, Boone, North Carolina / Graduated with honors / December 1995

BACHELOR OF ARTS, POLITICAL SCIENCE AND HISTORY
Meredith College, Raleigh, North Carolina / Graduated with honors / May 1993

BOARDS AND PROFESSIONAL AFFILIATIONS

Certifications: Economic Development Course, UNC-Chapel Hill, 1999

Boards: Chair of Global TransPark Development Commission's Marketing Advisory Group; Neuse River Development Authority Board of Directors; North Carolina East Board of Directors, NC Ports Committee Board of Directors, Carteret County Chamber of Commerce Board of Directors, Secretary/Treasurer of Carteret County Transportation Committee

Affiliations: North Carolina Economic Developers Association, American Planning Association

Resume

TIMOTHY W. KANA, PhD, PG
Senior Scientist

Education

PhD, Geology (Coastal Processes), 1979, University of South Carolina (USC)
MS, Geology (Coastal Geology), 1976, USC
BA, Natural Sciences (Geological Oceanography), 1971, The Johns Hopkins University

Experience Highlights

Dr. Kana is an internationally recognized coastal scientist with over 20 years' experience in studies of geomorphology, coastal processes, impacts of sea-level rise, estuarine sedimentation, and beach nourishment design. He has supervised over 100 projects in the coastal zone and has been senior author of over 175 journal articles, proceedings papers, technical and consulting reports, and book chapters. Kana has conducted field reconnaissance surveys at more than 50 sites ranging from the Caribbean to Kuwait, France, West Africa, Alaska, and most of the U.S. East and Gulf Coasts.

Pioneering work by Dr. Kana includes:

- Methodology for establishing objective setback lines for coastal development based on the "profile volume" at a particular site. This methodology was incorporated into law in South Carolina (Beach Management Act of 1988/1990).

- Relocation of Captain Sams Inlet (SC), an innovative plan for beach nourishment which resulted in permanent restoration of a two-mile beach for only $300,000 (1983). [This inlet was successfully relocated again in 1996.]

- Post-*Hugo* beach and dune restoration plan developed less than one month after the storm (1989). Kana represented the State of South Carolina in negotiations with FEMA for this $10 million project which helped restore 65 miles of beaches to pre-*Hugo* conditions.

- Two of the earliest case studies of the potential impacts of sea-level rise on coastal wetlands for the U.S. Environmental Protection Agency, which quantified the controlling physical conditions and processes for tidal wetlands evolution.

Dr. Kana has completed coastal erosion and sedimentation studies at a number of tropical sites, including St. Lucia, Jamaica, St. Croix, Grand Cayman, Bimini, and Andros Island. This work involved sediment sampling, mapping of nearshore reefs, measurement of coastal processes, hurricane hindcasts, turbidity measurements, riverine and estuarine profiling, and delineation of mangrove swamps.

A 1990 project in Jamaica involved a design for reduction of turbidity and renourishment of a resort beach. This project required identification and confirmation of the source of episodic turbidity, location of suitable beach-quality sand deposits, and design of a nourishment plan that was sensitive to adjacent reefs.

Expert Testimony (1982-present)

Qualified and admitted in the following areas:

- Marine geology
- Coastal processes
- Estuarine processes
- Beach erosion

He served as a U.S. representative on a United Nations panel studying shoreline erosion in Togo and Benin, West Africa (1979) and testified as an expert witness on shoreline processes in connection with the *Exxon Valdez* oil spill in Prince William Sound, Alaska (1989-1993).

Teaching

- Designed and taught the Corps of Engineers' graduate course in Coastal Engineering Field Methods.
- Visiting professor at Texas A&M in coastal sediment processes and in field methods.
- Laboratories in soil mechanics and physics.

Experience Highlights

Dr. White is an internationally recognized coastal specialist with more than 20 years of experience in coastal processes. Areas of specialization include sediment transport, methods of monitoring coastal projects, statistical methods for quantifying project behavior,, and all types of instrumentation. Book chapters, proceedings, reports, and invited journal papers document technical expertise in these areas. Dr. White has been principal investigator in major field investigations on all continental U.S. coastlines (Atlantic, Pacific, Gulf, and Great Lakes) and has been the investigator in charge of data collection on international projects at Kuala Baram (Malaysia) and Rio Grande (Argentina).

Pioneering work includes the following.

- *Instrumentation systems:*
  - Sand-tracer dyeing, sampling, and analysis techniques for Sea Grant's Nearshore Sediment Transport Study (California).
  - Laboratory calibration methods, theoretical development, and field deployment of optical backscatter sensors and various acoustic sensors for sediment monitoring (Lake Michigan, Texas, and North Carolina).
  - Electronic data acquisition systems and mechanical sensor deployment/retrieval systems for sensors in both low and high wave environments.
- *Analysis systems:*
  - Methods for translating optical and acoustical measurements into sediment concentrations and fluxes.
  - Objective statistical methods for judging performance of coastal projects, predictive abilities of theories and numerical models, and data quality.
  - Procedures, methods, and techniques for design of monitoring plans for coastal projects of jetty design (Texas and California), beach nourishment (South Carolina), and sand management (California, Michigan, North Carolina, and South Carolina).
- *Predictive methods for coastal behavior:*
  - Internationally acclaimed field test of all available methods for predicting sand transport onto the beach from the seabed.
  - Field tests of methods for predicting total sediment transport along the shore.
  - Development and testing of different methods of predicting transport of finer suspended sediments.

Previous river-related work:

- On the upper Mississippi River, estimates were made of concentrations of sediment due to barge resuspension of various river sediments.
- Developed new instrumentation to determine the flow field and sediment transport in and near the Colorado River (Texas). Current meters, wave gauges, and optical sediment-sensor systems were combined into unique systems and deployed in storm conditions. Recommendations were made for correcting the channel shoaling and alleviating the navigation hazard.
- Analysis of hurricanes, storm waves, wind waves, and tides for elevations of the Stono River (Charleston, SC) bridge replacement. Deployment and data analysis of current meters, wave sensors, and tide gauges for use in scour-protection design.
- Deployment of current meters, wave gauges, and tide gauges to determine flow conditions for design and construction of a port railroad bridge trestle in Tierra del Fuego, Argentina.
- Principal investigator of Cooper River bridge replacement hydraulic analysis. Work on this largest bridge ever built in South Carolina includes deployment and analysis of 12 tide and current gauges plus hydraulic modeling.

CSE

BEACH NOURISHMENT

Coastal Science & Engineering (CSE) has developed plans and supervised construction of the majority of beach nourishment projects in South Carolina during the past 15 years. Among our most innovative projects was the restoration of two miles of beach along Seabrook Island (SC) by inlet relocation, a project that required excavation of a new inlet and closure of an unstable migrating inlet. Upon closure, the shoals of the abandoned tidal delta welded to the shoreline by natural processes, creating a beach over 1,000 feet wide. The project eventually added over 1.5 million cubic yards to Seabrook's beach at a total cost of about $300,000. We have also engineered more traditional nourishment projects involving excavation and placement by hydraulic dredges. Constructed projects through 1999 involved nearly 10 million cubic yards at a cost of ~$28 million.

Project Location	Year Constructed	Cost ($)	Volume Cubic Yards	**
• Myrtle Beach, SC	1985-1987	$4,500,000	850,000 by truck	P/D/CM
• Seabrook Island, SC	1983	$300,000	1,500,000 by inlet relocation	P/D/CM
• Seabrook Island, SC	1983	$250,000	250,000 by scrapers	P/D/CM
• Pawleys Island, SC	1988	$100,000	55,000 by scrapers	P/D
• Isle of Palms, SC	1982-1984	$100,000	150,000 by scrapers	P/D
• Myrtle Beach, SC	1982-1983	$150,000	150,000 by scrapers	P/D
• Kuwait Waterfront Project	1984-1986	$7,000,000 est.	600,000 by truck	P
• Isle of Palms, SC	1984	$1,000,000 est.	350,000 by dredge	P
• Myrtle Beach, SC*	1989-1990	$2,500,000	395,000 by truck	P/D/CM
• North Myrtle Beach, SC*	1989-1990	$1,900,000	377,000 by truck	P/D/CM
• Surfside Beach, SC*	1990	$500,000	70,000 by truck	P
• Garden City, SC*	1990	$1,700,000	165,000 by truck	P
• Pawleys Island, SC*	1990	$600,000	220,000 by scrapers	P
• Debidue Island, SC	1990	$950,000	180,000 by scrapers	P/D/CM
• Seabrook Island, SC	1990	$1,550,000	685,000 by dredge	P/D/CM
• Rose Hall, Jamaiça	1990	$200,000	10,500 by truck	P/D/CM
• Hunting Island, SC	1991	$2,920,000	755,500 by dredge	P/D/CM
• Edisto Beach, SC	1995	$1,600,000	150,000 by dredge	P/D/CM
• Seabrook Island, SC	1996	$600,000	1,250,000 by inlet relocation	P/D/CM
• Debidue Island, SC	1997-1998	$950,000	267,000 by truck	P/D/CM
• Seabrook Island, SC	1998	$85,000	75,000 by scrapers	P/D/CM
• Pawleys Island, SC	1999	$800,000	270,000 by truck	P/D/CM

[*Post-Hurricane *Hugo*; **P = preliminary design/planning, D = final design, CM = construction manager]

CORRESPONDENCE

INDEX

A. Comments Concerning Applicants Responses to Agency Review Comments

1) Memorandum, October 24, 2000, William Wescott, Coastal Coordinator, N.C. Wildlife Resources Commission, Habitat Conservation Program to J. W. Forman, Stroud Engineering
2) Letter, October 6, 2000, Milt Rhodes, SEPA Coordinator, Division of Water Quality to J. W. Forman, Stroud Engineering
3) Memorandum, October 2, 2000, Michael D. Marshall, James Patrick Monaghan, Division of Marine Fisheries to Melba McGee, Environmental Review Coordinator, Department of Environmental and Natural Resources (NCDENR)
4) Memorandum, October 30, 2000, Stephan Hall Division of Parks and Recreation to Melba McGee, Environmental Review Coordinator, NCDENR

B. Responses to Agency Comments by Consultants for the Applicant

1) Letter, September 13, 2000, J. W. Forman, Jr., P.E., Stroud Engineering to James Patrick Monaghan, Division of Marine Fisheries
2) Letter, September 13, 2000, J. W. Forman, Jr., P.E., Stroud Engineering to Franklin T, McBride, North Carolina Wildlife Resources Commission, Division of Inland Fisheries
3) Letter, September 13, 2000, J. W. Forman, Jr., P.E., Stroud Engineering to Milt Rhodes, Division of Water Quality
4) Letter, September 13, 2000, J. W. Forman, Jr., P.E., Stroud Engineering to Stephan Hall, Division of Parks and Recreation
5) Letter, September 13, 2000, J. W. Forman, Jr., P.E., Stroud Engineering to Shannon Stewart, Division of Water Quality, Non-Discharge Branch

C. Comments From Department of Environment and Natural Resources Departmental Review

Re: #1046 Bogue Banks Restoration Plan, Draft EIS, Carteret County

Dear Ms. McGee:

Please find attached letters from the commenting agencies from the initial review of the referenced draft EIS by the Department of Environment and Natural Resources. In all cases the letters indicate that revisions to the DIES and responses provided to each reviewer sufficiently address each reviewers concerns.

Copies of the letters from each reviewer are attached for your information. Also attached are copies of the initial review comments as provided by your office to Doug Huggett and subsequently to this office, and copies of the response letters to each reviewer from this office. All of this correspondence will be attached to the EIS with the index of correspondence.

It is important that review of the EIS proceed on a timely basis. Even though the referendum was voted down by County residents, the Towns of Pine Knoll Shores and Indian Beach are proceeding with preparations to construct a beach nourishment project during the dredging window of years 2001 and 2002. That project will be based on the findings and criteria set out in the referenced EIS.

Doug Huggett has agreed to contact me on the next steps we must take to complete review of the EIS.

If you have any questions concerning the enclosed documents or need additional information, please give me a call.

Sincerely,

STROUD ENGINEERING, P.A.

J. W. Forman, Jr., P.E.
Project Engineer

MEMORANDUM

TO: J.W. Forman
Stroud Engineering

FROM: William Wescott, Coastal Coordinator
Habitat Conservation Program

William Wescott

DATE: October 24, 2000

SUBJECT: Bogue Banks Beach Restoration Plan: Comments regarding consultant responses and the final report of benthic invertebrate and demersal fish resources.

We requested a copy of a USACE study investigating the impacts beach nourishment had on benthic invertebrates. Our Coastal Coordinator in Washington received a copy of the study on October 23, 2000. After reviewing the study and consulting with coastal geologists we are able to respond to your September 13, 2000 letter.

Apparently benthic studies have been diligently undertaken to collect and identify the nearshore and offshore benthic communities that would be impacted by the proposed beach nourishment project. The inclusion of this information in the final EIS will address our concerns regarding non-specific and incomplete data.

We remain concerned for foraging shorebirds during all times of the year (breeding season, migration, wintering). If beach nourishment occurs then nourishment activities should be scheduled to avoid peak biological activity of invertebrates. We still advocate that a better long-term solution for protecting beachfront development is to establish wider setbacks on all structures as they are rebuilt after being lost to the sea.

Thank you for the opportunity to comment on this project. We look forward to reviewing a complete EIS document. If you need to discuss these comments please call William Wescott at (252) 946-6481.

Dear Mr. Forman:

The Division of Water Quality (Division) has reviewed the responses to initial comments raised during agency review of the Bogue Banks Beach Restoration Plan Draft Environmental Impact Statement. The responses included in this letter submitted by Stroud Engineering and the modifications to the DEIS adequately address the Division's concerns regarding the project's impact to the surrounding environment. Please be advised that the project should meet the turbidity standard set forth in the 401 Water Quality Certification to be issued by the Division.

Sincerely,

THROUGH: Michael D. Marshall MDM

FROM: James Patrick Monaghan, Jr. JPMJ.

DATE: October 2, 2000

SUBJECT: 1046 -- Bogue Banks Beach Renourishment

This memo is in response to a letter from J.W. Forman, Jr., P.E., Stroud Engineering, dated September 13, 2000.

We have reviewed the applicant's response to our comments on the EIS. Based upon further review of the EIS and recent literature that has come to our attention we recommend the following:

1. **Continue monitoring the offshore borrow areas and nearshore intertidal deposit areas during the summer of 2001. Also, monitor these areas immediately following renourishment and for a period of time sufficient to determine recovery rates of the fauna.**

2. **A dredging window of November 15 through April 15.**

We appreciate the opportunity to comment on this project.

MEMORANDUM

TO: Melba McGee

FROM: Stephen Hall

SUBJECT: Response to Comments – DEIS – Beach Restoration Plan, Bogue Banks

REFERENCE: 1046

In our review of the DEIS, we had concerns about the potential for impacts to piping plovers (*Charadrius melodus*) and loggerhead sea turtles (*Caretta caretta*), both federally and state listed as Threatened. We also had concerns about the use of dredge spoil material from Brandt Island, the site of a colony of an undescribed and apparently very rare butterfly. The applicant (letter from J.W. Forman to S.P. Hall, 9/13/00) has addressed each of these concerns to our satisfaction.

Re: Draft Environmental Impact Statement
Bogue Banks Beach restoration Plan
Project # 1046

Dear Mr. Monaghan:

The comments of your Division on the referenced EIS were greatly appreciated. Responses to the comments of the Division of Marine Fisheries are provided in this letter and the enclosures.

Enclosed with this letter is the "Final Report of The late fall 1999 assessment of benthic invertebrate and demersal fish resources in the offshore mining sites prior to sand mining." This report will replace the preliminary report included with the Draft EIS reviewed by your staff. Also enclosed are revised sections to the Draft EIS. On the revised pages, the replaced text is crossed out, and the revised text is in italics.

The original schedule for implementation of this project included placement of and on the beach during the coming winter months of years 2000 and 2001. Funding for that County wide project did not materialize as hoped. For that reason the scope of the project has been revised so that the municipalities of Emerald Isle, Pine Knoll Shores, Indian Beach and Salter Path (An unincorporated township of Carteret County) can implement nourishment projects as funding sources are developed. Nourishment projects in each of the communities will be implemented based on the design and constraints outlined in this EIS and any subsequent Major CAMA Permit issued based on this EIS. The Project description, Section 1.4 of the EIS has been revised to reflect this change. A copy of those revisions are included for your review.

Comment: In our review of the scoping document for this project (memorandum dated January 26, 2000) we requested that research be conducted to determine recovery times for benthic populations that are destroyed by pumping and depositing materials. This research has not been fully addressed in the EIS. We realize that sampling needs to continue through early fall for an accurate description of species diversity and species abundance to be completed. We cannot speculate as to what the potential impacts might be from the present EIS. ***We recommend that one complete year of field work be conducted in the offshore borrow areas and the nearshore intertidal deposit areas. Adequate time for data analyses, report preparation, and report review should be allowed and a complete review of these results should be made in the EIS.*** *If possible, data on the benthos should be collected from nearshore and intertidal areas of Fort Macon, Atlantic Beach, and Emerald Isle where pumping has occurred. We* *can provide the research design if requested. We also recommend that the particle size of the existing beach be the size pumped onto the beach since the literature indicates this will lessen recovery times.*

Response: The University of North Carolina, Institute of Marina Sciences, Charles H. (Pete) Peterson have completed the initial phase of the sampling meeting the criteria you have outlined. The results of those studies are provided in the attached report which will replace the preliminary report provided in the draft EIS. Physical and biological impacts and recovery will be monitored systematically following a sampling plan recommended by Dr. Peterson or recognized experts. Your input into that monitoring effort is requested. UNC-IMS has in their possession existing baseline data throughout Bogue Banks. We anticipate using these data when they become available in the published literature to compare construction and post-construction sampling. We requested these data for inclusion in the EIS but were informed that analyses are not available until published. Time is of the essence on this project. The severely eroded condition of the beach means any delay in implementation of a project could lead to higher property damages and losses. Given the existing body of research on impacts to benthic organisms and the natural variability of these systems, we believe that additional pre-nourishment sampling and research will not provide definitive results or allow prediction of impacts more accurate than can be deduced from the experiences in the literature. We believe that the proposed plan will result in reasonably rapid recovery because it will follow the practices discussed below.

There have been numerous studies of recovery of benthic fauna on nourished beaches. Many factors effect the recovery including grain size compatibility of nourishment sand with existing beach sand, seasonal relationship of nourishment to growth period of benthic fauna, depth of sand placed on the beach, levels of turbidity associated with various nourishment sand sources and ability of certain fauna to migrate vertically through the nourished sand. Monitoring of Phase one of the Myrtle Beach Renourishment Project (Jutte, Van Dolah and Levision, March 1999) found that benthic infauna largely recovered after two to three months. The study found that, in some cases, nourishment actually resulted in enhancement of biological assemblages.

The impact of nourishment on beach macro invertebrates has been shown to be highly variable. Virtually all published studies report some initial impact (either confirmed by direct sampling after nourishment, or by inference), However, recovery rates (compared to pre-nourishment densities) have been found the range from days to weeks (e.g. Jutte, et. al. 1999; Gorzelany and Nelson, 1987) to several years (eg. Cutler and Mahadeva, 1982). Studies by Donaghue (1999) at Pea Island (NC) and Peterson et. al.(2000) at Atlantic Beach (NC) quoted by the correspondent generally found longer recovery times the the majority of other researchers, including Van Dolah et/ al (1992) and Baca and Lankford (1987). A fundamental reason for the disparity in results among the various investigators is the extreme natural variability of population densities depending on seasons, variations in sediment compatibility between the natural beach and the nourishment sand, and the frequency of storms. It is generally accepted that the biological populations will recover more slowly if:

Nourished sands do not closely match the native sand grain size distribution,
Nourishment is performed during periods of peak larval recruitment,
The scale of the projects is large relative to the cross-shore dimension, and
Projects are repeated frequently, causing disruption of successive growing cycles.

No study has proven total loss of benthic populations due to nourishment or scraping. The concern is over the rate and scale of recovery compared to natural beaches. The proposed project design seeks to reduce impacts and accelerate recovery in the following ways:

Selection of borrow area the most closely matches the desirable characteristics for the indigenous benthic fauna. Borrow area A has the best overfill ratios but is slightly coarser and has twice the shell content as the native beach. Borrow areas B1 and B2 have lower percentages of shell and slightly finer mean grain size (yielding moderately higher overfill ratios).Some investigators (eg. Peterson, 2000, personal communications) have suggested that borrow areas may be preferable for recruitment and recovery of beach organisms. Others (eg., Stewart, NCDENR-DWQ, comments) suggest borrow area A will yield sediments that produce fewer overall impacts on the nearshore environment. Regardless of which borrow area is selected, the differences compared to the natural beach, are considered relatively small because of the wide range of sediment sizes that occur between the foredune and inshore zone along Bogue Banks.

Nourishment will be performed during periods of low biological recruitment periods (eg., late fall, winter and early spring months).

The scale of the project in the cross-shore dimension is moderate (approximately 50 cy/ft), comparable to nourishment projects that have demonstrated rapid biological recovery such as Myrtle Beach (Baca, et.al, 1987; Jutte et. al, 1999)

- The project will be large enough given the low background erosion rate of the site to avoid frequent repeat nourishment every couple of years so that successive growth cycles are not interrupted as is the case now with frequent beach scraping (bull dozing).

The only means available to verify the impact of the nourishment on the Bogue Banks beach and borrow area fauna is to monitor the impacts through a program that includes characterization of both the physical and biological conditions before, immediately following and for a period sufficient to determine full recovery of the biological resources in the borrow area and on the beaches and to determine the physical performance of the nourishment project.

The Bogue Banks nourishment project will include a program of monitoring of impacts. Specific objectives of the monitoring will be as follows:

1. Document and quantify physical changes in the beach and nearshore zone,
2. Determine the ecological impacts and recovery rates of beach and nearshore biological resources following nourishment, and
3. Document the physical and biological impact and recovery of sand bottom habitats in the borrow area.

Comment: Another primary concern on this project is the time window for dredging. We strongly recommend that the time be shortened from October1 through May 15 to December 1 through March 31. This should reduce effects on recruitment of finfish and minimize effects on traditional beach fisheries.

It appears that, due to funding constraints, the project will have to be constructed in segments as funding becomes available in each of the individual municipalities on Bogue Banks. Construction windows may, therefore, be shortened. However, because of economic considerations and weather contingencies, the applicant wishes to have available the longest possible window for construction. By current state and federal policies, that window runs from November 1 (end of turtle nesting season) to May 15 (beginning of turtle nesting season) in North Carolina.

We believe that the responses provided herein should provide you and your staff with a better understanding of the Bogue Banks Project and the measures to be implemented as part of the project to minimize and to measure the physical and biological impacts of the project.

We would appreciate a timely review of the enclosed information and a response as to the adequacy of the EIS with the revisions indicated. That response should be made to this office to my attention.

If you have questions on any aspect of the project, please feel free to call me.

Sincerely,

STROUD ENGINEERING, P.A.

Re: Draft Environmental Impact Statement
Bogue Banks Beach restoration Plan
Project # 1046

Dear Mr. McBride:

The comments of your Division on the referenced EIS were greatly appreciated. Responses to the comments of the staff biologists with the Wildlife resources Commission are provided in this letter and the enclosures.

Enclosed with this letter is the "Final Report of The late fall 1999 assessment of benthic invertebrate and demersal fish resources in the offshore mining sites prior to sand mining." This report will replace the preliminary report included with the Draft EIS reviewed by your staff.

The original schedule for implementation of this project included placement of and on the beach during the coming winter months of years 2000 and 2001. Funding for that County wide project did not materialize as hoped. For that reason the scope of the project has been revised so that the municipalities of Emerald Isle, Pine Knoll Shores, Indian Beach and Salter Path (An unincorporated township of Carteret County) can implement nourishment projects as funding sources are developed. Nourishment projects in each of the communities will be implemented based on the design and constraints outlined in this EIS and any subsequent Major CAMA Permit issued based on this EIS. The Project description, Section 1.4 of the EIS has been revised to reflect this change. A copy of those revisions are included for your review.

Comment: The DEIS indicates that erosion is responsible for loss of beach, dune and maritime forest habitats and a wide range of wildlife resources. If this document seeks to identify ceuses of lost wildlife resources and habitat then losses attributed to human disturbance, landscape alteretions and development should also be included as contributing factors especially since this document indicates that Bogue Banks oceanfront has reached 90 percent build-out.

Response: It is not within the scope of the draft EIS to identify causes of lost wildlife resources except for such impacts that might occúr as a result of placement of sand on the beach from the designated borrow areas. Significant habitat losses can be attributed solely to erosion of the beach and the subsequent bulldozing of the beach undertaken to protect property from the ocean. With a stable berm fronting the dune as exist along the nourished beach areas of the Town of Atlantic Beach, the need for annual bulldozing of the beachfront would be eliminated allowing vegetation and the macro invertebrates to recolonize the beach, including the berm and dune face, and reestablish habitat that would otherwise be lost indefinitely.

This is illustrated by a survey of Sea Beach Amaranth conducted during August 2000 of the beaches of Bogue Banks from Bogue Inlet to Beaufort inlet. Twenty-three (23) plant individuals were identified along the entire island by the survey. Of those, 20 were located along the beach in portions of the Town of Atlantic Beach that have been nourished in the last ten years. The individual plants were found on the foredune at and above the dune toe. The stable beach that remains as a result of the nourishment projects in Atlantic Beach has created habitat for this endangered plant to flourish. On the remaining beach including Pine Knoll Shores, Salter Path, Indian Beach and Emerald Isle, only three individuals plants were identified. These were located 4 to 5 feet above the dune toe in Salter Path in an area were extensive beach scraping has occurred. It that area the dune is subject to loss because there is no significant berm width fronting the dune. The vegetation, dunes and dry beach areas that make up wildlife habitat on natural beaches require a long term stable beach for protection from the ocean. The nourishment project will provide that stability along the other beaches of Bogue Banks west of Atlantic Beach.

Of the approximately 335 miles of North Carolina's barrier islands from the Virginia border to Little River Inlet, only 143 miles or 43 percent is either developed or subject to development. The remaining 190 miles or 57 percent remains undeveloped and, for the most part, will remain so in perpetuity. A significant portion of the undeveloped barrier islands are accessible only by boat.

In Carteret County the numbers are even more dramatic. The County's barrier islands stretch from Ocracoke Inlet to Bogue Inlet, approximately 81 miles (measured on a County map). The undeveloped portions, from Beaufort Inlet to Ocrackoe inlet, make up 57 miles or approximately 70 percent of the total barrier island length. The developed portion of the County, Bogue Banks (excluding Fort Macon State Park), makes up 24 miles or approximately 30 percent of the County's total barrier island length. The Bogue Banks Project will not alter that distribution. Along the beach of Bogue Banks, the nourishment project will add the following:

Approximately 100 acres of dry beach (i.e., 16.8 miles, 50 feet wide)
Approximately 30 acres of stable dunes that evolve naturally by aeolian processes versus the unnatural bull dozing of coarse grained sand dunes that has occurred each year since 1995.

Comment: The reviewer referred to studies by C. R. Donahue and Peterson et. al. Indicating that beach nourishment causes a severe depletion of in numbers of macro invertebrates (shorebird food). Population recovery rates of macro invertebrates are dependent on recruitment from pelagic larval stocks and recruit from neighboring beaches.

Response: While these studies are important, the nourishment experience in the cases covered in those case studies differs greatly from that which is proposed at Bogue Banks.

Scale: The Pea Island nourishment site is only one mile long but received a total of approximately 500 c.y. / ft over seven years (versus (50 c.y. / ft. for the proposed project).
Frequency of Nourishment: The Pea Island site was nourished eight times between 1991 and 1997.
Sediment Grain size Compatibility: The Pea Island site received sand much finer than the natural beach (m_z=3.67 phi versus native beach 2.33 phi, Peterson, et. al, 2000).
Timing: Both studies involved beach fill placement during the active biological recruitment times in late spring. We anticipate beach fill operations for the Bogue Banks project to be during the optimal environmental windows as directed by the regulatory agencies via permit conditions.

Comment: We are very concerned for foraging shorebirds during all times of the year (breeding season, migration, wintering). North Carolina's coast is nesting habitat for species such as the willet, American oystercatcher, Wilson's plover, and piping plover and we often think of habitat for these as the most important to protect. However, our coast is also serves as very important wintering and migration habitat for many species of shorebirds. Therefore, we are not only concerned about beach renourishment during the breeding season, but throughout the entire year, especially when considering the cumulative impacts of large-scale renourishment projects. <u>We do not believe that the direct and cumulative impacts to intertidal macro invertebrates and shorebirds have been adequately addressed in the DEIS.</u>

Response: The assessment of the benthic invertebrate resources at Bogue Banks conducted by Peterson and Wells has been revised to include (enclosed for your review and inserted into the revised EIS as Appendix C) states that certain macro invertebrates and fish species are present along inshore and offshore areas at Bogue Banks. Therefore, dredging sand from offshore borrow areas and nourishing the shoreline may bury intertidal macrofauna and reduce the available food resource to birds that feed on these organisms. However, direct impacts to macro invertebrates associated with this project will be reduced for several reasons. Dredging and filling activities will occur largely during winter months, avoiding the larval recruitment period of many of these species, including mole crabs (early October) and coquina clams (spring and summer) (Donaghue, 1999). Additionally, studies have shown that intertidal macrofauna can recolonize a nourished area within one or two seasons (Ross and Lancaster, 1996; National Research Council, 1995; Reilly and Bellis, 1978), therefore, impacts will be temporary. Lastly, sand of similar grain size to the existing beach will be used to reduce changes in physical characteristics of the beach that may affect nourishment impacts on invertebrates (Donaghue, 1999; Peterson et al, 1999; Hackney et al, 1996).

Indirect impacts imposed on shorebirds that feed on macro invertebrates will be minimized as well. After impacts to macrofauna have occurred and numbers of these species are depressed, birds that prey upon these invertebrates, including the threatened piping plover, would likely move to adjacent undisturbed beach areas and other suitable feeding areas for the temporary period of population re-establishment. Because macro invertebrates recolonize rapidly, no long term impacts to these organisms or the shorebirds that prey upon them are anticipated with this project.

Comment: The large scale beach nourishment project will bury whole populations of intertidal macro invertebrates may preclude rapid recovery of those populations and does not allow for shorebirds to shift their foraging to nearby sites.

Response: There have been numerous studies of recovery of benthic fauna on nourished beaches. Many factors effect the recovery including grain size compatibility of nourishment sand with existing beach sand, seasonal relationship of nourishment to growth period of benthic fauna, depth of sand placed on the beach, levels of turbidity associated with various nourishment sand sources and ability of certain fauna to migrate vertically through the nourished sand. Monitoring of phase one of the Myrtle Beach Renourishment Project (Jutte, Van Dolah and Levision, March 1999) found that benthic infauna largely recovered after two to three months. The study found that, in some cases, nourishment actually resulted in enhancement of biological assemblages.

The impact of nourishment on beach macro invertebrates has been shown to be highly variable. Virtually all published studies report some initial impact (either confirmed by direct sampling after nourishment, or by inference), However, recovery rates (compared to pre-nourishment densities) have been found the range from days to weeks (e.g. Jutte, et. al. 1999; Gorzelany and Nelson, 1987) to several years (eg. Cutler and Mahadeva, 1982). Studies by Donahue (1999) at Pea Island (NC) and Peterson et. al.(2000) at Atlantic Beach (NC) quoted by the correspondent generally found longer recovery times the the majority of other researchers, including Van Dolah et/ al (1992) and Baca and Lankford (1987). A fundamental reason for the disparity in results among the various investigators is the extreme natural variability of population densities depending on seasons, variations in sediment compatibility between the natural beach and the nourishment sand, and the frequency of storms. It is generally accepted that the biological populations will recover more slowly if:

Nourished sands do not closely match the native sand grain size distribution,
Nourishment is performed during periods of peak larval recruitment,
The scale of the projects is large relative to the cross-shore dimension, and
Project are repeated frequently, causing disruption of successive growing cycles.

No study has proven total loss of benthic populations due to nourishment or scraping. The concern is over the rate and scale of recovery compared to natural beaches. The proposed project design seeks to reduce impacts and accelerate recovery in the following ways:

Selection of borrow area the most closely matches the desirable characteristics for the indigenous benthic fauna. Borrow area A has the best overfill ratios but is slightly coarser and has twice the shell content as the native beach. Borrow areas B1 and B2 have lower percentages of shell and slightly finer mean grain size (yielding moderately higher overfill ratios).Some investigators (eg. Peterson, 2000, personal communications) have suggested that borrow areas may be preferable for recruitment and recovery of beach organisms. Others (eg., Stewart, NCDENR-DWQ, comments) suggest borrow area A will yield sediments that produce fewer overall impacts on the nearshore environment. Regardless of which borrow area is selected, the differences compared to the natural beach, are considered relatively small because of the wide range of sediment sizes that occur between the foredune and inshore zone along

Bogue Banks.

Nourishment will be performed during periods of low biological recruitment periods (eg., winter and early spring months).

The scale of the project in the cross-shore dimension is moderate (approximately 50 c.y./ ft), comparable to nourishment projects that have demonstrated rapid biological recovery such as Myrtle Beach (Baca, et.al, 1987; Jutte et. al, 1999)

The project will be large enough given the low background erosion rate of the site to avoid frequent repeat nourishment every couple of years so that successive growth cycles are not interrupted as is the case now with frequent beach scraping (bull dozing).

The only means available to verify the impact of the nourishment on the Bogue Banks beach and borrow area fauna is to monitor the impacts through a program that includes characterization of both the physical and biological conditions before, immediately following and for a period sufficient to determine full recovery of the biological resources in the borrow area and on the beaches and to determine the physical performance of the nourishment project.

The Bogue Banks nourishment project will include a program of monitoring of impacts. Specific objectives of the monitoring will be as follows:

1. Document and quantify physical changes in the beach and nearshore zone,
2. determine the ecological impacts and recovery rates of beach and nearshore biological resources following nourishment, and
3. document the physical and biological impact and recovery of sand bottom habitats in the borrow area.

Comment: With a total project length (16.8) miles, this is one the longest beach nourishment projects in the last 20 years. The DEIS presents beach nourishment as a "sacrificial shore-protection technique". There are many examples of how beach nourishment provides at best only minimal protection from the encroaching sea and there are examples of the sand from beach nourishment being washed away within weeks of deposition. We question if this is a wise expenditure of public monies considering the cost of the renourishment, potentially short duration of the benefits and the adverse impacts to the fish and wildlife resources dependent on the project area.

Response: Beach nourishment is not a panacea for shore protection and beach management. Each location must be evaluated on its own merits as a candidate site for a successful nourishment project. For beaches with very high background erosion rates of 10 to 50 feet per year, the economics of beach nourishment will be very different from Bogue banks, which has background erosion rates of 1 to 3 feet per year (N.C. Division of Coastal Management, Long Term Average Annual Shoreline Change Rates, Updated through 1992). Carteret County is fortunate to have a beach nourishment project at Atlantic Beach that demonstrates convincingly the Bogue Banks is an excellent location for beach nourishment. The respondents are advised to drive the beach of Bogue Banks from west to east. From the healthy beaches at the west end of Emerald Isle to Atlantic Beach, the berm is narrow (in many places only a low tide beach exist), there is evidence if extensive structural damage to buildings and access decks and walkways, extensive loss of natural dune and adjoining maritime forest and underbrush where present, and evidence that at least 80 percent of the beach has been scraped to provide dune protection since the fall of 1999. The physical change in the beach shape upon entering the town limits of Atlantic Beach is dramatic. There is a wide berm, stable dunes with vegetation and little or no evidence of structural damage to ocean front buildings and decks. The performance of the nourished beach at Atlantic Beach provides physical evidence of a wider dry beach and reduced storm damage throughout the 1990's compared to exposed (non-nourished) beaches in the project area. The reviewer is referred to section 2.2.2 , Physical Impacts, of the draft EIS for a review of the physical factors that make Bogue Banks and excellent site for successful beach nourishment.

We are not aware of any beach nourishment projects constructed in North Carolina where the beaches have washed away in weeks following placement. If such projects do exist, please identify the projects so that the details of the projects can be investigated to determine the reasons for failure.

We believe that the responses provided herein provide you and your staff with a better understanding of the Bogue Banks Project and the measures to be implemented as part of the project to minimize and to measure the physical and biological impacts of the project.

We would appreciate a timely review of the inclosed information and a response as to the adequacy of the EIS with the revision indicated. That response should be made to this office to my attention.

If you have questions on any aspect of the project, please feel free to call me.

Sincerely,

STROUD ENGINEERING, P.A.

Re: Draft Environmental Impact Statement
Bogue Banks Beach restoration Plan
Project # 1046

Dear Mr. Rhodes:

The comments of your Division on the referenced EIS were greatly appreciated. Responses to the comments of the staff of the wetlands unit and the planning branch of the Division are provided in this letter and the enclosures.

Enclosed with this letter is the "Final Report of The late fall 1999 assessment of benthic invertebrate and demersal fish resources in the offshore mining sites prior to sand mining." This report will replace the preliminary report included with the Draft EIS reviewed by your staff. Also enclosed are revised sections of the Draft EIS. On the revised pages, the replaced text is crossed out, and the revised text is in italics.

The original schedule for implementation of this project included placement of and on the beach during the coming winter months of years 2000 and 2001. Funding for that County wide project did not materialize as hoped. For that reason the scope of the project has been revised so that the municipalities of Emerald Isle, Pine Knoll Shores, Indian Beach and Salter Path (an unincorporated township of Carteret County) can implement nourishment projects as funding sources are developed. Nourishment projects in each of the communities will be implemented based on the design and constraints outlined in this EIS and any subsequent Major CAMA Permit issued based on this EIS. The Project description, Section 1.4 of the EIS has been revised to reflect this change. A copy of those revisions are included for your review.

Comment: Please supply the Division with a notification of the borrow area selection once it has been made.

Response Three borrow areas have been selected for use in the project, areas, A, B1 and B2. These areas are proposed because they contain the beach-compatable sediments. Use of borrow area A will result in the lowest overfill ratios on the beach, the most durable fill, and will be the most cost effective to excavate using a hopper dredge, a technique preferred over others by some regulatory agencies. Borrow areas B1 and B2 contain somewhat finer material and will result in slightly higher overfill ratios. The higher overfill ratios will result in placement of more cubic yards of material to achieve the same adjusted beach profile and project durability. The additional costs associated with the additional sand volumes may be offset by the economies available due to the proximity of borrow areas B1 and B2 to the beaches.

Comment: The project must meet the turbidity standards set forth in the 401 Water Quality Certification for this project:

Response: Turbidity resulting from the disposal activities on the beach is addressed in section 5.9 of the Draft EIS. Results from two studies of turbidity associated with beach nourishment operations showed that, in both studies, turbidity did not exceed 25 ntu's outside the discharge area. Due to the low mud content of the borrow area sediments identified in borrow areas A, B1 and B2 (Appendix E, Table E6 of the Draft EIS), generally less than 4 percent, we believe that the project will be able to meet the requirements of the 401 Water Quality Certification.

Comment: It is desired that work be conducted between the months of November and April to limit the degree and severity of impact to environmental resources.

Response: It appears that, due to funding constraints, the project will have to be constructed in segments as funding becomes available in each of the individual municipalities on Bogue Banks. Construction windows may, therefore, be shortened. However, because of economic considerations and weather contingencies, the applicant wishes to have available the longest possible window for construction. By current state and federal policies, that window runs from November 1 (end of turtle nesting season) to May 15 (beginning of turtle nesting season) in North Carolina.

We believe that the responses provided herein should provide you and your staff with a better understanding of the Bogue Banks Project and the measures to be implemented as part of the project to minimize and to measure the physical and biological impacts of the project.

We would appreciate a timely review of the enclosed information and a response as to the adequacy of the EIS with the revisions indicated. That response should be made to this office to my attention.

If you have questions on any aspect of the project, please feel free to call me.

Sincerely,

STROUD ENGINEERING, P.A.

Re: Draft Environmental Impact Statement
Bogue Banks Beach restoration Plan
Project # 1046

Dear Mr. Hall:

The comments of your Division on the referenced EIS were greatly appreciated. Responses to the comments of the Division of Parks and Recreation are provided in this letter and the enclosures.

Enclosed with this letter is the "Final Report of The late fall 1999 assessment of benthic invertebrate and demersal fish resources in the offshore mining sites prior to sand mining." This report will replace the preliminary report included with the Draft EIS reviewed by your staff. Also enclosed are revised sections to the Draft EIS. On the revised pages, the replaced text is crossed out, and the revised text is in italics.

The original schedule for implementation of this project included placement of and on the beach during the coming winter months of years 2000 and 2001. Funding for that County wide project did not materialize as hoped. For that reason the scope of the project has been revised so that the municipalities of Emerald Isle, Pine Knoll Shores, Indian Beach and Salter Path (An unincorporated township of Carteret County) can implement nourishment projects as funding sources are developed. Nourishment projects in each of the communities will be implemented based on the design and constraints outlined in this EIS and any subsequent Major CAMA Permit issued based on this EIS. The Project description, Section 1.4 of the EIS has been revised to reflect this change. A copy of those revisions are included for your review.

Comment: One of the potential borrow areas is located within Bogue Inlet. As stated on p. 5-8, if this area is chosen as a source for dredge material, habitat for the piping plover (Charadrius melodus), federally and state listed as threatened, may be lost. We strongly recommend that this area, along with other areas located within the inlets or on the accreting ends of the banks, be excluded as potential borrow sites.

Response: The applicant agrees to delete the shoals in and around Bogue inlet as a potential source of borrow material for the beach nourishment project.

Comment: Possible impacts to the loggerhead sea turtle (Caretta caretta), federally and state listed as Threatened, are also identified (p. 5-8). Impacts may result from the use of inappropriate dredge materials, changes in beach profiles, or from disposal activities taking place within the nesting or hatching periods. The use of nest relocations is proposed to mitigate for some of these impacts, but we regard this *as the least desirable form of mitigation. Instead, we recommend that the standard measures supported by the US Fish and Wildlife Service and the US Army Corps of Engineers be followed regarding the (1) the types of sediments that are acceptable for disposal; (2) the beach profile created by renourishment. Beach nourishment should take place strictly in the off-season for sea turtle nesting– November through April– not as currently requested (p. 4-10) for the months of October and May.*

Response: To minimize impacts to nesting sea turtles in the project area, standard protocol adopted by the U. S. Fish and Wildlife Service and used in previous beach nourishment projects in North Carolina will be followed. This protocol includes the following guidelines:

1. Only beach quality sand suitable for sea turtle nesting, successful incubation, and hatchling emergence shall be used for beach nourishment on the project site. Furthermore, sand of similar grain size to the existing beach will be used to reduce any changes in physical characteristics of the beach that may affect nest survival.

2. Immediately after completion of the beach nourishment project and prior to the next three nesting seasons, beach compaction shall be monitored and tilling shall be conducted as required to reduce the likelihood of impacting sea turtle nesting and hatching activities.

3. Immediately after completion of this project and prior to the next three nesting seasons, monitoring shall be conducted to determine if escarpments are present and escarpments shall be leveled as required to reduce the likelihood of impacting sea turtle nesting and hatching activities.

4. Carteret County will ensure that contractors doing the beach nourishment and dredging work fully understand sea turtle protection measures.

5. Beach nourishment and dredging activities are planned to begin after November 1 and be completed before May 1. If any filling occurs after May 1, the pipeline will be placed along the landward edge of the berm.

6. If any beach nourishment or dredging activities take place during the period from May 1 through November 15, a standardized nest monitoring and relocation plan will be implemented in addition to the monitoring that already occurs. The plan incorporates monitoring of the beach disposal area each morning from the beginning of the nesting season until all equipment is removed from the beach and the relocation of any nests laid within the project area. Using standard nest relocation techniques, all nests will be located to a suitable nursery beach, agreed to prior to the start of relocation effort by the U.S. Fish and Wildlife Service and the North Carolina Wildlife Resources Commission. Hatching success of relocated nests will be monitored and reported.

7. Immediately after completion of this project and prior to May 1 for three subsequent years, sand compaction will be monitored in the area of restoration in accordance with a protocol agreed to by the Service, the State regulatory agency, and Carteret County. At a minimum, the protocol provided under 7a and 7b below will be followed. If required, the area will be tilled to a depth of 36 inches. All tilling activity must be completed prior to May 1. A report on the results of compaction monitoring will be submitted to the Service prior to any tilling actions being taken. An annual summary of compaction surveys and the actions taken will be submitted to the Service. This condition will be evaluated annually and may be modified if necessary to address sand

compaction problems identified during the previous year.

7a. Compaction sampling stations shall be located at 500-foot intervals along the project area. One station will be at the seaward edge of the dune/berm line (when material is placed in this area); one station will be midway between the dune line and the high water line; and one station will be located just landward of the high water line. At each station, the cone penetrometer shall be pushed to a depth of 6, 12, and 18 inches three times (three replicates). Material may be removed from the hole if necessary to ensure accurate readings of successive levels of sediment. Replicates will be located as close to each other as possible, without interacting with the previous hole and/or disturbed sediments. The three replicate compaction values for each depth will be averaged to produce final values for each depth at each station. Reports will include all 27 values for each transect line, and the final 9 averaged compaction values.

7b. If the average value for any depth exceeds 500 psi for any two or more adjacent stations, then that area will be tilled prior to May 1 of the following year. If values exceeding 500 psi are distributed throughout the project area but in no case do those values exist at two adjacent stations at the same depth, then consultation with the Fish and Wildlife Service will be sought to determine if tilling is required. If a few values exceeding 500 psi are present randomly within the project area, tilling will not occur.

8. Visual surveys for escarpments along the project area shall be made immediately after completion of the beach nourishment project and prior to May 1 for three subsequent years. Results of the surveys will be submitted to the Service prior to any action being taken. Escarpments that interfere with sea turtle nesting or that exceed 18 inches in height for a distance of 100 feet will be leveled to the natural beach contour by May 1. The Service will be contacted immediately if subsequent reformation of escarpments that interfere with sea turtle nesting or that exceed 18 inches in height for a distance of 100 feet occurs during the nesting and hatching season to determine the appropriate action to be taken. If it is determined that escarpment leveling is required during the nesting or hatching season, the Service will provide a brief written authorization that describes methods to be used to reduce the likelihood of impacting existing nests. An annual summary of escarpment surveys and actions taken will be submitted to the Service.

9. From March 1 through April 30 and November 1 through November 15, staging areas for construction equipment will be located off the beach to the maximum extent practicable. Nighttime storage of construction equipment not in use will be off the beach to minimize disturbance to sea turtle nesting and hatching activities. In addition, all construction pipes that are placed on the beach will be located as far landward as possible without compromising the integrity of the dune system. Temporary storage of pipes on the beach will be in such a manner so as to impact the least amount of nesting habitat and shall likewise not compromise the integrity of the dune systems.

These guidelines have been incorporated into the revised EIS in section 3.15. By planning to perform the majority of the project during off-season months, monitoring beach hardness, and relocating nests found in unsuitable habitat if project completion delays occur, impacts to nesting loggerhead sea turtles will be minimized.

Comment Use of dredge spoils deposited at Brandt Island (p. 4-6) may potentially affect an undescribed butterfly that is currently known to exist only at Fort Macon State Park, Brandt Island, Radio Island, and

Bear Island. Use of dredge materials stored in the large pit on Brandt Island would probably cause little impact, but we would be very concerned if any dredge materials are taken from areas of the island that have been stabilized by development of a grass cover.

Response: The applicant agrees to eliminate the dredge spoil islands at Brandt Island as a source of borrow material for the beach nourishment project..

We believe that the responses provided herein should provide you and your staff with a better understanding of the Bogue Banks Project and the measures to be implemented as part of the project to minimize and to measure the physical and biological impacts of the project.

We would appreciate a timely review of the enclosed information and a response as to the adequacy of the EIS with the revisions indicated. That response should be made to this office to my attention.

If you have questions on any aspect of the project, please feel free to call me.

Sincerely,

STROUD ENGINEERING, P.A.

Re: Draft Environmental Impact Statement
Bogue Banks Beach restoration Plan
Project # 1046

Dear Ms Stewart:

The comments of your Division on the referenced EIS were greatly appreciated. Responses to the comments of the staff of the Non-discharge Branch of the Division are provided in this letter and the enclosures.

Enclosed with this letter is the "Final Report of The late fall 1999 assessment of benthic invertebrate and demersal fish resources in the offshore mining sites prior to sand mining." This report will replace the preliminary report included with the Draft EIS reviewed by your staff. Also enclosed are revised sections of the Draft EIS. On the revised pages, the replaced text is crossed out, and the revised text is in italics.

The original schedule for implementation of this project included placement of and on the beach during the coming winter months of years 2000 and 2001. Funding for that County wide project did not materialize as hoped. For that reason the scope of the project has been revised so that the municipalities of Emerald Isle, Pine Knoll Shores, Indian Beach and Salter Path (an unincorporated township of Carteret County) can implement nourishment projects as funding sources are developed. Nourishment projects in each of the communities will be implemented based on the design and constraints outlined in this EIS and any subsequent Major CAMA Permit issued based on this EIS. The Project description, Section 1.4 of the EIS has been revised to reflect this change. A copy of those revisions are included for your review.

Comments: Related to comment concerning impacts associated with selection of borrow areas.

Response: It appears that, due to funding constraints, the project will have to be constructed in segments as funding becomes available in each of the individual municipalities on Bogue Banks. Construction windows may, therefore, be shortened. However, because of economic considerations and weather contingencies, the applicant wishes to have available the longest possible window for construction. By current state and federal policies, that window runs from November 1 (end of turtle nesting season) to May 15 (beginning of turtle nesting season) in North Carolina.

Comment: Comment related to meeting the turbidity standards in the 401 Water Quality Certification for this project.

Response: Turbidity resulting from the disposal activities on the beach is addressed in section 5.9 of the Draft EIS. Results from two studies of turbidity associated with beach nourishment operations showed that, in both studies, turbidity did not exceed 25 ntu's outside the discharge area. Due to the low mud content of the borrow area sediments identified in borrow areas A, B1 and B2 (Appendix E, Table E6 of the Draft EIS), generally less than 4 percent, we believe that the project will be able to meet the requirements of the 401 Water Quality Certification.

Comment: Related to construction schedule:

Response: It appears that, due to funding constraints, the project will have to be constructed in segments as funding becomes available in each of the individual municipalities on Bogue Banks. Construction windows may, therefore, be shortened. However, because of economic considerations and weather contingencies, the applicant wishes to have available the longest possible window for construction. By current state and federal policies, that window runs from November 1 (end of turtle nesting season) to May 15 (beginning of turtle nesting season) in North Carolina.

We believe that the responses provided herein should provide you and your staff with a better understanding of the Bogue Banks Project and the measures to be implemented as part of the project to minimize and to measure the physical and biological impacts of the project.

We would appreciate a timely review of the enclosed information and a response as to the adequacy of the EIS with the revisions indicated. That response should be made to this office to my attention.

If you have questions on any aspect of the project, please feel free to call me.

Sincerely,

Dear Sirs:

Enclosed please find a response from the Departments SEPA coordinator concerning the Bogue Banks beach renourishment Draft Environmental Impact Statement. The SEPA coordinator has indicated that several comments have been received requesting additional information or clarification, and that these issues must be addressed through a revision of the Environmental Document. Therefore, it is requested that you enter into negotiations with the various commenting agencies in an effort to resolve or address these issues. After such negotiations, a revised EIS document should be prepared which addresses the review agency concerns, and twelve (12) copies of the revised document should be submitted to this office, at which time I will transmit the documents to the SEPA coordinator for additional review.

Please feel free to contact me at (919) 733-2293 if you would like to discuss this matter further.

Sincerely,

Doug Huggett

FROM: Melba McGee
Environmental Review Coordinator

RE: #1046 Bogue Banks Restoration Plan, DEIS, Carteret County

DATE: May 5, 2000

The proposed project has been circulated and reviewed by our internal divisions.

Our review efforts raised a number of issues that will need to be addressed before this project is released for state review. After revisions have been made, I recommend the revised document be reviewed again internally prior to State Clearinghouse review.

Thank you for the opportunity to respond.

North Carolina Wildlife Resources Commission

Charles R. Fullwood, Executive Director

MEMORANDUM

TO: Melba McGee
Office of Legislative & Intergovernmental Affairs

FROM: Franklin T. McBride, Manager
Habitat Conservation Program

DATE: April 27, 2000

SUBJECT: Comments for Bogue Banks Beach Restoration Plan, Draft Environmental Impact Study (DEIS), Carteret County. Project # 1046.

Staff biologists with the Wildlife Resources Commission have reviewed the DEIS. Our comments are provided in accordance with provisions of the Fish and Wildlife Coordination Act (48 Stat. 401, as amended; 16 U.S.C. 661 et. seq.), the Clean Water Act of 1977 (as amended) and the North Carolina Environmental Policy Act (G.S. 113A-1 et seq., as amended; 1 NCAC-25).

Carteret County is proposing to renourish 16.8 miles of oceanfront beaches in the towns of Pine Knoll Shores, Salter Path, Indian Beach and Emerald Isle. The identified sources of sand for this proposal are located offshore from the project site.

The DEIS indicates that erosion is to blame for loss of beach, dune and maritime forest habitats and a wide range of wildlife resources. If this document seeks to identify causes of lost wildlife resources and habitat then losses attributed to human disturbance, landscape alterations and development should also be included as contributing factors especially since this document indicates that Bogue Banks oceanfront has reached 90% build-out.

Recent studies by C. R. Donoghue "*The Influences of Swash Processes on Donax variablis and Emerita talpoida*" and C. H. Peterson, D. H. M. Hickson, and G. G. Johnson "*Short-term Consequences of Nourishment and Bulldozing on the Dominant Large Invertebrates of the Sandy Beach*" indicate that beach renourishment causes a severe depletion in numbers of macro invertebrates (shorebird food). Population recovery rates of macro invertebrates are dependent on recruitment from pelagic larval stocks and recruitment from neighboring beaches.

FROM: Milt Rhodes
Division of Water Quality

SUBJECT: Bogue Banks Beach Restoration Plan Environmental Impact Statement Document and FONSI, DENR# 1046, DWQ# 12652

The Division of Water Quality (Division) has reviewed the Draft Environmental Impact Statement document regarding the Restoration of Bogue Banks Beach and offers the following comments.

This document was reviewed by staff in the wetlands unit and planning branch of the Division for consistency with the State Environmental Protection Act. The full comments are attached to this letter, but in summary, these issues should be addressed in the final document.

1. Please supply the Division with a notification of the borrow area selection once it has been made.

2. The project must meet the turbidity standards set forth in the 401 Water Quality Certification for this project during construction.

3. It is desired that work be conducted between the months of November and April to limit the degree and severity of impact to environmental resources.

Thank you for the opportunity to comment. If you have questions regarding these comments, please contact Milt Rhodes at (919) 733-5083 x 366.

MEMORANDUM

TO: Melba McGee

FROM: Stephen Hall SH

SUBJECT: DEIS – Beach Restoration Plan, Bogue Banks

REFERENCE: 1046

The assessment is well-written and appears to be quite thorough. It identifies several potential impacts, however, that are of concern to the Division:

- One of the proposed borrow areas is located within Bogue Inlet. As stated on p. 5-8, if this area is chosen as a source for dredge material, habitat for the piping plover (*Charadrius melodus*), federally and state listed as Threatened, may be lost. We strongly recommend that this area, along with any other areas located within the inlets or on the accreting ends of the banks, be excluded as potential borrow sites.
- Possible impacts to the loggerhead sea turtle (*Caretta caretta*), federally and state listed as Threatened, are also identified (p. 5-8). Impacts may result from the use of inappropriate dredge materials, changes in beach profiles, or from disposal activities taking place within the nesting or hatching periods. The use of nest relocations is proposed to mitigate for some of these impacts, but we regard this as the least desirable form of mitigation. Instead, we recommend that the standard measures supported by the US Fish and Wildlife Service and the US Army Corps of Engineers be followed regarding the (1) the types of sediments that are acceptable for disposal; (2) the beach profile created by renourishment. Beach renourishment should take place strictly in the off-season for sea turtle nesting -- November through April -- not as currently requested (p. 4-10) for the months of October and May.
- Use of the dredge spoils deposited at Brandt Island (p. 4-6) may potentially affect an undescribed butterfly that is currently known to exist only at Fort Macon State Park, Brandt Island, Radio Island, and Bear Island. Use of dredge materials stored in the large pit on Brandt Island would probably cause little impact, but we would be very concerned if any dredge materials are taken from areas of the island that have been stabilized by development of a grass cover.

MEMORANDUM

TO: Milt Rhodes
THROUGH: John Dorney, DWQ
FROM: Shannon Stewart, DWQ
DATE: April 10, 2000
SUBJECT: Bogue Banks Beach Restoration Plan, Carteret County

Based on a review of the subject EIS, the Division of Water Quality has the following comments:

1. The EIS considers four possible borrow areas for the Bogue Banks Beach Restoration project. In section 3.16.1 of the EIS, it states that borrow area A provides the most promising deposits in terms of beach compatibility and potential yield of beach-quality sediments. Borrow Area A had the lowest R_A value, which indicated that approximately 85% of the deposit would be stable as beach fill in the project area. The other three potential borrow areas (B1, B2, and C) yielded R_A values substantially higher than borrow area A. As noted in the EIS, these areas would therefore require proportionately higher excavation volumes to achieve the same performance as borrow area A. The EIS also states that only a portion of borrow area A will be required to satisfy the nourishment volume requirements of this project – ample beach-quality sediments exist in this location.

   Section 2.3.1 of the EIS lists the selection of borrow areas as an "unresolved issue" at this point in the project. It states that "it will be uncertain until bids are received which combinations of dredge type and borrow area will yield the most cost-efficient project." The Division of Water Quality supports the use borrow area A as the exclusive source for beach-quality sediments for this project. As compared to the other three proposed borrow areas, the use of borrow area A as the sole source for beach sediments would require less material, would improve the durability of the nourishment project, would minimize changes in types and densities of nearshore species, and would reduce the rate of fill loses therefore minimizing turbidity in nearshore waters. Although borrow areas B1 and B2 may result in lower costs related to travel distances, they will have greater impacts on the nearshore environment in and around the project area.

   The Division of Water Quality would also like to request that when a decision is reached on the selection of a borrow area(s) appropriate documentation be provided for comment.

SUBJECT: Review of ~~SCH~~# 00-1046 DEPT DATE: 4·11·2000

___ A COPY OF ALL COMMENTS RECEIVED BY THE SCH IS REQUESTED   ___ REVIEWER COMMENTS ATTACHED

Review Comments:

___ This document is being reviewed for consistency with the NC Coastal Management Program pursuant to federal law and or NC Executive Order 15. Agency comments received by SCH are needed to develop the State's consistency position.

Project Review Number (if different from above) ______________.

A consistencyposition will be developed based upon our review on or before ___________.

___ A Consistency Determination document ___is, or ___may be required for this project pursuant to federal law and or NC Executive Order 15. Applicant should contact Steve Benton or Caroline Bellis in Raleigh, phone (919)733-2293, for information on proper document format and applicable state guidelines and land use plan policies.

___ Proposal is in draft form, a consistency response is inappropriate at this time. A Consistency Determination should be included in the final document.

___ A Consistency Determination Document (pursuant to federal law and/or NC Executive Order 15) is not required.

- ___ A consistency response has already been issued.
  Project Number ___________ Date Issued __________
- ___ Proposal involves < 20 Acres and or a structure < 60,000 Square Feet and no AEC's or Land Use Plan problems.
- ___ Proposal is not in the Coastal Area and will have no significant impacts on any land or water use or natural resources of the Coastal Area.

✓ A CAMA Permit ✓ is, or ___ may be required for all or part of this project. Applicant should contact _______________ in _________________, phone #_____________, for information.

___ A CAMA Permit ___has already been issued, or___is currently being reviewed under separate circulation. Permit Number____________ Date Issued___________

___ Other (see attached).

State of North Carolina Consistency Position:

___ The proposal is consistent with the NC Coastal Management Program provided that all conditions are adhered to and that all state authorization and/or permit requirements are met prior to implementation of the project.

___ The proposal is inconsistent with the NC Coastal Management Program.

___ Other (see attached).

RE: Bogue Banks Beach Restoration Plan – SEPA Draft Environmental Impact Statement

Please accept these comments regarding the proposed project on behalf of Environmental Defense, our 10,000 members in North Carolina and 300,000 members nationwide. In general, we have serious concerns regarding the large-scale, persistent and cumulative effects of this and related beach engineering projects, and the adequacy with which impacts from these projects are addressed. We recognize and acknowledge the efforts of the project sponsor and authors of the draft EIS to address the issues of highest controversy surrounding beach engineering, and offer the following comments regarding those issues for which we have particular concerns:

1) Cumulative and Long Term Impacts: In general, our dominant concern regarding beach engineering projects, particularly ones of such extensive spatial (and potentially temporal) magnitude, is the inadequate assessment of cumulative and long-term impacts to living marine resources and essential fish habitats. Specifically, the impacts of these projects are assessed on a piecemeal, or project-by-project basis, rather than as components of a statewide and regionwide beach engineering effort. We recognize that scientific studies examining the impacts of engineering operations on beach, intertidal and nearshore fauna are ongoing and not yet complete, but enough information exists to warrant a programmatic EIS on *all* of these activities for the North Carolina coast, if not the entire southeast region. We have requested such an evaluation of the Corps of Engineers (see Attachment 1) in a letter dated September 8, 2000. The Corps' response was that such an evaluation was too costly to undertake at the present time.

   Although the current project is proposed to be a one-time placement of sand, designed to "restore the sand deficit and provide for average yearly losses over a decade or so" (DEIS, Section 2.1, p. 2-2), it is clearly stated at the end of the introduction (Section 1.4, p. 1-3) that it is unlikely the entire project could be constructed within the same environmental window. Indeed, it appears that, given the funding needs of the communities, the project will stretch over several environmental windows. We are concerned about the downstream impacts of such discontinuous construction, which, as pointed out in Section 5.4.5 (page 5-2, second paragraph) are not insignificant.

North Carolina Office · 2500 Blue Ridge Road · Suite 330 · Raleigh, NC 27607 · Tel 919 881 2601 · Fax 919 881 2607

www.environmentaldefense.org

2) Definition of Project Success: As acknowledged in Section 2.2.2 (p. 2-2) one of the major controversies with respect to beach engineering is the development of criteria, or lack thereof, for defining project success. Given the magnitude of resources required for the proposed project, there ought to be a clearly defined set of criteria by which to measure project success, particularly if state cost-share funds are obtained for any portion of the project as discussed in Section 2.3.3. The DEIS state in Section 2.2.2 that "Success will be defined in relation to how closely the postnourishment volume erosion rate compares with the estimated prenourishment volume erosions rate" (page 2-3), yet fails to identify a range of values which would constitute an acceptable or "successful" erosion rate. Although achievement of a certain rate of erosion may constitute success in an engineering sense, it may not necessarily translate into visible success for the project sponsors (i.e., the communities, and potentially state taxpayers if cost-share funding is obtained). Considering that this project is supposed to serve as "prototype" for future beach maintenance efforts (Section 2.1, page 2-1) and as a basis for determining a "long-range solution" from amongst three alternatives (Section 2.4, page 2-5), development of specific evaluation criteria by the project sponsors, rather than the contracted engineering company, would appear to be critical.

3) Project Purpose: Among the four stated objectives (Section 1.3, page 1-2) of the project is "preservation of the environmental, cultural and aquatic resources of the county". We maintain that this project as designed (mainly due to the extensive geographic scale) protects only the unnatural, i.e., manmade "environmental resources". The three remaining planning objectives are a more realistic statement of purpose. Beach engineering projects are rarely, if ever, consistent with protection of the natural environment, and we are unaware of any such projects that have enhanced the nation's living marine resources. We also disagree with the statement that Bogue Banks serves to draw human activity away from the more pristine shores of Shackleford and Core Banks. Although not accessible by vehicle, there is ample transportation available to these locations via public and private ferries, and certainly the number of privately owned boats anchored in Back and Core Sounds during the summer months does not indicate that the public is dissuaded from visiting these areas.

4) Consideration of Alternatives: The DEIS states that "Property abandonment and relocation at a large scale would leave the beach degraded for many years because it would necessarily become a piece-meal process" (page 1). Yet, as referenced previously, the DEIS indicates that if approved, project construction would itself be piecemealed. A retreat and relocation alternative can be planned to initially target those structures most at risk, and can be implemented gradually, rather than in one massive effort. Indeed, should this project be approved, development of a phased relocation and/or exit strategy should be considered, particularly if cost-share funding is obtained. Given that the community plans to reevaluate the costs and benefits of renourishment after a decade of monitoring (Section 2.2.2), development of such a strategy would be proactive. That being said, having once obtained the necessary approval for a beach engineering project (especially if other funding sources are obtained), it is highly likely that the local communities will naturally expect approval for a second project, at an even greater economic and environmental cost.

Also, under the no-action alternative in Section 4.2, page 4-2 one of the stated, yet unquantified, environmental impacts of this alternative is "chronic impacts to beach fauna". We presume that this would be the result of beach scraping. We disagree with this statement, as it implies that placement of dredged sand on the beach would *not* impact beach fauna and that beach scraping would not occur should the project move forward. Incidentally, we find it interesting that "loss of recreational beach" is listed as a quantifiable environmental impact, considering the subjective and intangible nature of the recreational experience, while no attempt is made to quantify the loss of biota.

5) Monitoring Program/Protocol: We applaud the commitment of the project sponsors to develop a comprehensive pre- and post-construction monitoring plan as outlined in Appendix C, and for initiating pre-project benthic monitoring. We feel that such efforts are absolutely necessary in order to assess project impacts accurately over the proposed 10-year project lifetime. We also feel that a periodic (once every three years), publicly available assessment of impacts should be conducted and the results used to adjust the implementation and maintenance of the project and develop a compensatory mitigation plan if warranted, especially if the communities elect to continue beach engineering as a management option. In light of the fact that environmental impacts are not quantified in the analysis of costs and benefits, we feel very strongly that the project sponsors be responsible for funding the monitoring program.

6) NC Marine Fisheries Commission Policies on Beach Dredge and Fill Activities: The North Carolina Marine Fisheries Commission (MFC) has statutory responsibility for protecting the marine and estuarine resources of North Carolina against impacts from both fishing and non-fishing threats. On November 16, 2000, the MFC approved a new policy for the protection of marine and estuarine resources under its authority from the effects of beach dredge and fill activities and related coastal engineering activities (copy attached). The Habitat and Water Quality Standing Advisory Committee of the NC Marine Fisheries Commission developed the policy in response to increasing number of beach engineering projects being developed and the inadequate consideration of cumulative and long-term impacts of these projects. This policy includes numerous issues that have so far not been adequately addressed in the DEIS.

   In addition, the MFC shares responsibility under state law for the development of Coastal Habitat Protection Plans (CHPPs). The statutory goal of these plans is the "net enhancement" of the value to the coastal fishery of each habitat type. The Coastal Ocean CHPP is currently in pre-draft form; it will shortly be issued in public draft. That draft will include a set of policies and procedures to protect the marine and estuarine resources of North Carolina against development activities including beach engineering activities. The CHPP will then be formalized in regulation. The CHPP and its adjunct regulations will become a part of the state's federal coastal zone management plan.

Finally, we would like to explicitly state several requests regarding the Bogue Banks Renourishment DEIS:

- When will a programmatic EIS or comprehensive assessment of beach engineering projects be performed, at least for the state of North Carolina?
- What are the project sponsors' criteria for project success?
- Is there a contract with a research institution to continue the pre-construction benthic monitoring, develop post-project benthic monitoring, as well as develop a pre- and post-construction intertidal monitoring program?
- Should state cost-share monies be obtained, are there plans to proactively develop phased exit strategies in the event that beach engineering is not found to be a viable management alternative?

Until these questions and the other issues we have raised can be sufficiently addressed, we do not feel that the Bogue Banks Renourishment project should move forward. We repeat our request that a programmatic EIS be conducted, including full assessment of cumulative impacts of the multiple projects at various stages of design. We reiterate our willingness to discuss any of the issues that we have raised.

We thank you for the opportunity to comment on this very important project.

Sincerely,

Michelle Duval

Dear Mr. Huggett:

Re: SCH File # 01-E-4300-0357; Draft Environmental Impact Statement Bogue Banks Beach Restoration Plan

The above referenced environmental impact information has been reviewed through the State Clearinghouse under the provisions of the North Carolina Environmental Policy Act.

Attached to this letter are comments made by State department(s) in the course of this review. The comment(s) need to be addressed in the Final Environmental Impact Statement. This document should be submitted to the State Clearinghouse upon completion for compliance with the North Carolina Environmental Policy Act.

Best regards.

Sincerely,

Chrys Baggett

Re: Bogue Banks Beach Restoration Plan

Dear Mr. Huggett:

I enclose here my comments on the Draft EIS for the Bogue Banks Beach Restoration Plan. I make these comments in my professional capacity as a coastal ecologist with the University of North Carolina at Chapel Hill. These opinions are derived from my 25 years of personal experience in quantitative monitoring of the major beach invertebrates on the beaches of Bogue Banks, my years of experimental analyses of how ecological processes on sand beaches are influenced by the physical character of the sediments, my personal experience with two beach nourishment projects at Fort Macon, my 30+ years of professional reading, research, and experience as a marine ecologist, my two decades of teaching barrier island ecology at Duke University and the University of North Carolina, and my recent experience as a member of the IRC charged with development of CHPPs, including the Coastal Ocean Habitat Protection Plan.

In my professional opinion, the proposed Bogue Banks Beach Restoration Plan is inadequately protective of the important natural resources of the intertidal beach and the coastal ocean, including especially the physical habitat and prey invertebrates required to sustain our recreationally and commercially important fisheries and the valued shorebirds of our beaches. Without (1) scientifically rigorous before-after monitoring of physical character of the sediments, impacts and recovery of the invertebrate prey, and consequences of turbidity and habitat change on the fishes, with required mitigation for any substantive impacts, (2) development of a state plan for assessing cumulative impacts based on results of a programmatic EIS covering all these sand mining and beach deposition projects along the entire coast of the state and beyond, as dictated by the range of the important fishes, (3) a match of sediment grain sizes to the natural sediments of the beach in a way that will protect the habitat value of the beach, and (4) restriction of the project to between Dec 1 and March 31 so as to minimize ecological damage and allow recovery to begin to develop during the ecologically significant spring-summer seasons, this project should not be granted a permit.

(1) Scientifically rigorous before-after monitoring of sediments, benthos, and fishes

The draft EIS is grossly deficient in its commitment to the monitoring that is necessary to evaluate the ecological impacts of the project and thereby allow the agencies to learn how to respond to future requests and how to condition projects to protect adequately the public trust resources. While it is true that monitoring of nourishment projects has been done in the past, this project is unique for its spatial scope, its application to pristine shores, and its context in the midst of potentially hundreds of miles of

similar projects coast-wide. Past beach nourishment projects have been done on short stretches of urbanized shore like Atlantic Beach, Wrightsville Beach, and North Topsail. The application to a pristine beach of such a length as to represent a significant fraction of the functional critical habitat for beach fishes, invertebrates, and shorebirds is unprecedented for North Carolina. Past monitoring projects attached to permit applications are almost uniformly poor scientifically, done merely to satisfy a regulatory burden in a way that typically produces inconclusive results. Monitoring should be designed up-front by and reviewed by professional statisticians so that the agency and the public can have reassurance that the important questions can be answered with adequate power to detect effects of ecological significance. That has not been done here. Here we are told that monitoring will be done by the Carteret County monitoring plan. There is no such plan, no detailed statistical design, and no binding commitment by the county, state, or the responsible party to funding such a project. In fact, the necessary before-project sampling has not even been done. In South Carolina projects, the offshore biology has been monitored before and after such projects in each of the four seasons of the year: this proposal includes pre-project monitoring of benthic invertebrates for only one season (autumn), yet the offshore fishery resources here are arguably even more important than off South Carolina. There are no data included on pre-project monitoring of the beach ecosystem and no design that could be evaluated statistically for its rigor and ability (power) to detect important changes. Granting a permit under such inadequacy is not in the public interest.

There is broad and essentially uniform consensus among the scientific community that the impacts of beach nourishment projects on fisheries through modification of their bottom and water column habitats are poorly understood. The monitoring that has been done for such projects in the past (1) has been too restricted to include all the potentially important impacts on fisheries, (2) has lasted for too short a time period to confidently demonstrate recovery, (3) has failed to meet standards of rigor and high power to detect large impacts, and/or (4) has been done for projects occurring on too small a scale to allow extrapolation to the cumulative effects of permitting many miles of beach nourishment. The impacts of concern include both phases of nourishment projects, the mining of sediments from the shelf and the deposition of sediments on the beach.

A minimally adequate monitoring design for either the mining site or the deposition site would include the following components. First, the monitoring design must begin with quantitative data taken before initiation of the project. Such "Before" observations must be made during each season of importance to the biota that comprise and use the habitat. A single year of such "Before" data is an absolute minimum necessary to make rigorous conclusions and multiple years of "Before" data are required to be completely comfortable in estimating the magnitude of effects with confidence. These "Before" data must include observations made in both the putative "Impact" areas and in "Control" areas that are sufficiently distant not to be affected by the project but sufficiently nearby and similar that they can serve to track conditions that would be expected in the "Impact" area in the absence of the project. The observations made during the "Before" period then need to be replicated in the "After" period in both the putative "Impact" areas and the "Control" areas. This monitoring needs to match the seasonal monitoring done during the "Before" period and needs to extend long enough in time to demonstrate recovery or allow inference of recovery with high statistical confidence. The "Control" area should have replication that involves statistically independent sites. This is preferable for the "Impact" areas too, but sometimes impossible because there may be only one project site. In any event, sufficient subsampling must be done at multiple locations to characterize the habitat and its utilization adequately. This monitoring design must be shown to be likely to have high statistical power to detect any magnitude of impact deemed important to fisheries biologists and managers. This requires an effective statistical design. Perhaps the best model for such rigorous project monitoring comes from the paper on BACI (Before-After-Control-Impact) designs by Stewart-Oaten et al. (1986: Ecology). Most monitoring associated with permits is incapable of statistically demonstrating even large impacts of the project with confidence because of inadequate statistical power in the design. The evaluation of cumulative impacts of beach nourishment on a large scale of tens of miles is a particular challenge, fundable perhaps only by creating a monitoring bank from contributions from multiple projects.

(2) Programmatic EIS for cumulative impacts and appropriate monitoring

Besides the needs to evaluate the impacts of this particular project on Bogue Banks, the responsible permitting authorities have a duty to evaluate the cumulative impacts of all such perturbations to the coastal ocean system. This requires first a programmatic EIS that applies the best scientific judgement, open to public review, analysis, and comment, as to cumulative impacts, especially on fishery populations and shorebirds. For a short stretch of urbanized shoreline, it is readily argued that most fish and shorebirds are mobile enough to move elsewhere to feed when their invertebrate prey resources are killed by beach nourishment. Similarly, when prey resources are mined along with sand from the offshore sand bodies, one can argue that the demersal fishes and crustaceans can feed elsewhere. But when projects are large enough and numerous enough and when projects are repeatedly done over time, then the potential for seriously limiting the production of fishes and birds greatly increases. Furthermore, if the physical sedimentary habitat is permanently altered or modified for the long term, then there is great potential for permanent limitation of the extent of critical fisheries habitat both on continental-shelf sand bodies (a limited habitat already in the southern portion of the state) and on intertidal beaches. Nowhere in this Draft EIS for Bogue Banks is there evidence that the public trust resources will be protected from cumulative spatial and cumulative temporal effects. Until such time that evidence exists, no permit should be granted for this project.

(3) Match of sediment grain sizes to protect habitat value of the beach

The recovery of natural ecological functioning of the beach habitat depends upon closely matching the sediment size distribution to that of the natural undisturbed beach. I have shown in a published paper based on study of a previous beach nourishment project on Bogue Banks (Peterson et al. 2000: Journal of Coastal Research) that the US ACOE requirements for matching sediment sizes are inadequate to allow recovery of function of the beach habitat within the following summer season. Incorporation of either too much shell (coarse material) or too much silt/clay (fine material) inhibits recovery. Too much shell inhibits burrowing by the beach invertebrates, which must burrow into the sediments to feed and avoid erosion and wave-transport off the beach face. Too much shell also prevents many shorebirds from feeding on the invertebrates that are present because coarse particles block the biomechanical ability of bills to extract invertebrate prey (see test in published paper by Quammen 1982: Marine Biology). Too much silt/clay likewise prevents sand burrowers from inhabiting a habitat that now lacks the interstitial spaces among sand grains and the penetrability required for burrowing. In addition, silt/clay is readily suspended causing enhanced turbidity, which clogs the filtration apparatus of these suspension-feeding beach invertebrates (mole crabs, coquina clams, some polychaetes, and amphipods) and inhibits surf fishes like pompano, bluefish, and Spanish mackerel from detecting their prey. We possess feeding data from experiments showing this feeding inhibition on pompano in the presence of elevated turbidity. The Bogue Banks project, as proposed in this Draft EIS, plans use of sediments that are much more dominated by shell fragments than the natural pristine Bogue Banks beaches. This will result in long-term (not just transient) reduction in beach invertebrate populations and thus habitat value for surf fishes and shorebirds. I base this judgement upon knowledge of the physical processes that affect sediments on the beach and upon my lab's survey of the biota of North Carolina beaches as a function of shell content. Silts and clays are gradually winnowed away from beach sediments as they become suspended in the water and make it turbid. Shell fragments, in contrast, are left behind to accumulate on beaches, and thus remain to degrade the beach habitat indefinitely until the next nourishment project is needed. Lower densities of the numerically and functionally important large burrowing invertebrates on shellier beaches are dramatic in our unpublished survey data. Thus, the choice to use shell-rich sediments in the Bogue Banks nourishment project will predictably degrade the critical habitat of the intertidal beach indefinitely. Such a poor match with pristine sediments should not be permitted.

(4) Restriction of the project to Dec 1 through March 31

Because of the seasonality of biological use and activity in both the subtidal sand body habitat and the intertidal beach habitat, sand mining and beach deposition should both be restricted to the colder months to minimize ecological injury and to speed up recovery in the next warm season. The draft EIS for the Bogue Banks project does not constrain the project adequately in light of what is known about biological seasonality to protect the functioning of these habitats. Our monitoring of beach invertebrates on Bogue Banks over a period of 25 years shows that the period of December 1 through March 31 is the proper window during which beach invertebrates like mole crabs and coquina clams have migrated to deeper waters, from which they can initiate recovery through migration and reproduction at the end of the project. Furthermore, our sampling of fish abundance at the sand bodies proposed for mining to conduct this Bogue Banks project demonstrated high abundances and high rates of feeding on bottom invertebrates of the sand bodies on November 29 and again in spring, with low levels in February after clod fronts had reduced water temperatures. The Draft EIS for Bogue Banks does not propose a time frame for the project that will adequately protect either of these habitats from the impacts of the project. A permit should not be granted until the window is narrowed to this Dec 1-March 31 season. Furthermore, the public is entitled to a commitment that such a window will be enforced by DCM: similar restrictions have not been enforced in the past and I have little confidence that they will be in the future, absent some new mechanism of assurance.

I trust that my concerns are clearly and fully enough articulated here. If any comments need further elaboration, please ask. In addition, if you need further information from our files, please ask.

Sincerely,

Charles H. Peterson

Dear Sirs:

This letter is in reference to the Bogue Banks Beach Restoration Plan Draft EIS (DEIS). As you may be aware, the DEIS completed its initial State Clearinghouse review on March 15th, 2001. It is my understanding that the State Clearinghouse has provided you with copies of the comments received by that office as of the March 15th deadline. In case this is not correct, I have provided a copy of these comments as well. In addition to these comments, an additional set of DEIS review comments were received in this office on March 16th, 2001. Although these comments were received one day after the official review period ended for the review, after discussion with the State Clearinghouse I have determined that it is appropriate and necessary that these comments be considered and addressed in Final Environmental Impact Statement (FEIS). Therefore, I must ask that you address all of the attached comments in the FEIS, and that 12 copies of the document be submitted to this office so that I may initiate the FEIS review process.

Please let me know if you have any questions concerning this matter. I may be reached at (919) 733-2293 or by e-mail at doug.huggett@ncmail.net.

Sincerely,

Doug Huggett

RE: Response to Comments dated 15 March 2001 from Dr. Charles H. Peterson, University of North Carolina Institute of Marine Sciences [Ref: EIS #01–E–0357] Bogue Banks Beach Restoration Plan (2049)

Dear Mr. Huggett:

I am writing on behalf of Carteret County and the Towns of Pine Knoll Shores and Indian Beach, in response to the above-referenced comments on the Bogue Banks nourishment project.

The correspondent has urged your agency to require that four conditions be met before a permit for the Bogue Banks nourishment is granted. I wish to outline herein how the applicant plans to meet certain of these conditions and to explain why others are not possible to achieve in any reasonable time or budget.

Dr. Peterson and his colleagues at UNC-IMS contributed valuable information and data in the development of the draft EIS under contract to Carteret County. They provided the initial biological samplings in November 1999 and February 2000, and prepared a detailed report which is Appendix C of the EIS.

Our project team has actively sought Dr. Peterson's guidance and recommendations for design of the project such that environmental impacts can be minimized. His contributions to the project have been important. We have also sought the advice of other experts [including Dr. Robert Van Dolah (SCDNR) and Dr. Bart Baca (Nova University)] and have reviewed the literature regarding impacts of dredging and beach fills on the fauna of similar project sites.

Early in the county's planning process (fall 1999), we were informed by Dr. Peterson that no quantitative biologic sampling data exist in and around our proposed borrow areas. As a result, the county, at its own initiative, contracted with UNC-IMS for a preproject monitoring that could be used as a baseline for future comparisons. The first of two planned samplings was completed by Dr. Peterson's group in November 1999. Detailed data from this survey are reported in Appendix C of the draft EIS.

UNC-IMS reportedly has completed numerous samplings of benthic organisms along the beach as part of a four-year study of the impacts of beach scraping. We requested relevant data from these samplings so they could be incorporated into the EIS but were informed by Dr. Peterson that they will not be available until one of his students completes a dissertation. As outlined in the draft EIS, we plan to use these data to estimate baseline beach conditions for the project when they become public.

Following are our responses to the four conditions outlined by Dr. Peterson.

Item 1) Rigorous before-after monitoring of sediments, benthos, and fishes.
The draft EIS (Appendix C) outlines the sampling protocols used by Dr. Peterson for his offshore surveys. The applicant proposes to follow up these samplings with additional benthic sampling in spring 2001 (preproject). Postproject sampling will be performed using similar sampling protocols and design in consultation with your agency and other reviewing agencies. Because it now appears that the project will be completed in several discrete segments by three towns and the county over several years, we are requesting guidance from NC DENR and National Marine Fisheries regarding what constitutes an acceptable level of biologic sampling. The Towns of Pine Knoll Shores and Indian Beach do not have unlimited resources to fund research that is more properly performed by universities or government agencies or that is more applicable to global concerns. However, the applicants realize the importance of sampling habitats over which their projects may produce direct and quantifiable impacts. Accordingly, we have recommended that the county and cooperating municipalities sponsor the following:

- A second preproject sampling of benthic organisms in spring 2001 in and around the planned borrow areas following the Peterson sampling design given in Appendix C of the draft EIS.

- Annual postconstruction sampling of benthic organisms in and around the borrow area(s) and beach for up to three years after completion of the Pine Knoll Shores and Indian Beach reaches on a schedule acceptable to state and federal agencies.

The results of Appendix C, as well as research published in the literature, suggest that quantification of impacts to fisheries by the proposed project is not possible by any reasonable amount of sampling of the water column for transient species. Such questions are global in nature and will require a major commitment of time and money to answer in any rigorous sense. We believe that the natural variation in pelagic species passing through and utilizing the borrow area(s) and beach is far too great to quantify impacts or prove cause and effect. This problem is not a straightforward sampling exercise. Therefore, the chance of any sampling schedule offering rigorous, predictive results is negligible.

Item 2) Programmatic EIS for cumulative impacts
The question of cumulative impacts is important and should be addressed in some manner by state and federal agencies. However, this is not a trivial exercise and certainly not one that can be accomplished in a reasonable amount of time. It will take years and millions of dollars to even begin to address this problem in any sort of rigorous way, given the wide range of variables that must be sampled, analyzed, modeled, and integrated. This is a global concern. I believe that years of effort would be required just to develop a scientific sample design or statistical model upon which professionals could agree. The question of cumulative impacts spans the disciplines of oceanography, geology, biology, chemistry,

water quality, fisheries, primary production, climate, rainfall, runoff, and anthropogenic inputs of man. This is not something that can be answered before the next damaging storm impacts Bogue Banks and, therefore, should not be a prerequisite for granting a permit for the project.

Item 3) Match sediment grain sizes.

The correspondent expressed concern about the shell percentage and advises that "high" shell content should not used. The draft EIS presents data for three borrow areas (A, B1, and B2). Borrow area A contains a deposit having about twice the shell content of the beach. Borrow areas B1 and B2 contain about the same 20 percent shell content as the native beach. As the draft EIS and permit application states in detail, the applicant proposes to use the particular combination of borrow areas that optimizes the match of grain sizes and costs of dredging. The applicant is continuing to collect borings in borrow areas B1 and B2 (beyond those reported in the draft EIS) in response to Dr. Peterson's recommendation to limit the shell percentage. In fact, more care has gone into the search for a good match of sediment types for this project than any previous nourishment along Bogue Banks. Other investigators have noted how poorly prior projects matched the sediments. (Atlantic Beach was too shelly and the Ramada Inn site was too fine.) The applicant believes that there is insufficient monitoring data from these prior projects to make any definite recommendations regarding shell content. If the agencies will provide quantitative criteria for nourishment sediment characteristics (specifically, a particular range of shell percentages) based on previously published studies, the applicant will strive to match them.

Item 4) Restrict the project to December 1 through March 31.

This restriction would be unprecedented, considering the number of nourishment projects that are completed during the biologically productive summer months. We are aware of no data or published reports that state these dates constitute the only acceptable window for dredging. The applicant has chosen to perform the work in cold-water months rather than request a permit for work in summer as other agencies have done. The period from around 1 November to around 1 May has been an accepted standard for construction outside the normal turtle-nesting period in many East Coast states. By shortening the window to only four months, it is highly unlikely that the project can be completed in one season. This means that equipment will have to re-mobilize and re-impact the project areas at considerable extra expense to the applicant.

If quantifiable data exist and state or federal agencies have a justifiable basis for establishing such a restrictive dredging window for the proposed project, the applicant is prepared to adjust the schedule. However, such restrictions should then be applied universally. I believe the schedule for dredging is important. However, to ultimately avoid any sense of arbitrariness, extensive biologic sampling on a monthly basis for many years should be performed by government agencies such that a sound basis for restricting the dredging window can be developed.

Finally, I would like to reiterate that what the applicant is proposing is a one-time project. It will be the first nourishment of Bogue Banks designed to match properly the texture of sediments in the borrow area with those of the native beach. The project will be performed in sections rather than in one complete pass over 16.8 miles such that adjacent areas have time to adjust and recover their biologic populations before the next sections are constructed. It will reduce the need for and frequency of beach scraping, a recurring adverse impact to biota in recent years. And it will allow dunes to build naturally with fine, windblown sediments that facilitate revegetation.

The present beach/dune system of Bogue Banks is not pristine. Its profile has been altered such that it is steeper and more vulnerable than the native beach to severe damage in storms. Coarse sand and pebbles common to the swash zone now reside in the foredunes, inhibiting revegetation. With loss of recreational beach has come a loss of turtle-nesting habitat and diminishment of a vegetative buffer between the ocean and development.

Bogue Banks is eroding, but not fast enough to create economic incentives to relocate. The proposed project, rather than continuing the present cycle of scraping after every storm, has a better chance of restoring the natural character of the beach and reducing the need to scrape. The project scale proposed by the applicant is sufficient to provide recreation and storm-protection benefits for at least one decade.

In closing, I wish to express my firm's commitment to executing the project in as environmentally sensitive a manner as practicable and reasonable. However, I do not believe it is possible for any project to achieve all four conditions recommended by Dr. Peterson. We will be happy to meet with your agency and UNC-IMS representatives at any time to develop an acceptable biological monitoring plan for the project.

Thank you for your consideration.

Yours truly,

Tim Kana

RE: Response to Comments dated 13 March 2001 from Environmental Defense
Bogue Banks Beach Restoration Plan (2049) [SCH File #01-E-4300-0357]

Dear Mr. Huggett:

This letter is in response to Environmental Defense comments dated 13 March 2001 on the above-referenced draft environmental impact statement.

Item 1) Concerns regarding cumulative and long-term impacts and schedule for construction
Response: The question of cumulative impacts is important and should be addressed in some manner by state and federal agencies. However, this is not a trivial exercise and certainly not one that can be accomplished in a reasonable amount of time. It will take millions of dollars to even begin to evaluate this problem in any sort of rigorous way, given the wide range of variables that must be sampled, analyzed, modeled, and integrated. This is a global concern. I believe that years of effort would be required just to develop a scientific sample design or statistical model upon which professionals could agree. The question of cumulative impacts spans the disciplines of oceanography, geology, biology, chemistry, water quality, fisheries, primary production, climate, rainfall, runoff, and anthropogenic inputs of man. This is not something that can be answered before the next damaging storm impacts Bogue Banks.

A growing body of research shows that borrow area dredging and beach nourishment produce short-term, temporary impacts (cf, Van Dolah et al, 1992; Jutte et al, 1999a; 1999b; referenced in the draft EIS, Appendix A). These can be minimized by proper matching of sediments and construction in colder months (as planned for the present project). After the project is complete, there will be nearly the same area of intertidal and offshore habitat available as before the project. It will simply be displaced seaward by the width of the new beach. Environmental studies of similar projects suggest impacted areas will recolonize rapidly. The primary questions for project monitoring are how fast will the borrow area and beach communities recover and how closely will the benthic populations match the native conditions. In theory, these should be easy questions to answer. But in reality, natural populations fluctuate over such wide ranges that there can never be assurance that a change in species numbers or diversity is due to anthropogenic impacts like dredging rather than some global impact such as water temperature change. Recently, South Carolina closed its spring shrimp fishery because the white shrimp larvae count was less than 5 percent of normal for this time of year. The decline was attributed to a prolonged cold snap where water temperatures fell below 45°F for more than 18 days. Such order-of-magnitude declines are common in natural systems and will occur off Bogue Banks as well, whether or not the project is constructed.

The correspondent expresses concern about downstream impacts if the project is performed discontinuously in sections and cites page 5-2 of the draft EIS. The study referenced (Roessler, 1998) relates to the possible effect of an offshore disposal mound near Beaufort Inlet encompassing nearly 30 million cubic yards. This artificial feature built over 30 years in connection with USACE navigation projects may have altered wave/current patterns along Atlantic Beach, although no historical data exist to prove this. The proposed project will not alter the nearshore bottom such that it changes the wave and current patterns to the detriment of downstream communities (cf, Appendix G). The scale of the borrow-area changes for the proposed project are dwarfed by changes around Beaufort Inlet and the offshore mound.

Regarding possible adverse end effects of the project, this will be minimized by tapering of the fill sections as described in the draft EIS and in responses to NCDENR comments in the correspondence section of the draft EIS. Adjacent unnourished areas will tend to benefit rather than suffer from the downstream spread of the beach fill. Many nourishment projects, in fact, are designed as "feeder" beaches whereby sand is placed every few years along an updrift reach in order to flow downcoast and nourish other sections (CERC, 1984). Probably the worst "end effects" occur in <u>natural</u> systems where shoals break free of inlets and bypass to the adjacent beach. As the process occurs, the beach in the lee of the shoal accretes rapidly while the adjacent sections erode. This has been documented in many places (cf, Kana et al, 1985; 1999) and is illustrated schematically in Figure A. The reason that natural shoal bypassing produces adverse end effects is because it tends to concentrate large volumes over short lengths of beach. The proposed project will spread sand relatively thinly and evenly along many miles of shoreline such that perturbations in the shoreline will be minimal.

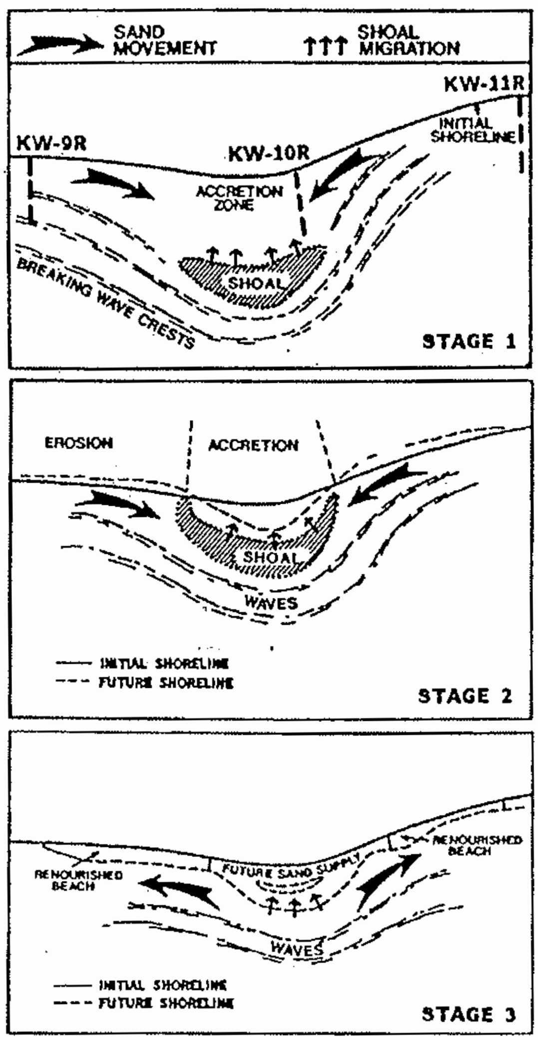

FIGURE A.

CSE

Item 2) Definition of project success
As engineers for the applicant, my firm is developing quantitative criteria for defining project success. The key variable is the volumetric erosion rate. In our review of prior studies, we found no historical profiles or surveys which could be used as a rigorous basis for predicting this rate. The only data available were linear shoreline change rates (eg, movement of mean high water or vegetation lines) and limited sets of wading depth profiles (not comprehensive for the entire project area). We used these data to extrapolate volumetric changes and estimate approximate beach fill requirements for 5-year, 10-year, and 20-year periods (CSE Stroud, 1999). The applicant has initiated annual surveys of the nearshore and has obtained two sets of 110 profiles spanning the length of Bogue Banks. Each profile extends about 1,000 ft offshore and documents changes to the outer bar.

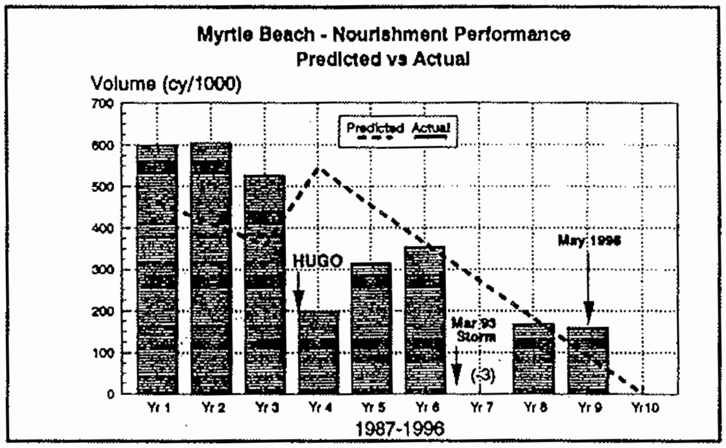
Enclosed is the first beach monitoring report covering the period June 1999 to June 2000. Also contained in the report are about 18 post-*Floyd* profiles from September 1999. The results show a range of erosion and accretion losses and provide more guidance for establishing project erosion rates. However, we consider these data to be insufficient to make any more refined long-term predictions because they only span one year. The applicant plans to resurvey the beach in June 2001 and update these data. As we have represented in the draft EIS, the anticipated volume losses are expected to be of the order 1-5 cy/ft/yr measured to closure depth. The rate will be closer to the high range if borrow areas B1 and B2 (less shelly deposits) are used and closer to the low range if area A (more shelly deposit) is used. Regardless of the rate, the applicant plans to perform annual surveys and quantify the fate of the beach fill such that a more rigorous erosion rate estimate can be developed for Bogue Banks over the next decade.

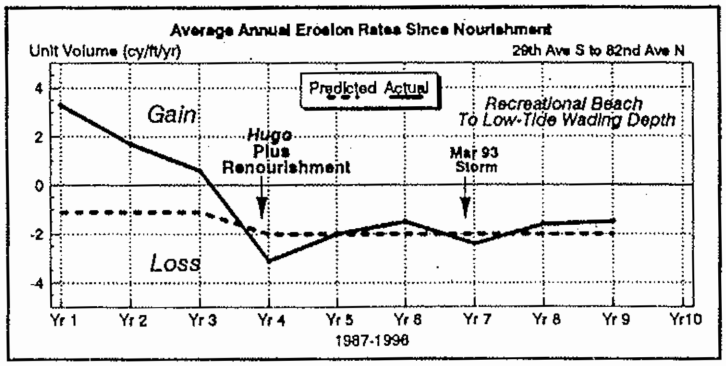
Figure B illustrates similar results for a project in Myrtle Beach (SC). In that particular project, the unit fill volumes were only about one-third the quantities proposed for Bogue Banks. Historical data suggest that Myrtle Beach and Bogue Banks have nearly equal long-term erosion rates.

CSE is in the process of developing "specific evaluation criteria" in consultation with the sponsoring communities. These will be particular to each borrow area(s). In general, the most appropriate criteria are volumetric erosion rates rather than some particular beach width because it is the littoral volume that is important in the long run. Short-term, beach-width fluctuations are poor predictive parameters because they are contour sensitive. For example, Hurricane *Floyd* produced a certain average dune recession (~12 ft) but matched it with seaward movement of mean high water (cf, CSE, 2000 – attached report).

CSE

FIGURE B.





Item 3) The correspondents question one aspect of the project purpose – "preservation of the environmental, cultural and aquatic resources of the county"

We disagree with the correspondent's contention that nourishment projects do not enhance or preserve the nation's living marine resources. It is well established that nourished beaches have restored turtle nesting habitat and vegetated dunes along many coasts that previously were armored with seawalls and had no such habitats (cf, National Academy of Sciences, NRC, 1990; 1995). Nearby Atlantic Beach is one such example. Others include Miami Beach (FL) and Myrtle Beach (SC). Pea Island (NC), a wildlife preserve, has received several inputs of nourishment to counter erosion and maintain protection to valuable back barrier habitats. Considering the biologic value of estuaries and lagoons, any soft solutions like nourishment that maintain the integrity of barrier islands will protect and preserve critical habitats to some degree.

The proposed project will reduce the need for and frequency of sand scraping. This will allow dunes to build gradually with appropriate-sized aeolian sand. Presently, most of the foredunes are composed of medium to coarse sand, pebbles, and shells, an unnatural sediment scraped from the surf zone after recent hurricanes. This is not enhancing the dune habitat.

While undeveloped Core Banks and Shackleford Banks are accessible by boat, only a tiny number of visitors (order of 1-2 percent) go there compared to the numbers visiting Bogue Banks. People want access to the shore. Carteret County strikes a model balance between less accessible beach preserves (~65 percent of shoreline) and accessible recreational beaches (~35 percent). Further, there are no roads through these preserves, unlike the Hatteras National Seashore.

CSE

4) Comment on consideration of alternatives regarding abandonment and relocation
The economics of nourishment versus property abandonment can always be refined. However, at present, they are skewed strongly in favor of maintaining the beach as described in detail in the draft EIS. The correspondents assert that the proposed project will be performed piecemeal just as property abandonment would be piecemeal. However, the definition of piecemeal is not the same in this case. Property abandonment would necessarily be done on a lot-by-lot basis with protracted delays and litigation likely. Nourishment, by contrast, is planned for long segments of beach that encompass hundreds of properties. The first segments planned (Pine Knoll Shores and Indian Beach/Salter Path) span over seven miles. This length would be considered a relatively long nourishment project by any standard (CERC, 1984). The Town of Emerald Isle is presently evaluating the feasibility of completing a three-mile project (Reach 3 and part of Reach 2) in 2002-2003. That reach encompasses nearly 200 properties. Each community must make careful decisions in the future regarding whether to continue nourishment or move toward abandonment. The problem now is that there are insufficient historical data to make this determination. The proposed project will offer an opportunity to establish on a site-by-site basis whether nourishment is viable for Bogue Banks. Evidence from the 1986 and 1994 nourishments of Atlantic Beach suggest overwhelmingly that it is viable in this setting. Further, some longtime opponents of coastal development such as Prof. Orrin Pilkey (Duke University) have stated that Bogue Banks is among the best candidate sites for nourishment in North Carolina.

Regarding the concern about beach scraping, the draft EIS makes clear that the proposed project will reduce the need for and frequency of sand scraping. We did not say it would eliminate it because certain contingencies may move property owners to demand scraping after a major storm. However, we expect the political pressure to scrape will be dramatically reduced after the projects just as it has been along Atlantic Beach. A tour of that site confirms that almost no sand scraping was performed after Hurricane *Floyd*, whereas the communities of Pine Knoll Shores, Indian Beach/Salter Path, and Emerald Isle scraped nearly the entire foredune.

5) Concerns regarding monitoring programs
The applicant is committed to a self-funded monitoring plan which will be developed in consultation with the appropriate regulatory agencies.

6) Concerns regarding proposed North Carolina Marine Fisheries Commission policies on beach dredge and fill activities
To the best of our knowledge, the referenced policies have not yet been certified by the state. The majority of issues raised by these new policies are addressed in the draft EIS. NCDENR has reviewed and approved the draft EIS. The applicants are striving to improve upon existing nourishment practice and work within the present regulatory framework. In fact, it will only be through properly designed and executed projects and long-term monitoring (as planned by the applicant) that state and federal

CSE

agencies can develop realistic and practical policies for protecting marine resources and maintaining the integrity of developed barrier islands via soft engineering solutions. The applicant expects to contribute knowledge regarding impacts after execution of the project such that our regulatory agencies may improve their management of coastal resources.

I hope the above responses adequately address the concerns raised by Environmental Defense. If you need additional clarification, please contact us at the earliest time.

Thank you for your consideration.

Yours truly,

Tim Kana

3 February 2000

Abstract

Carteret County is planning to conduct a nourishment project to rebuild the beaches along Bogue Banks. The proposed project will require borrowing sand from three areas south of Pine Knoll Shores, Salter Path and Indian Beach. In order to determine the proposed project's impact on potentially significant submerged cultural resources, Stroud Engineering, P.A. and CSE Baird LLC contracted with Tidewater Atlantic Research, Inc., (TAR) of Washington, North Carolina to conduct a systematic proton precession magnetometer and side scan sonar survey. The proposed remote sensing survey was designed to locate and identify submerged cultural resources in the study areas and generate sufficient data to make an initial assessment of each target's significance and provide insight into the necessity for avoidance or additional investigation. That survey was carried out between 7 and 13 December 1999. No magnetic or acoustic anomalies were identified in either Borrow Area A or Borrow Area B-1. In Borrow Area B-2, 10 magnetic anomalies were identified near the western end of the survey area. Seven of those targets contained signature characteristics indicative of significant submerged cultural resources. Because they could be associated with an historic shipwreck, either avoidance or additional investigation to positively identify the nature and significance of material generating the seven anomalies is recommended. If avoidance of the area is possible, no additional investigation should be necessary.

List of Figures

Introduction

Stroud Engineering, P.A., is working with Carteret County on beach renourishment projects on Bogue Banks. The source material for the project has been identified as three areas south of Pine Knoll Shores, Salter Path and Indian Beach. In order to determine the proposed project's effects on potentially significant submerged cultural resources, Stroud Engineering, P.A. and CSE Baird LLC contracted with Tidewater Atlantic Research, Inc., (TAR) of Washington, North Carolina to conduct a systematic proton precession magnetometer and side scan sonar survey to locate, identify and assess the significance of any underwater cultural material in the proposed borrow areas.

The investigation conducted by TAR was designed to provide accurate and reliable identification, assessment and remote sensing documentation of submerged cultural resources in the prospective project areas in terms of the criteria established in compliance with the National Historic Preservation Act of 1966, as amended and the Archaeological and Historic Preservation Act of 1979, as amended. The results of the investigation will provide Stroud Engineering, P.A. and CSE Baird LLC with the archaeological data essential for complying with submerged cultural resource legislation and regulations.

The methodology employed by TAR combined state of the art technology, experienced personnel and an investigative technique designed to generate appropriate historical and remote sensing data. Fieldwork activities associated with the project were carried out between 7 and 13 December 1999. Analysis of the remote sensing data identified 10 anomalies within the western part of Borrow Area B2. Seven of those targets contained signature characteristics indicative of significant submerged cultural resources and were recommended for further investigation. No magnetic or acoustic anomalies were detected in Borrow Areas A or B1.

Coordination for the survey was provided by Bill Forman, Stroud Engineering, and Phil McKee, CSE Baird. The field project staff included Dr. Gordon P. Watts, Jr., the principal investigator, archaeologists Raymond Tubby and Steve Brodie and archaeological assistants Mark Padover and Mike Phillips. Data analysis, historical research and report preparation were carried out by Gordon Watts, Raymond Tubby and Robin Arnold. All members of the project staff exceed the minimum standards for archaeological personnel identified by the Department of Interior and the North Carolina Division of Archives and History.

Project Location

The three Carteret County Borrow Areas are located south of Bogue Banks between Atlantic Beach and Emerald Isle. Borrow Area A forms an "L"-shaped polygon south-southeast of Salter Path and Indian Beach. Borrow Area B-1 is a long rectangular polygon offshore of and roughly parallel to the shoreline of the west extremity of Atlantic Beach and Pine Knoll Shores. Borrow Area B-2 is a long rectangular polygon offshore of and roughly parallel to the shoreline of Salter Path, Indian Beach and eastern Emerald Isle (Figure 1).

North Carolina State Plane Coordinates, NAD 1983 for Borrow Area A are:

Point	Northing	Easting
A	331043.56	2624077.59
B	341655.89	2623855.74
C	341761.05	2628865.86
D	338728.96	2628929.75
E	338861.61	2635193.01
F	331281.44	2635354.35

North Carolina State Plane Coordinates, NAD 1983 for Borrow Area B-1 are:

Point	Northing	Easting
A	350432.77	2670926.10
B	348405.98	2656162.79
C	346614.84	2644048.87
D	344906.79	2644085.74
E	346309.33	2656016.78
F	348359.78	2670922.61

North Carolina State Plane Coordinates, NAD 1983 for Borrow Area B-2 are:

Point	Northing	Easting
A	340961.55	2610140.28
B	342151.31	2616103.44
C	345657.97	2640081.60
D	343904.64	2640269.91
E	340397.98	2616480.06
F	338957.74	2610391.36

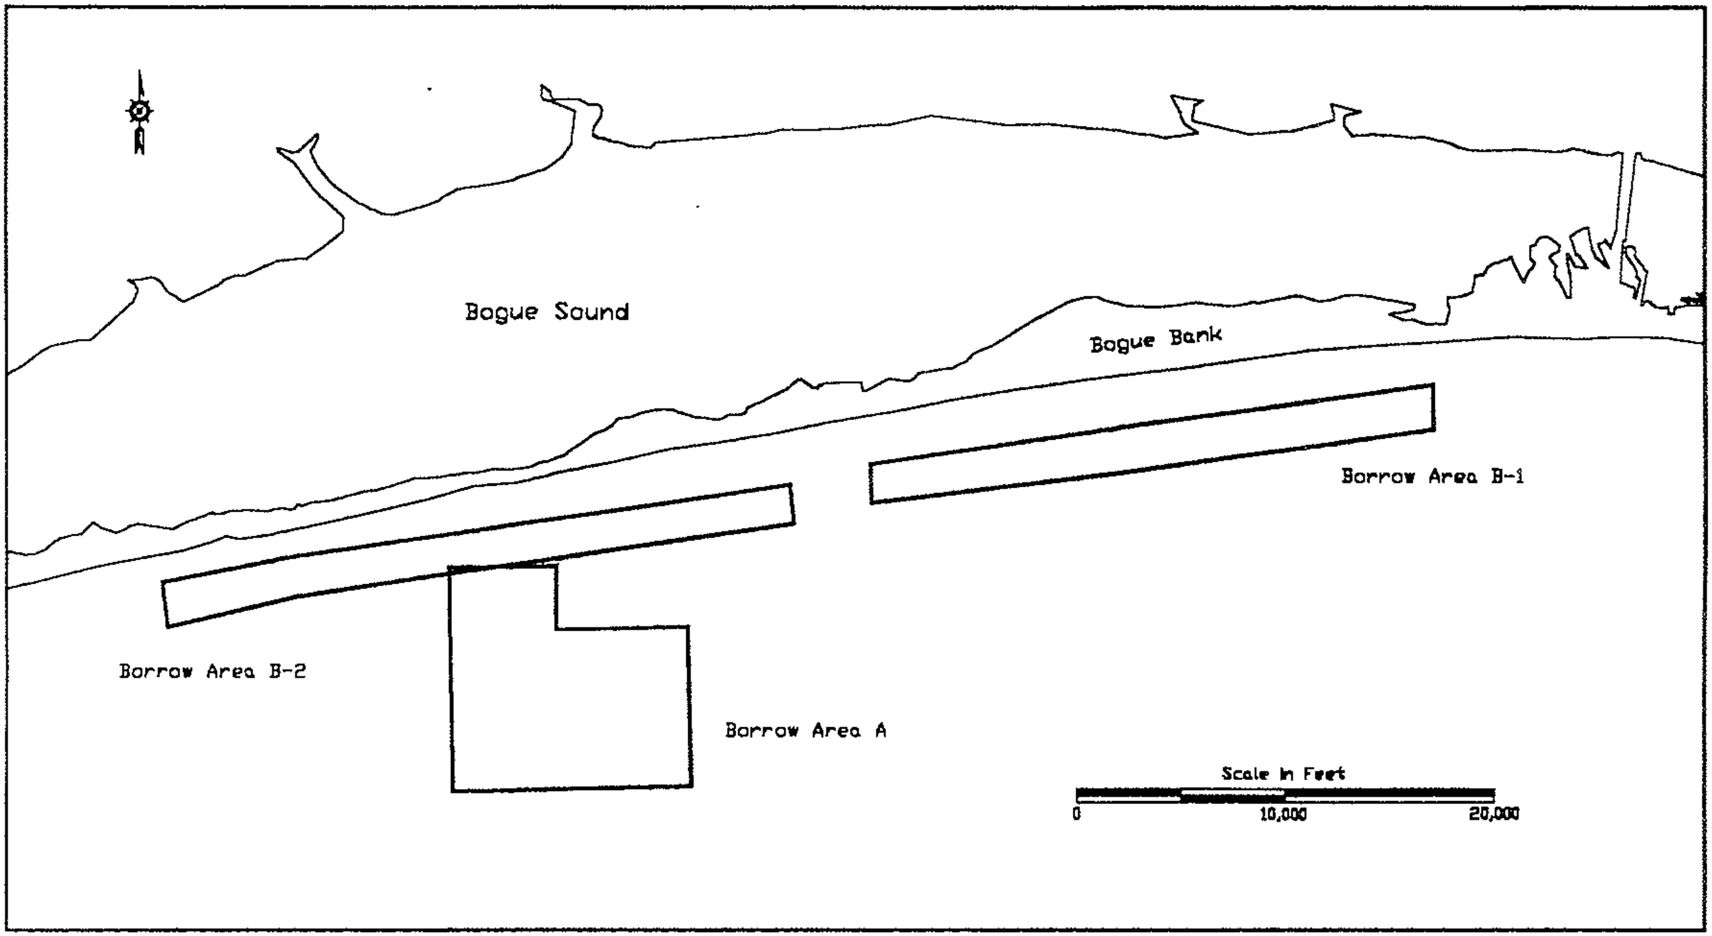

Figure 1. Project Location Map.

Project Research Objectives

The Bogue Banks Borrow Area survey was initiated in order to comply with the criteria of National Historic Preservation Act of 1966, as amended, through 1992 (36 CFR 800, Protection of Historic Properties), the Abandoned Shipwreck Act of 1987 (*Abandoned Shipwreck Act Guidelines*, National Park Service, *Federal Register*, Vol. 55, No. 3, 4, December 1990, pages 50116-50145) and the Secretary of Interior's Standards and Guidelines for Archaeology and Historic Preservation (*Federal Register* 48, No. 190, 1983). In keeping with the intent of that legislation and associated regulations Stroud Engineering and CSE Baird determined that a remote sensing survey would be necessary to assess the potential impact of proposed project activities on submerged cultural resources in the project areas. The remote sensing survey conducted by TAR was designed to identify magnetic and/or acoustic anomalies that might be generated by shipwreck resources, assess the potential significance of each one and determine the necessity for additional investigation designed to generate data to support a preliminary determination of National Register of Historic Places eligibility.

Research Methodology

Literature, Historical and Archival Research

In order to generate historical data to facilitate identification of shipwreck remains in the Beaufort/Morehead vicinity, records from a variety of repositories were examined. At the Underwater Archaeology Unit in Kure Beach, the archaeological site files were surveyed for both historic and prehistoric submerged archaeological sites in the Beaufort Inlet area. Similar surveys of site file inventories were also conducted in the Anthropology Department Research Laboratory and the Program in Maritime History and Underwater Research at East Carolina University in Greenville, North Carolina.

A literature and archival investigation was also initiated by a survey of secondary source materials associated with the historical development of eastern North Carolina. The survey focused on documentation of activities such as exploration, colonization, development, agriculture, industry, trade, shipbuilding, commerce, warfare, transportation and fishing that would have been contributing factors in the loss of vessels in the vicinity of the proposed borrow areas. In examining each of these factors special attention was devoted to activities associated with navigation in the vicinity of Beaufort Inlet.

Preliminary wreck specific information was collected from such secondary sources as: *The Encyclopedia of American Shipwrecks* (Berman 1972); *Merchant Steam Vessels of the United States 1807 - 1868* (Lytle and Holdcamper 1952); *Disasters to American Vessels, Sail and Steam, 1841-1846* (Lockhead 1954); *Shipwrecks of the Civil War, The Encyclopedia of Union and Confederate Naval Losses* (Shomette 1973); *Shipwrecks of the Western Hemisphere* (Marx 1971); *Shipwreck Encyclopedia of The Civil War: North Carolina, 1861-186* (Spence 1991) and other published materials. Additional information was also generated by a survey of selected North Carolina newspapers, the Wreck Information List of the U.S. Hydrographic Office, National Oceanic and Atmospheric Administration and maritime records associated with Beaufort and Morehead City. Select historic maps and charts preserved in the collections of the National Archives Cartographic Branch in College Park, MD and North Carolina repositories of cartographic data were also examined.

Relevant sources of shipwreck data preserved in the North Carolina Division of Archives and History in Raleigh; Underwater Archaeology Unit of the Division of Archives and History at Kure Beach; the Steamship Historical Society, Baltimore; Mystic Seaport Museum, Connecticut; the National Archives and the Mariners Museum at Newport News, Virginia were surveyed for site specific data associated with the Beaufort Inlet, Bogue Bank and Shackleford Bank areas. TAR personnel also contacted and interviewed the head of the Underwater Archaeology Unit, area archaeologists, historians and other individuals knowledgeable in maritime history and shipwreck research to solicit their assistance in generating wreck data.

Field Investigations

To reliably identify submerged cultural resources, TAR conducted a systematic remote sensing survey of the proposed borrow areas identified in the Scope of Work. TAR personnel utilized 31-foot and 25-foot vessels to conduct the survey. In order to fulfill the requirements stated in the Scope of Work, TAR employed both magnetic and acoustic remote sensing equipment. A combination of magnetic and acoustic remote sensing equipment represent the "state-of-the-art" in submerged cultural resource location technology and offers the most reliable and cost effective method of locating and identifying potentially significant targets. Data collection was controlled using a differential global positioning system (DGPS). The DGPS produces the highly accurate coordinates necessary to support a sophisticated navigation program and assure reliable target location.

Magnetic Remote Sensing

An EG&G Geometrics 866 dual channel proton precession magnetometer capable of plus or minus 0.1 gamma resolution was employed to collect magnetic data in the survey areas. To produce the most comprehensive magnetic record, data were collected on a two-second interval and the sensor was deployed and maintained in the water column at a depth of 10 to 12 feet above the bottom surface. An analog recorder provided a continuous permanent record of the magnetic background and target signatures. Because of the historical nature of the area, magnetic data were collected along transects spaced on 100-foot intervals and recorded on both an analog recorder and as a data file associated with the computer navigation system. Data from the survey were contour plotted using QuickSurf computer software to facilitate anomaly location and definition of target signature characteristics. All magnetic data were correlated with the acoustic remote sensing records.

Acoustic Remote Sensing

A 500 kHz Klein 521 high resolution side scan sonar was employed to collect acoustic data in the survey area. During the survey, the side scan sonar transducer was deployed and maintained at a 10-foot elevation above the bottom surface. Because of the historical nature of the area and the requirements for collecting magnetic data, acoustic data were also collected along transects spaced on 100-foot intervals. Sonar range scales were selected to provide a combination of 100% coverage of the survey area and high target signature definition. Acoustic data were recorded on a two channel wet-paper recorder and tied to the magnetic and positioning data by the computer navigation system event marking program.

Positioning System

A differential global positioning system (DGPS) was used to control navigation and data collection in the survey areas. The system has an accuracy of plus or minus three feet, and can be used to generate highly accurate coordinates for the computer navigation system. Differential corrections were received from the United States Coast Guard Beacon at Fort Macon, North Carolina. A Furuno GP-35 differential global positioning system was employed in conjunction with on-board IBM compatible 486-66 BSI and Pentium 233MMX ProStar computers loaded with a Coastal Oceanographics Hypack navigation and data collection software program. All magnetic and acoustic records were tied to positioning events generated by Hypack. Positioning data generated by the navigation system were tied to magnetometer records by regular annotations to facilitate target location and anomaly analysis. Annotations included lane number, date, start and end of lane, direction and target identification.

Data Analysis

To ensure reliable target identification and assessment, analysis of the magnetic and acoustic data were carried out as it was generated. Using QuickSurf contouring software, magnetic data generated during the survey were contour plotted at 10 gamma intervals for analysis and accurate location of the material generating each magnetic anomaly. Magnetic targets were isolated and analyzed in accordance with intensity, duration, areal extent and signature characteristics. Sonagram signatures associated with magnetic targets were analyzed on the basis of configuration, areal extent, target intensity and contrast with background, elevation and shadow image.

Data generated by the remote sensing equipment were developed to support an assessment of each magnetic and acoustic signature. Analysis of each target signature included consideration of magnetic and sonar signature characteristics previously demonstrated to be reliable indicators of historically significant submerged cultural resources. Assessment of each target included recommendations for additional investigation to determine the exact nature of the cultural material generating the signature and its potential National Register significance. Historical evidence was developed into a background that identified possible correlations with magnetic targets. A magnetic contour map of each survey area was produced to aid in the analysis of each target. All targets were listed and described and a map produced that showed their location within the project area.

Historical Overview of Beaufort/Morehead City Vicinity

Among the earliest residents of Shackleford Banks and Cape Lookout during the late 1600s and early 1700s were whalers, who established a series of temporary camps and shelters amid the dunes. By the 1720s, Cape Lookout and Shackleford Banks became a more permanent base of operations for New England whalers (Angley 1982:5). When Beaufort was appointed as "a port for the unloading and discharging [of] vessels," in 1722 it was clear that successful development would also depend on trade entering and clearing through Beaufort Inlet (Paul 1970:370-373; Angley 1982:8). Unlike many of the inlets along the North Carolina coast, Beaufort Inlet was relatively stable and offered a safe and deep channel for ship traffic (Stick 1958:312).

Not all of the vessels bound for Beaufort were successful in navigating the inlet. In November 1718, the pirate Blackbeard lost two vessels on or near the bar. Both the ship *Queen Anne's Revenge* and the sloop *Adventure* were run aground, perhaps deliberately. Many of the crew of the *Queen Anne's Revenge* and the *Adventure* were abandoned on Shackleford Banks while Blackbeard and a hand-picked crew sailed for Bath in the remaining sloop.

Although Beaufort remained a relatively unimportant port during the 18th century it did play a small role in Revolutionary War maritime activity. While the blockade imposed upon the American coast by the British Navy seriously impacted trade for many Colonial ports, shipping through Beaufort provided a portion of the supplies needed by the Patriots in North Carolina. In the years that followed the Revolution, North Carolina experienced an increase in the volume of maritime trade and shipbuilding. Just after the turn of the century, Beaufort Inlet was described as one of the best on the North Carolina coast, with "the channel being generally 3 1/4 to 3 1/2 fathoms" deep. Beaufort was also mentioned as having a fairly vigorous, though small, shipbuilding industry (Tatham 1806). In 1810, Jacob Henry, a former representative from Carteret County to the North Carolina House of Commons, commented upon the local shipbuilding industry at Beaufort:

> The principal trade carried on here is ship building in which they have acquired a very considerable reputation.... Live oak and Cedar are the timbers principally used but the stock is by no means so abundant as it has been. Some of the swiftest sailors and best built Vessels in the United States have been launch'd here, particularly the Ship *Minerva*, a well known Packet between Charleston and New York. There are at present five Vessels at the Stocks, two of which are ready to be launch'd (Newsome 1929:399).

The Beaufort vicinity was severely battered by a hurricane that struck the area in 1815. The storm, later described as "being one of the most violent and disastrous ever known upon the coast," brought about significant changes to the bar at Beaufort. The bar was "injured so that but 12 feet could be brought over it at low water." Fortunately, the channel eventually recovered from the storm's damage and by 1830, the depth on the bar had increased to 18 feet at mean low water. By 1854, the bar channel had decreased to a depth of 15 1/2 feet and migrated slightly to the south (United States Congress, Senate Executive Document, No. 78, 33rd Congress, pp. 3-4).

Around 1841, John Motley Morehead, governor of North Carolina, had a vision of establishing a port facility at the eastern terminus of the Atlantic and North Carolina Railroad. A decision was finally reached in 1855 to locate the proposed port and rail facility on Sheppard's Point (Konkle 1922:339-340).

The editor of the Greensboro *Patriot* described the conditions and natural advantages which he believed would benefit maritime traffic through Beaufort Inlet to the new port facility at Morehead City in September 1858:

> The inlet at Beaufort Harbor is, we understand, about three-quarters of a mile wide, extending from the point on the Shackleford banks on the east to the point at Fort Macon on the west. Ships drawing from eighteen to twenty feet can cross the bar with safety. Ships crossing the bar, enter the harbor near the Shackleford banks, then bear in a westwardly direction toward Fort Macon. From the bar at the inlet, across the Sound to Beaufort, is about three miles, this being about the widest part of the harbor. The channel is in the form of a half-moon, one horn running eastwardly along the Shackleford banks, called Core Sound, and the other westwardly by Morehead and Carolina cities, which are situated on Bogue Sound. The deepest water is along Newport river, which runs in nearly a north direction between Morehead City and Beaufort, touching the railroad wharf in the former place. The main channel is about one mile wide, so that the inside of the channel would be some two miles from Beaufort, though vessels drawing from nine to ten feet water can approach the Beaufort wharves at full tide. Running up the channel about three miles from the bar, we come to the railroad wharf at Morehead City, where vessels drawing eighteen feet can approach with ease, and unload and take in lading with the greatest safety (Konkle 1922:341-342).

Within six months, the rail and port facility at Morehead City was prospering, much to the chagrin of the people of Beaufort. Ships were continually calling at the wharfs and being loaded with cargoes directly from train cars:

> Here a steamer drawing twenty feet of water, and the locomotive weighing twenty or thirty tons, with its whole train, may be along side each other; and this, too, on each side of the wharf at the same time, while in front other vessels may be loading or discharging cargoes (Konkle 1922:360-361).

The development of Morehead City was soon disrupted by the Civil War. On 22 March 1862, Union forces occupied Morehead City. Four days later Union troops crossed the Newport River and took control of Beaufort. Fort Macon also fell into Union forces under General Ambrose E. Burnside following a fierce one-day siege (Stick 1958:148-153). Preceding the final assault on Fort Macon, a Union gunboat and one or two smaller vessels were positioned inside Beaufort Inlet, controlling the approaches and exits to Bogue and Core Sounds. On 22 April, several Union vessels anchored near Harker's Island to the east of Beaufort, including the steamer *Alice Price* that served as General Burnside's temporary headquarters. When the fall of Fort Macon was imminent, Confederate forces burned the bark *Glen* to keep it out of Union hands. On 26 April, Colonel Moses J. White, commander of Fort Macon, surrendered to Generals Parks and Burnside on Shackleford Banks (Angley 1982:34; Stick 1958:148-153).

The occupation of Fort Macon and the surrounding vicinity provided Union naval forces with access to a deep-water port and a place of rendezvous that was used to support the blockading squadron throughout the remainder of the war. During December 1864 and January 1865, fleets under Admiral David Porter massed at Beaufort Harbor in preparation for their assault on Fort Fisher in Wilmington, the last major stronghold of the Confederacy in North Carolina. During the Civil War at least five Confederate vessels were captured at sea in the Cape Lookout area: the schooners *Edwin, Julia, Revere* and *Louisa Agnes* were captured in 1861 and the steamer *Banshee* was taken on 21 November 1863 (Angley 1982:35; Price 1948). One Confederate vessel was lost in the vicinity as a result of enemy action. On 9 July 1864, the side-wheel steamer *Pevensey* was chased ashore and blown up on Bogue Banks, approximately nine miles west of Beaufort Inlet (Hill 1975:11-13). Not all of the known shipwrecks near Beaufort were a result of enemy action. On 12 June 1863, the USS *Lavender* ran aground in heavy seas near Cape Lookout Shoals while en route from the Delaware Capes to Charleston. The *Lavender* was a screw tug of 173 tons. On 20 July 1865, the 186-ton Union screw steamer *Quinnebaugh* went ashore on Beaufort bar in rough weather after her machinery failed. The *Quinnebaugh* was transporting Union troops, refugees and civilians north at the time of her loss (Shomette 1973:88-89; Berman 1972:141; Lytle and Holdcamper 1975:291).

Six years after the Civil War, the federal government began measures to reduce the severity of maritime disasters along the coast by establishing the United States Lifesaving Service. In 1874, seven stations were established along the North Carolina coast. In 1875, a similar station was authorized by Congress for Cape Lookout, though it would be another ten years before it was finally built. Over the following years three other stations were established on Core Banks, and a facility was also established near Fort Macon, just west of Beaufort Inlet (Angley 1982:35-36; Stick 1958:169-170, 310-313).

Menhaden fishing became an important source of income for the Cape Lookout-Beaufort area in the years following the Civil War. From 1865 to 1873, the state's first menhaden processing plant was in operation on Harker's Island. By the turn of the century several plants were in operation at Beaufort and at various points on Bogue and Core Sounds (Hill 1975:16-18).

Growth of Beaufort and Morehead City as ports was slow during the late-19th and early 20th centuries. In the 1880s, the federal government began work on the improvement of Beaufort Inlet in the hopes of increasing the amount of maritime trade to the port communities. The depth over the bar in the later 19th century was just over 15 feet, but it was said that "the harbor entrance was rapidly deteriorating; its width, measured from Fort Macon to Shackleford Point, having increased 500 feet between the years 1864 and 1880" (Stick 1958:312; Angley 1982:39-40). By 1880, the width of the inlet had increased an additional 900 feet. As a means to prevent further erosion, jetties were constructed from both shores into the inlet. Over the next five years, five jetties were constructed on Shackleford Point and another six on Fort Macon Point. By 1889, the deterioration of the inlet had been brought under control (Angley 1982:40; Stick 1958:312).

Between 1905 and 1907, the channel across Beaufort Inlet bar was dredged to a depth of 20 feet at mean low water. A 20-foot channel, 200 feet wide, was also provided inside the inlet to the wharves at Morehead City. A smaller channel, seven feet deep and 100 feet wide, was dredged to the wharves along the Beaufort waterfront (Angley 1982:40). The Army Corps of Engineers submitted several reports between 1907 and 1914 that indicated that both Morehead City and Beaufort were growing centers of maritime trade. The majority of vessels utilizing the two ports were fishing boats and small, shallow-draft cargo vessels (Angley 1982:41). Beaufort Inlet was described in 1907 as being limited in importance:

> The present commerce through the inlet is small, owing in a large measure to the hitherto shallow draft of not generally more than 12 feet at mean low water that could be carried across the bar.
>
> The present annual commerce of Beaufort, N. C., the principal place on the water adjacent to this harbour, amounts to about 64,000 tons annually, valued at $3,500,000, of which only about one-fourth to one-fifth passes through the inlet (United States Congress, House Document No. 1454, p. 3).

Statistics for 1912 reflect that 12 sailing and 35 gasoline powered vessels totaling 570 net tons were registered at Morehead City. For the same year, the registry at the rival port of Beaufort listed 175 sailing vessels, 240 gasoline powered vessels and 6 barges with a net registered tonnage of 6,005 (Angley 1982:42; United States Congress, House Documents No. 1022:4-11 and No. 1108:6-7).

A number of vessels travelling along the coast became victims of maritime hazards. Between 1 July 1898 and 30 June 1908, 82 vessels were reported lost off the North Carolina coast (United States Congress, House Document No. 315, pp. 5-6). Several of those shipwrecks had themselves become hazards to navigation. On 20 and 27 February 1891, notices were printed in the Wilmington *Weekly Star* that the federal government was in the process of removing wrecks that had become obstacles to other vessels:

> Masters and owners of vessels engaged in the coastwise trade will be glad to know that the commanding Officer of the USS *Yantic* has been ordered to cruise along the coast from Sandy Hook to Charleston, S. C. and to destroy, as far as practicable, all abandoned wrecks which are dangerous to navigation. There are a number of these wrecks on the coast of North Carolina and Virginia.
>
> Off the North Carolina coast the *Yantic* will find the schooner *Dudley Farlin*, twenty-four miles northwest of Bodie Island Light; the schooner *Mollie J. Saunders*, seven miles southeast of the same light; the steamer *Glenrath*, south by west of Cape Lookout Light, four or five miles further in shore, the steamer *Aberlady Bay*, and a sunken wreck eighteen miles east-northeast of Frying Pan Shoal Lightship (Wilmington *Weekly Star*, 20 and 27 February 1891).

In a 1897 Congressional report the hazards found at Cape Lookout to maritime traffic were summarized by the captain of the life-saving station at Cape Lookout:

> I ascertain that, since 1888, 19 schooners, 6 steamships, and 1 bark were disabled or ashore around Cape Lookout that would have been unharmed in all probability, if a safe harbor had been near. Two of these steamships and many of the schooners proved total losses. Unknown wrecks are occasionally discovered on or near the shoals. Nine large vessels have been anchored south of the beach at one time during northeasters. When the wind shifted they had to go to sea. Twenty-two schooners have been seen at one time laying to under the lee of Lookout Shoals during a northeast gale, and 57 vessels have been sighted passing by in one day. The locality is being frequented more and more as seafaring men learn the advantage of it. The great danger at present is being caught in the great bight with a southerly gale (United States Congress, House Document No. 25, p. 5).

To prevent vessels from wrecking near Cape Lookout a lighthouse had been in use, but mariners often complained that the light was difficult to see. As a remedy, a lightship was placed at Cape Lookout Shoals in 1904 and remained in operation until 1933 when it was removed (Holland 1968:32-35; Stick 1958:310). In addition to the lightship, a lens lantern was erected in 1900 on Cape Lookout Bight for the "large number of vessels that seek a lee under Cape Lookout" (Holland 1968:32).

During World War I, Cape Lookout Bay served as a rendezvous and staging area for convoys bound for Europe, and Morehead City was occasionally used as a distribution point for war supplies. From 1926 to 1938, the federal government made considerable improvements to the Port of Morehead City by increasing the depth of the channel through Beaufort Inlet to 30 feet (Stick 1952:237-238). In 1923, the tug *Juno* sank in the Beaufort Inlet channel causing considerable difficulty for other vessels to pass. The *Juno* was eventually dynamited to clear the entrance. This earlier event may have been a contributing factor in recognizing the need for channel improvements (*The Evening Dispatch*, 23 July 1923; Berman 1972:128).

Hostilities in the Cape Lookout vicinity were much more evident during the events of World War II. For example, on the night of 18 March 1942, German submarines sank three tankers in the Cape Lookout area: the *Papoose*, the *W. E. Hutton* and the *E. M. Clark*. Five days later another tanker, the *Naeco* was sunk in the same vicinity (Stick 1952:234). As a result of the high number of vessel losses occurring during the early stages of the war, defensive measures were put into place. Coastal communities were systematically blacked out, a more efficient convoy system was devised and additional planes and patrol vessels were put into service for the Cape Lookout area and North Carolina coast in general (Stick 1952:237-239).

In the early 1950s, improvements were once again undertaken at Morehead City. By the summer of 1954, a project to widen the 30-foot channel to 300 feet to the terminal facilities, construct a 600-foot turning basin and dredge a 12-foot channel in Bogue Sound along the city's commercial waterfront was nearly completed (Angley 1982:48). By 1954, the main shipping channel to Beaufort had also been dredged to a depth of 12 feet and a width of 100 feet. The improvements could easily accommodate sports and commercial fishing vessels and pleasure craft, but was inadequate to handle large, deep-draft cargo vessels (Angley 1982:48). Since the mid-1950s, regular maintenance dredging has been undertaken at the channels leading into the Morehead City and Beaufort harbors. Today, Morehead City continues as a major deep-water port with several large vessels arriving monthly.

Summary of Findings

Investigation of the three borrow areas off Bogue Bank identified a total of 10 magnetic anomalies. No magnetic and/or acoustic anomalies were identified during remote sensing of Borrow Area A or Borrow Area B-1 (Figures 2, 3, 4). All ten of the identified anomalies were located in the western part of Borrow Area B-2 (Figures 5, 6). Analysis of the target signatures suggest that seven of the anomalies could be associated with shipwreck remains. It is recommended that those seven targets be avoided. In the event that they cannot be avoided, additional investigation is recommended to identify the nature and assess the significance of material generating the signatures. The remaining three targets contained signature characteristics suggestive of single ferrous objects and are not recommended for additional investigation.

Borrow Area A

No magnetic and/or acoustic targets were identified in Area A.

Borrow Area B-1

No magnetic and/or acoustic targets were identified in Area B-1.

Borrow Area B-2

Target Designation: B2-01

Signature Type: Dipolar

State Plane	Northing	Easting	Intensity	Duration
	2611456	341287	262	6

Potential: Low

Target B2-01 was located in the western end of Borrow Area B-2. The magnetic signature was identified on lane 1 and the contoured signature consisted of data from the anomaly identified as 1.2 in the magnetometer records. The detectable signature had a maximum intensity of 262 gammas and a maximum duration of 6 two-second pulses (Figure 7). The contoured dipolar signature covered an area of approximately 19,800 square feet. No sonar signature was associated with the material generating the magnetic signature. The signature characteristics, intensity and duration suggest that material generating the anomaly could be a single ferrous object such as pipe, cable, anchors or other similar debris. However, as the anomaly lies on the

edge of the survey area, it may potentially be associated with a significant cultural resource adjacent the current project area. In the event that the proposed project would impact the anomaly location, consideration should be given to identifying and assessing the potential historical significance of the material associated with the target.

Target Designation: B2-02

Signature Type: Dipolar

State Plane	**Northing**	**Easting**	**Intensity**	**Duration**
	2612965	341596	59	5

Potential: Low

Target B2-02 was located in the western end of Borrow Area B-2. The magnetic signature was identified on lane 1 and the contoured signature consisted of data from the anomaly identified as 1.1 in the magnetometer records. The detectable signature had a maximum intensity of 59 gammas and a maximum duration of 5 two-second pulses (Figure 8). The contoured dipolar signature covered an area of approximately 11,220 square feet. No sonar signature was associated with the material generating the magnetic signature. The signature characteristics, intensity and duration suggest that material generating the anomaly could be a single ferrous object such as pipe, cable, anchors or other similar debris. However, because of a possible spatial association with targets B2-03, B2-04, B2-06 and B2-09 the target may represent scattered debris associated with a shipwreck. In the event that the proposed project would impact the anomaly location, consideration should be given to identifying and assessing the potential historical significance of the material associated with the target.

Target Designation: B2-03

Signature Type: Dipolar

State Plane	**Northing**	**Easting**	**Intensity**	**Duration**
	2613207	341371	27	5

Potential: Low

Target B2-03 was located in the western end of Borrow Area B-2. The magnetic signature was identified on lane 4 and the contoured signature consisted of data from the anomaly identified as 4.1 in the magnetometer records. The detectable signature had a maximum intensity of 27 gammas and a maximum duration of 5 two-second pulses (Figure 9). The contoured

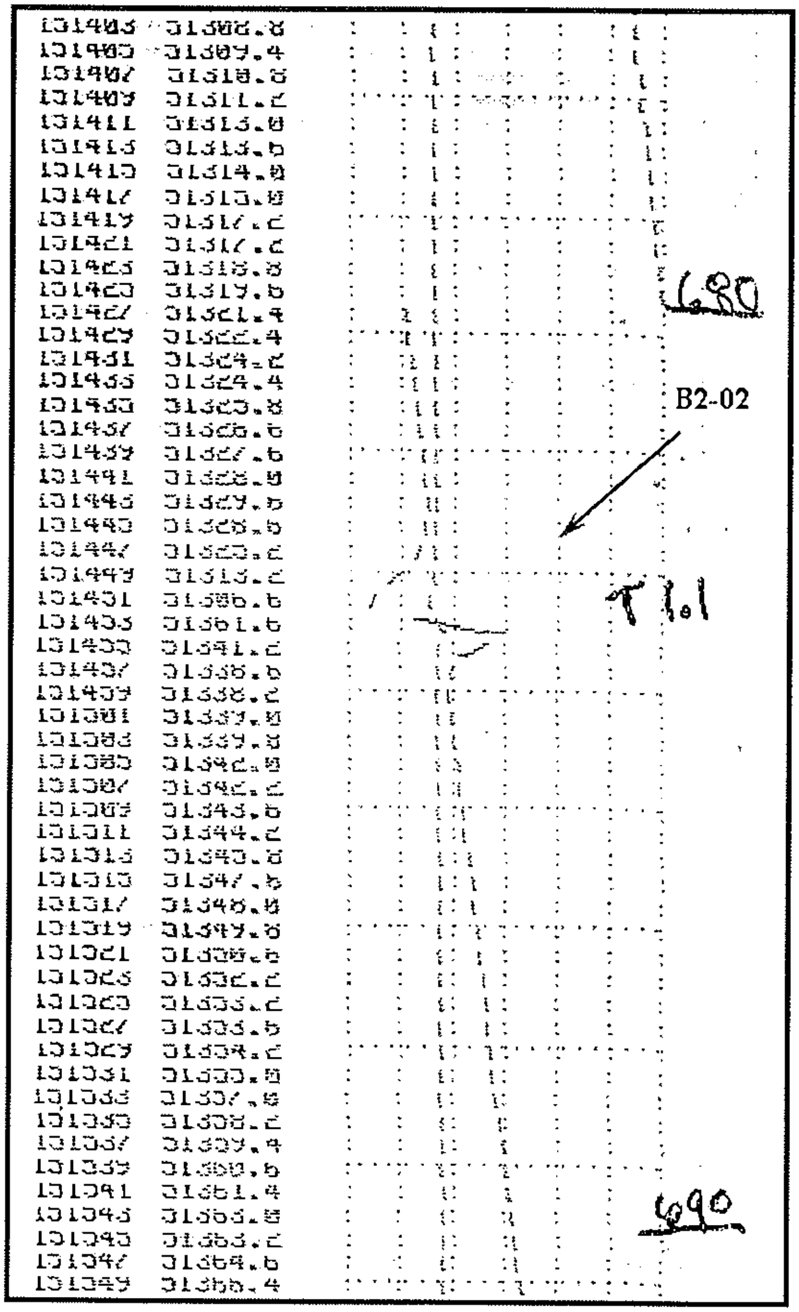

Figure 8. Magnetic Target B2-02.

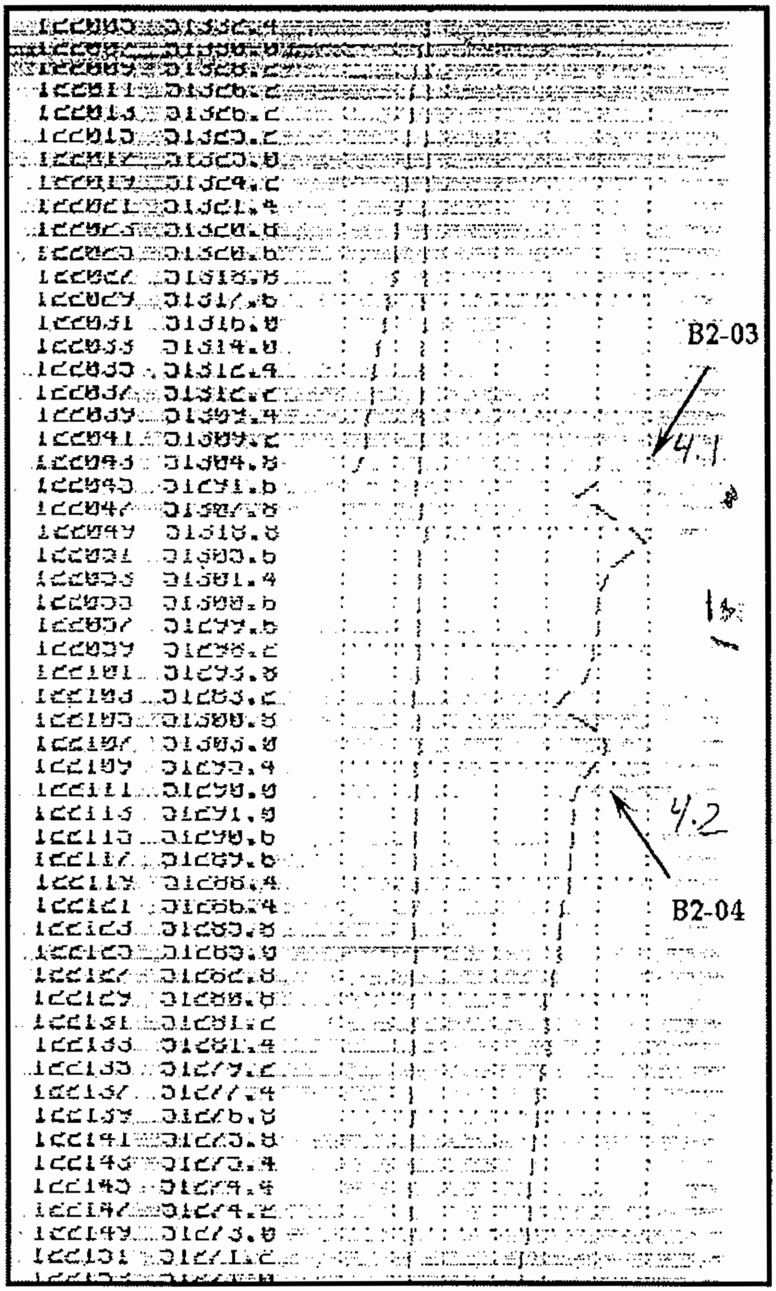

Figure 9. Magnetic Targets B2-03 and B2-04.

dipolar signature covered an area of approximately 8,800 square feet. No sonar signature was associated with the material generating the magnetic signature. The signature characteristics, intensity and duration suggest that material generating the anomaly could be a single ferrous object such as pipe, cable, anchors or other similar debris. However, because of a possible spatial association with targets B2-02, B2-04, B2-06 and B2-09 the target may represent scattered debris associated with a shipwreck. In the event that the proposed project would impact the anomaly location, consideration should be given to identifying and assessing the potential historical significance of the material associated with the target.

Target Designation: B2-04

Signature Type: Dipolar

State Plane	Northing	Easting	Intensity	Duration
	2613393	341404	20	6

Potential: Low

Target B2-04 was located in the western end of Borrow Area B-2. The magnetic signature was identified on lane 4 and the contoured signature consisted of data from the anomaly identified as 4.2 in the magnetometer records. The detectable signature had a maximum intensity of 20 gammas and a maximum duration of 6 two-second pulses (Figure 9). The contoured dipolar signature covered an area of approximately 9,500 square feet. No sonar signature was associated with the material generating the magnetic signature. The signature characteristics, intensity and duration suggest that material generating the anomaly could be a single ferrous object such as pipe, cable, anchors or other similar debris. However, because of a possible spatial association with targets B2-02, B2-03, B2-06 and B2-09 the target may represent scattered debris associated with a shipwreck. In the event that the proposed project would impact the anomaly location, consideration should be given to identifying and assessing the potential historical significance of the material associated with the target.

Target Designation: B2-05

Signature Type: Dipolar

State Plane	Northing	Easting	Intensity	Duration
	2614359	341393	50	5

Potential: Low

Target B2-05 was located in the western end of Borrow Area B-2. The magnetic signature was identified on lane 6 and the contoured signature consisted of data from the anomaly identified as 6.0 in the magnetometer records. The detectable signature had a maximum intensity of 50 gammas and a maximum duration of 5 two-second pulses (Figure 10). The contoured dipolar signature covered an area of approximately 8,000 square feet. No sonar signature was associated with the material generating the magnetic signature. The signature characteristics, intensity and duration suggest that material generating the anomaly could be a single ferrous object such as pipe, cable, anchors or other similar debris. The sharp, low intensity signature does not appear to represent the more complex types often associated with shipwreck remains. No additional investigation of the target is recommended in conjunction with the proposed project.

Target Designation: B2-06

Signature Type: Dipolar

State Plane	Northing	Easting	Intensity	Duration
	2612754	341037	49	7

Potential: Low

Target B2-06 was located in the western end of Borrow Area B-2. The magnetic signature was identified on lane 6 and the contoured signature consisted of data from the anomaly identified as 6.1 in the magnetometer records. The detectable signature had a maximum intensity of 49 gammas and a maximum duration of 7 two-second pulses (Figure 11). The contoured dipolar signature covered an area of approximately 14,025 square feet. No sonar signature was associated with the material generating the magnetic signature. The signature characteristics, intensity and duration suggest that material generating the anomaly could be a single ferrous object such as pipe, cable, anchors or other similar debris. However, because of a possible spatial association with targets B2-02, B2-03, B2-04 and B2-09 the target may represent scattered debris associated with a shipwreck. In the event that the proposed

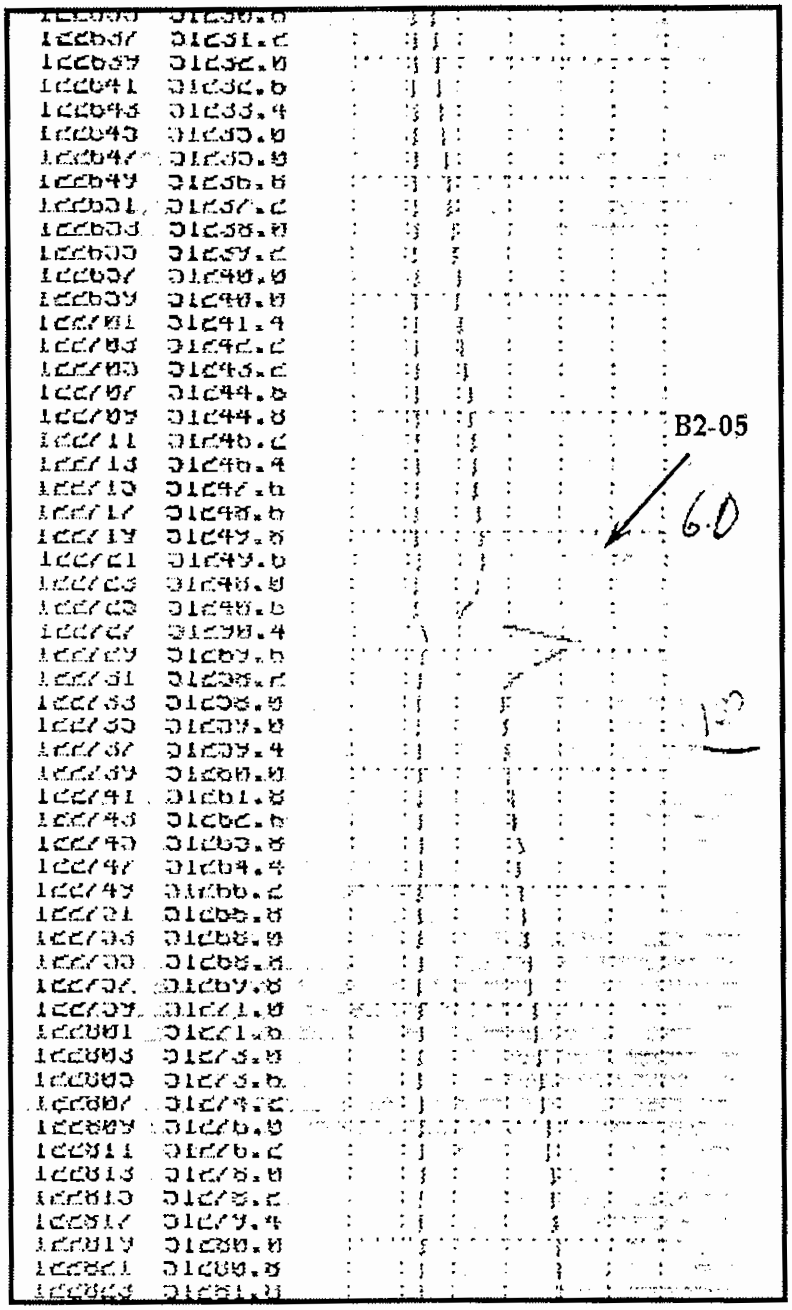

Figure 10. Magnetic Target B2-05.

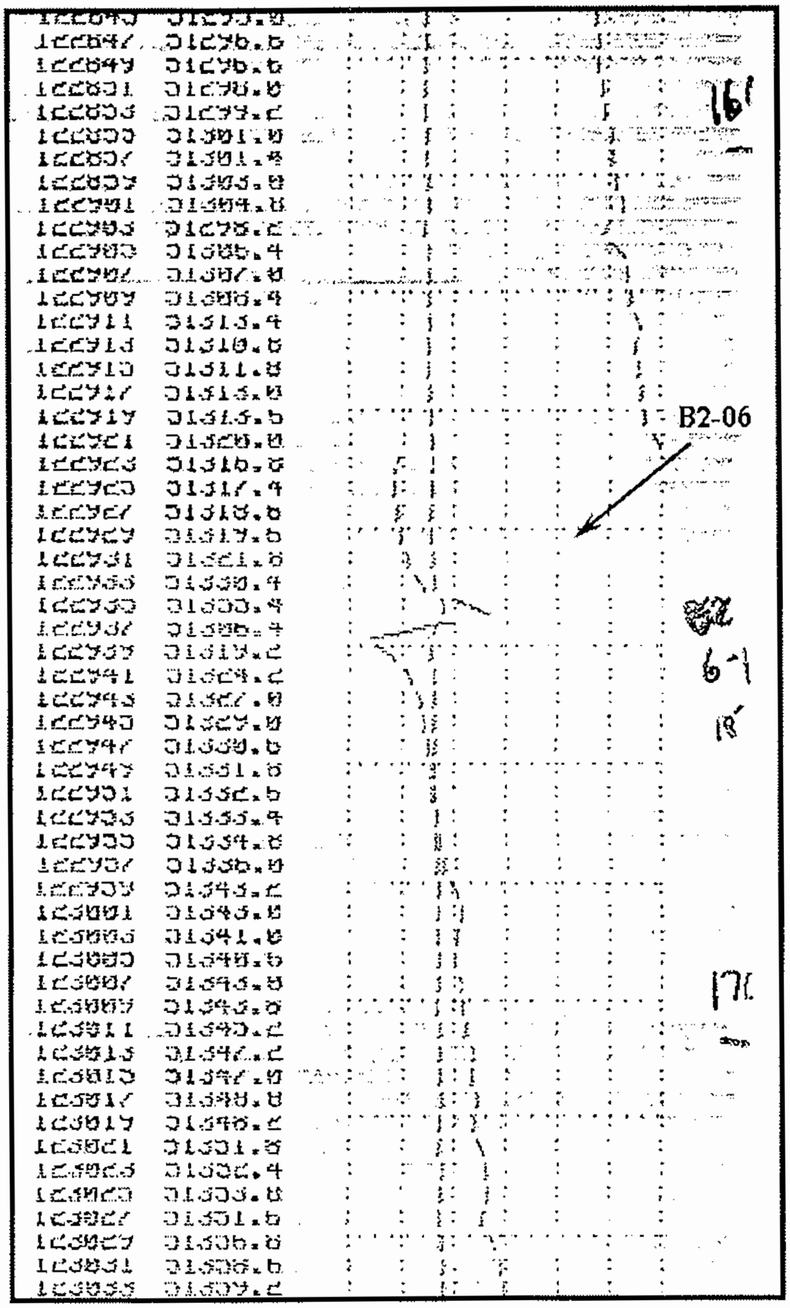

Figure 11. Magnetic Target B2-06.

project would impact the anomaly location, consideration should be given to identifying and assessing the potential historical significance of the material associated with the target.

Target Designation: B2-07

Signature Type: Positive Monopolar

State Plane	Northing	Easting	Intensity	Duration
	2611216	340557	82	5

Potential: Low

Target B2-07 was located in the western end of Borrow Area B-2. The magnetic signature was identified on lane 8 and the contoured signature consisted of data from the anomaly identified as 8.1 in the magnetometer records. The detectable signature had a maximum intensity of 82 gammas and a maximum duration of 5 two-second pulses (Figure 12). The contoured positive monopolar signature covered an area of approximately 12,000 square feet. No sonar signature was associated with the material generating the magnetic signature. The signature characteristics, intensity and duration suggest that material generating the anomaly could be a single ferrous object such as pipe, cable, anchors or other similar debris. The sharp, moderate intensity signature does not appear to represent the more complex types often associated with shipwreck remains. No additional investigation of the target is recommended in conjunction with the proposed project.

Target Designation: B2-08

Signature Type: Dipolar

State Plane	Northing	Easting	Intensity	Duration
	2610512	340108	22	7

Potential: Low

Target B2-08 was located in the western end of Borrow Area B-2. The magnetic signature was identified on lane 11 and the contoured signature consisted of data from the anomaly identified as 11.1 in the magnetometer records. The detectable signature had a maximum intensity of 22 gammas and a maximum duration of 7 two-second pulses (Figure 13). The contoured dipolar signature covered an area of approximately 11,310 square feet. No sonar signature was associated with the material generating the magnetic signature. The signature characteristics, intensity and duration suggest that

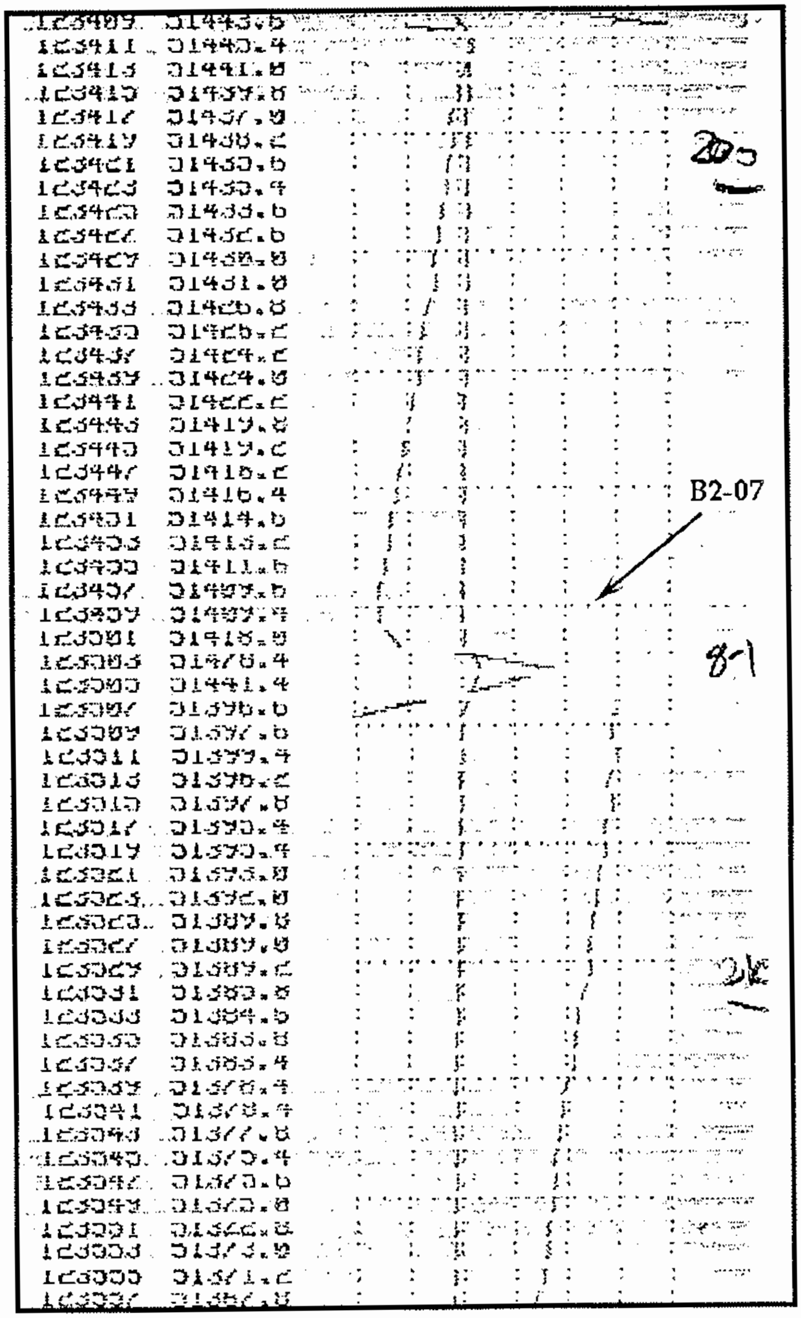

Figure 12. Magnetic Target B2-07.

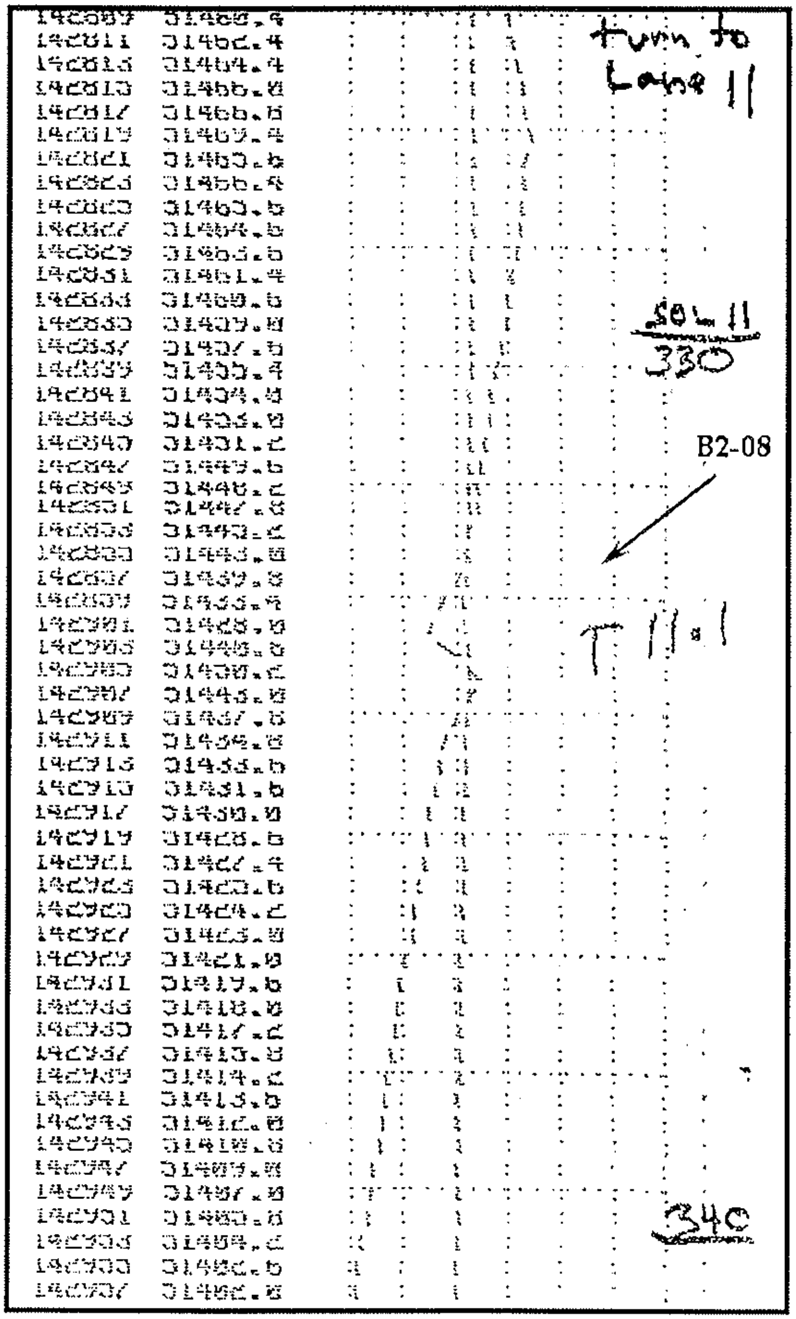

Figure 13. Magnetic Target B2-08.

material generating the anomaly could be a concentration of ferrous objects such as the fasteners of a vessel or other similar hardware. It is possible that the anomaly could be associated with the remains of a vessel as the signature characteristics are similar to those low intensity and long duration anomalies demonstrated to be associated with the remains of wooden hull vessels. In the event that the proposed project will impact the anomaly location, consideration should be given to identifying and assessing the potential historical significance of the material associated with the target.

Target Designation: B2-09

Signature Type: Negative Monopolar

State Plane	Northing	Easting	Intensity	Duration
	2613222	340888	49	5

Potential: Low

Target B2-09 was located in the western end of Borrow Area B-2. The magnetic signature was identified on lanes 8 and 9 and the contoured signature consisted of data from the anomalies identified as 8.2 and 9.1 in the magnetometer records. The detectable signature had a maximum intensity of 49 gammas and a maximum duration of 5 two-second pulses (Figure 14). The contoured negative monopolar signature covered an area of approximately 23,000 square feet. No sonar signature was associated with the material generating the magnetic signature. The signature characteristics, intensity and duration suggest that material generating the anomaly could be a single ferrous object such as pipe, cable, anchors or other similar debris. However, because of a possible spatial association with targets B2-02, B2-03, B2-04 and B2-06 the target may represent scattered debris associated with a shipwreck. In the event that the proposed project would impact the anomaly location, consideration should be given to identifying and assessing the potential historical significance of the material associated with the target.

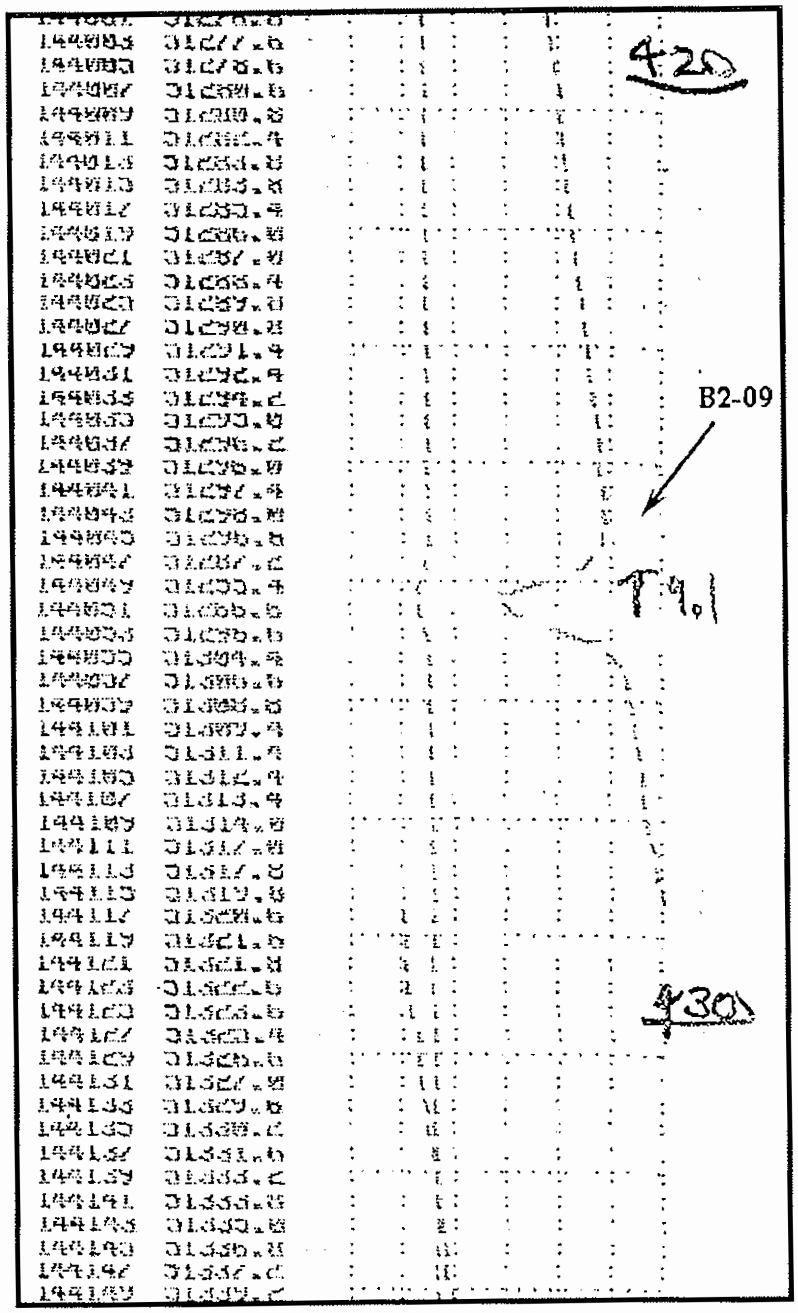

Figure 14. Magnetic Target B2-09.

Target Designation: B2-10

Signature Type: Multi-component

State Plane	Northing	Easting	Intensity	Duration
	2611288	339080	32	7

Potential: Low

Target B2-10 was located in the western end of Borrow Area B-2. The magnetic signature was identified on lane 23 and the contoured signature consisted of data from the anomaly identified as 23.1 in the magnetometer records. The detectable signature had a maximum intensity of 32 gammas and a maximum duration of 7 two-second pulses (Figure 15). The contoured multi-component signature covered an area of approximately 14,250 square feet. No sonar signature was associated with the material generating the magnetic signature. The signature characteristics, intensity and duration suggest that material generating the anomaly could be a single ferrous object such as pipe, cable, anchors or other similar debris. The sharp, low intensity signature does not appear to represent the more complex types often associated with shipwreck remains. No additional investigation of the target is recommended in conjunction with the proposed project.

Conclusions and Recommendations

A survey of historical and archaeological literature and archival background research confirmed considerable evidence of maritime activity along the southeastern North Carolina coast. That evidence suggests a high probability for submerged cultural resources in the waters around Beaufort Inlet. Discovery of what appears to be the remains of Blackbeard's *Queen Anne's Revenge* and several Civil War vessels reinforce that hypothesis. Both Beaufort and Morehead City provided early settlers with centers of transportation and trade and bases of operations to exploit the natural resources of the Carolina coast. Yet in spite of nature and the scope of maritime activity, there is only one reference to a specific vessel lost in the immediate vicinity of the proposed project. That vessel is the Civil War blockade runner *Pevensey* that was run ashore at the site of the Iron Steamer Pier. No known sites exist in the survey areas in the files of the Underwater Archaeology Unit of the Division of Archives and History.

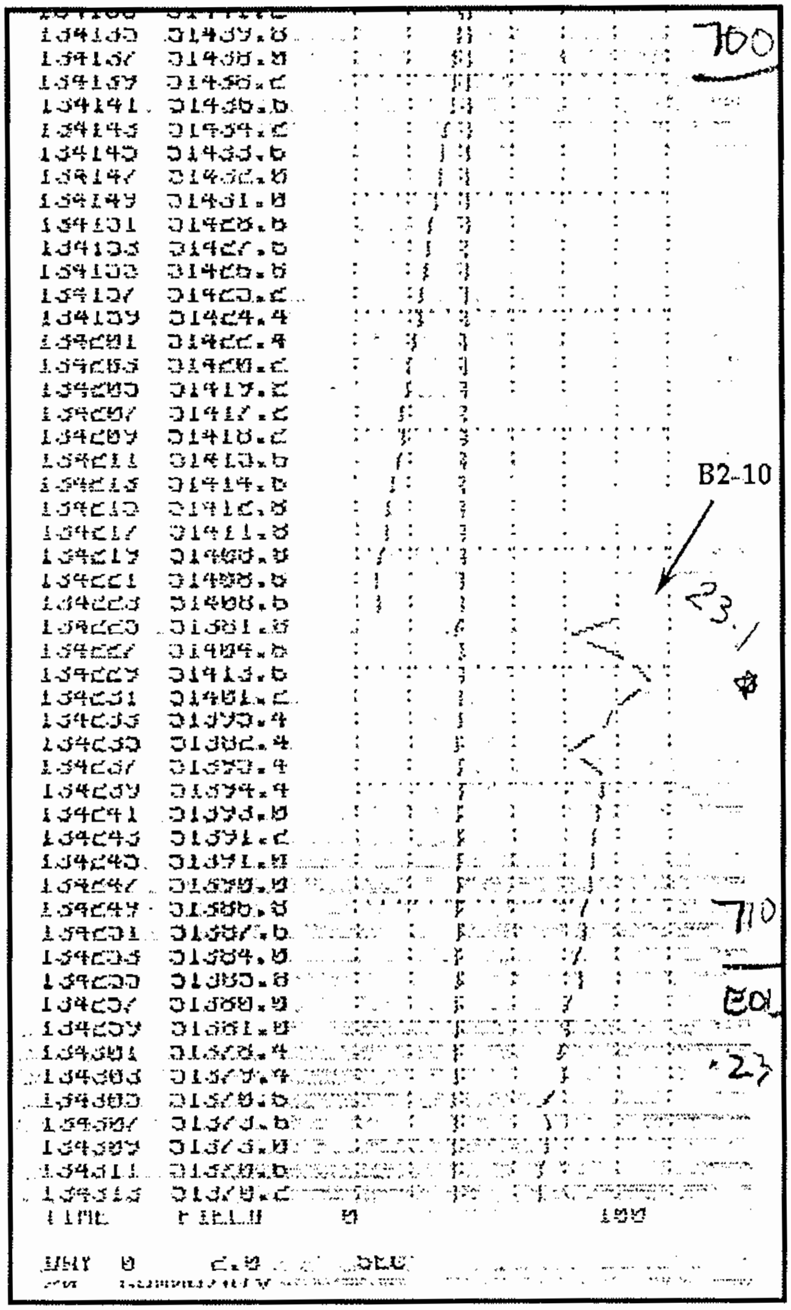

Figure 15. Magnetic Target B2-10.

Analysis of the remote sensing data revealed no magnetic and/or acoustic anomalies in either Borrow Area A or Borrow Area B-1. On the basis of that analysis, no additional investigation of the area is recommended in conjunction with the proposed project.

Analysis of the remote sensing data for Borrow Area B-2 confirmed the presence of 10 magnetic anomalies in the western part of the survey area. Seven of those targets contained signature characteristics consistent with significant submerged cultural resources. Analysis of the target signatures suggests that five of the anomalies, B2-02, B2-03, B2-04, B2-06 and B2-09, may be spatially associated and could represent scattered debris from a shipwreck. Another target, B2-08, contained signature characteristics similar to those commonly associated with wooden hull vessels. Though the final anomaly, B2-01, exhibited signature characteristics suggestive of a single ferrous object its location along the northern edge of the survey area does not rule out a possible association with a significant cultural resource lying adjacent to the project area. The remaining three targets, B2-05, B2-07 and B2-10, contained signature characteristics suggestive of single ferrous objects. With the exception of the above seven anomalies, the proposed project will have no impact on potentially significant submerged cultural resources.

In order to provide reasonable assurance that proposed dredging does not impact targets B2-01, B2-02, B2-03, B2-04, B2-06, B2-08 and B2-09, a buffer zone should be established around each anomaly location. Unfortunately, there is no concrete data regarding the establishment of an effective buffer zone around submerged cultural resource sites. In the absence of such data and due to the nature of the high energy environment off Bogue Banks, it may be appropriate to establish a buffer zone 250 feet in circumference around the center of the target coordinates. In order to assess the buffer zone effectiveness, the target environment at each site should be periodically monitored to determine what, if any, change has occurred. In the event that the target locations cannot be avoided, diver investigation of the seven anomalies is recommended to identify and assess their National Register of Historic Place's eligibility.

TABLE OF CONTENTS

1. Introduction/Purpose

This benthic assessment was conducted under contract with Carteret County, North Carolina in anticipation of a beach renourishment project for Bogue Banks. The purpose of this report is to describe the results of a single fall 1999 sampling of the benthic invertebrates and surficial sediments at the offshore borrow areas and nearby controls and the results of three (late fall-winter-spring) sets of trawl samples for demersal fishes and invertebrates around the borrow areas. This information may ultimately be incorporated into a monitoring scheme and helps in the short term to describe the biological resources at risk in the offshore system. Benthic invertebrates are commonly used in environmental assessments because they are sedentary and show the imprint of any environmental perturbation and because they are important trophic links to higher levels on the food chain, demersal predatory fishes, birds, and crustaceans (Warwick 1993). Many of these consumers have value as targets of commercial and/or recreational fisheries or as attractive charismatic wildlife (McLachlan 1983).

There are several environmental issues relating to the benthic habitat and biological resources that arise in considering a beach renourishment project (e.g., Naqvi and Pullen 1982, Reilly and Bellis 1983, Nelson 1989, Van Dolah et al. 1992, Peterson et al. 2000). The most significant include: (1) impacts to and recovery of the benthic invertebrate community at the borrow areas; (2) potential impacts to commercially or recreationally important demersal fishes and crustaceans in part because of these effects on their benthic invertebrate prey; (3) impacts to and recovery of the benthic invertebrate community on the intertidal and shallow subtidal beach; and (4) potential impacts to commercially and recreationally important fishes in the surf zone and/or shorebirds in large part because of these effects on their benthic invertebrate prey and because of enhanced turbidity along the shoreline.

Each of these issues deserves consideration and typically requires some field monitoring before and after renourishment to evaluate the actual resulting impacts. Because the benthic invertebrate community at the offshore borrow sites changes across the seasons, it is appropriate to sample in multiple seasons (fall and spring, at a minimum, but during four seasons in most previous studies – see Van Dolah et al. 1994) both before and after the renourishment project to assess impacts and recovery. Because renourishment was originally planned for winter 2000-2001, an initial set of samples was collected in the late fall of 1999 to provide fall baseline data to characterize the benthic invertebrate community at the prospective offshore borrow sites and at nearby control sites, which were not planned to be mined, prior to any disturbance from the renourishment project. This report includes a description of results from an analysis of the fall1999 samples. We also include here a complete analysis of composition of surface sediment samples in each of the borrow sites and control sites so as to characterize the sedimentary habitat in which the invertebrates live. Sedimentary habitat is the prime factor that controls abundance and composition of soft-bottom invertebrate communities (Snelgrove and Butman 1994).

The test of the impacts of removing sand from any of the three "Borrow Areas" A, B1, and B2 (Fig. 1) requires the use of a BACI (Before-After-Control-Impact) experimental design (Green 1979, Stewart-Oaten et al. 1986). Such a design is required to separate spatial and temporal variation from impacts of the sand mining activity. In a BACI design, samples from impact (Borrow) areas would be compared with those from control (undisturbed) areas both before and after the sand is removed. Control areas would have no sand removed but would otherwise be affected by all other impacts, i.e. storms, shrimping, etc., that affect the impact area. These samples taken before the removal of the sand can be compared with identically conducted samplings made after sand mining to evaluate impacts. In addition, the design also calls for spring sampling both before and after the removal of sand to assess the seasonal component, for a minimum of 4 sampling periods to complete the assessment of impacts. This report describes only the first of those samplings and thus does not include any spring sampling of the Borrow Areas or any sampling of the intertidal beaches.

Assessment of the significance of the offshore mining of sands for the renourishment also involves evaluation of potential impacts on demersal fishes and crustaceans at the Borrow Area (e.g., Van Dolah et al. 1992). Impacts could occur directly during sand mining and indirectly through modification of the prey community. This effect on prey could last for some unknown time. The fish and crustacean community also changes seasonally so sampling is needed to document presence and relative abundance of demersal fish and crustaceans and to describe their utilization of benthic invertebrate prey. This report describes results of trawl sampling on three dates, late fall, winter, and spring.

No sampling has yet taken place to serve explicitly as the before-renourishment monitoring data for the intertidal invertebrates of Bogue Banks beaches or for sea turtles. The invertebrate community of the intertidal beaches is so strongly seasonal and dynamic within the warm season that sampling to provide baseline information should most appropriately occur throughout the warm season, with subsequent identically designed sampling to assess potential impacts and recovery but after the project has been completed. The complete design for such beach monitoring would include "before and after" (BACI) sampling of control beaches where no renourishment occurs (Green 1979, Stewart-Oaten 1986).

2. Description of Sampling and Analytic Methodologies

A. Benthic Invertebrate Resources

Core sampling was conducted during late fall 1999 from 20 sites, 10 of which were inside and 10 of which outside the three potential borrow areas (Fig. 1). This sampling produced a total of two hundred core samples to characterize the invertebrate macrofauna at all three prospective borrow sites and at control sites near each borrow site (Fig. 1). Ten replicate core samples were taken at each of six sites in Borrow Area A and at each of two sites from Borrow Area B-1 and Borrow Area B-2. Ten replicate cores were also taken at each of ten control sites: six around Borrow Area A and two near each Borrow Area B site. Exact locations of each site were determined using a handheld GPS with differential receiver (Table 1). Water depths ranged from 35 feet at the inshore sites to 47-49 feet at the offshore sites. Cores were taken by divers using a cylindrical corer 9.9 cm in internal diameter (each covering a surface area of 76.4 cm^2) with 500-μm mesh across the top to prevent loss of surface animals. Replicates were haphazardly positioned at each systematically distributed (see Fig. 1) sample station within a 3-m^2 area. All core samples were taken to a depth of 10 cm. After being transported to the boat, the contents were emptied from the core tubes into plastic bags, labeled, and sealed. Immediately upon returning to the lab, the material from the cores was sieved through a 500-μm mesh. Material retained on the sieve was preserved in a 5% aqueous solution of buffered formalin. Rose Bengal vital stain was added to the samples to facilitate sorting. After a week, the formalin was drained off through a 500-μm sieve and replaced with 70% ethanol. Subsequently, animals were separated from detritus by hand picking and identified to family. Several benthic impact studies including especially those by Warwick (1988) of IMER in Plymouth, England have demonstrated that analysis of response at the level of family preserves all the information about community patterns without the high costs of proceeding to species level.

At the same time that the macrofaunal cores were taken, divers collected three 2.65cm-diameter cores to a depth of 2 cm at each site to sample the meiofauna (fauna smaller than 0.5mm and greater than 0.063mm). These samples were iced onboard ship, preserved in the lab with a 5% aqueous solution of formalin, and archived for possible analysis, if required.

Benthic sled sampling was used to collect belt transect samples of larger, more sparsely distributed animals such as hermit crabs and sand dollars. The sled has matching steel blades on both the top and the bottom so that it functions properly no matter how it lands on the bottom. To produce a belt transect, the sled (25 cm tall with a 63 cm wide blade) was towed 15.8 m along the bottom by a line extending to the boat and sampled the top 6 cm of sediment. Sediment passes through the 6 mm mesh and larger organisms are retained. A taut-line buoy attached to the sled allowed for accurate positioning along the marked course. We sampled only on a flat-calm day (9 December 1999) at sea to prevent the sled from bouncing and to control its positioning. Using this sled, we took 40 belt transect samples of 10 m^2 each. This design yielded two replicate belt transect samples at each of the 20 sampling sites (Fig. 1). Animals found in the sled samples were identified, counted, and recorded. Species not immediately identifiable in the field were collected and returned to the lab for identification.

B. Demersal Fish and Crustaceans

In order to provide a semi-quantitative characterization of demersal fishes and crustaceans, including commercially or recreationally important species, that occupy the potential borrow areas and may conceivably be impacted directly by dredging operations or indirectly by loss of their benthic invertebrate prey, we sampled the demersal species of the three borrow areas. This sampling design is similar to that conducted by Van Dolah et al. (1994) in assessing impacts of sand mining on demersal fishes and invertebrates for beach renourishment at Folly Beach, South Carolina. Replicate trawl samples were taken on 29 November 1999, on 4 February 2000, and on 11 May 2000 from the R/V Capricorn using timed 20-minute otter-trawl tows at 4.02k/hr with a 12.3-m otter trawl. Thus the trawl would cover 16,492 m^2 of bottom area if there were no currents. The actual bottom area covered varied according to wind and tidal currents during any specific tow, which is why tows were standardized by time and speed rather than distance covered. These trawl samples were distributed as follows: 4 in Borrow Area A and 2 in each of Borrow Areas B-1 and B-2. The contents of each tow were identified to species, counted, and recorded. In addition, stomachs of up to 20 replicate individual fish of the most abundant species were removed, and preserved by formalin injection onboard ship. Stomach contents for up to twenty of the eight most common fish species from the November trawl survey were identified (when possible) and divided into major taxonomic group (e.g. polychaete, decapod, bivalve, etc.). Fish guts were examined from both inshore areas and offshore areas when possible. The divided categories were then weighed to the nearest 0.0001 g. Detailed inspection of some of the diet remains allowed identification to the family, genus or species level of some of the gut contents.

C. Sediments

At each site where macrofaunal cores were collected, divers also took core samples for grain-size analysis of sediments. Composite bottom samples were obtained at each of the ten Borrow Area sites and each of the ten control sites. Using PVC sampling tubes (16.5 cm [6.5 in] long and 2.5 cm [1 in] wide), divers collected 3 replicate samples of the upper 2 cm of the bottom within a 3-m^2 area at each of the twenty sites. Sample tubes were tightly capped, then brought to the surface and returned to the laboratory for analysis. Loss of fine-grained material, which can occur with conventional grab samplers, is minimized by using diver collections. Samples were assumed to be representative of the surficial material in which most of the macrofauna live.

In the laboratory, the replicate sediment samples were combined in a single container, then washed three times to remove salts and placed in a drying oven. After recording the bulk sample weight, a Calgon dispersant was added and the fine-grained (mud) component (by definition less than 0.063 mm diameter) was rinsed through a #230 mesh wet sieve. The remaining material (sand + gravel/coarse shell) was reweighed and prepared for sieve analysis. Prior to sieving the sand-sized fraction, the gravel/coarse shell fraction (by definition more than 2 mm in diameter) was removed with a #10 mesh sieve and weighed. A Tyler mechanical splitter was used to obtain a 25 g subsample of the remaining material (sand) which was then sieved at ¼ phi intervals (Carver 1971).

Each sieve stack was placed in a mechanical ro-tap for 20 minutes. Individual sieve fractions were weighed and recorded. Small amounts of fine-grained sediment that had not previously washed through the wet sieve were collected in a pan at the bottom of the sieve stack and, for computational purposes, were included with the wet-sieved material. Percentages of gravel/coarse shell, sand, and fine-grained sediment were computed from the bulk sample weights, and percentages of each size fraction in the sand range were computed from the 25 g splits that were sieved. Mean and standard deviation were computed using Excel software and mean phi values were converted to millimeters using the standard conversion, $phi = -log_2(mm)$, where mm corresponds to the intermediate diameter in mm (Folk 1974).

3. Results

A. Benthic Invertebrate Resources

Table 2 (2a for per-core results and 2b normalized to per square meter) presents the results of analyses of the 200 core samples taken to describe the benthic macrofauna at the three Borrow Areas and the surrounding Controls for each. Total macrofaunal densities were slightly greater at the offshore sites (14.1 invertebrates per core at Borrow Area A and 9.3 per core averaged over nearby Control sites) than at the inshore sites (9.7 invertebrates per core averaged over Borrow Areas B-1 and B-2 and 6.6 per core averaged over nearby Control sites). Results suggest slightly higher macrofaunal abundances in the Borrow Areas than in their respective Control Areas (Fig. 2). To test whether these possible differences are the consequence of differences in surficial sediments, we regressed average invertebrate density in cores against mean phi for each sampling site, conducting a separate analysis for the offshore and inshore sites. The inshore sites revealed no significant relationship (Fig. 3a) with a p-value of 0.28. The analogous regression for the offshore sites (Fig. 3b) was statistically significant at $p < 0.0001$, but the direction of the effect was reversed from normal expectation. Benthic infaunal abundance might normally be expected to be lower where sediments are coarser except when fine sediments are organically rich enough to create local reducing conditions and generate toxic hydrogen sulfide. However, here the two anomalous treatment sites in the offshore area with high shell content and low phi values had the highest densities of infaunal invertebrates (Fig. 3b). This relationship may be the indirect consequence of surficial shell inhibiting fish and invertebrate predation on infauna.

The higher taxonomic composition of the benthic infauna sampled in cores did not vary greatly over the sample sites. Over all sites polychaetes accounted for 65 % to 75 % of the total macrofauna in these late-fall 1999 samples. Because of the dominance by polychaetes, they exhibited the same patterns across depth and treatment (Fig. 4) as the total macrofauna (Fig. 2). Other common groups in order of abundance were bivalves (Fig. 5), nemerteans, small crustaceans, echinoderms, and gastropods (Fig. 6). The Appendix presents all the raw data.

Table 3 (3a for per-belt transect results and 3b normalized to per square meter) describes the results of analysis of all 40 belt transects for larger benthic invertebrates. The inshore sites revealed higher numbers of these larger invertebrates than the offshore sites. Borrow Area A contained 3.1 larger invertebrates per $10m^2$ belt transect and its nearby Control sites averaged 2.8, as compared to the average of Borrow Areas B-1 and B-2, which was 0.7 and their nearby control sites of 1.2 (Table 3). No consistent difference appeared between Borrow and Control Areas in this data set (Fig. 7). Gastropods were the most common taxon represented in these samples (Fig. 8), followed by echinoderms (Fig. 9).

B. Demersal Fish and Crustaceans

Trawl sampling detected relatively large numbers of demersal fishes occupying the seafloor habitat during late fall, declining by early February, and increasing again by early May (Table 4 presents the results of trawling for fishes and crustaceans on 29 November 1999; Table 5 presents the 4 February 2000 results; and Table 6 presents the 11 May 2000 results). Fish and mobile crustaceans caught in the trawls showed site averages ranging from 16,531 to 37,149 per km^2 in November, from 1,087 to 9,882 per km^2 in February, and 488 to 120,536 per km^2 in May (Tables 4-6).

In November, offshore areas were dominated by spot, which accounted for more than 50% of total catch and was sufficiently abundant there to create a pattern of slightly higher fish densities offshore than inshore. In addition to spot, pinfish, pigfish, and croaker were the most common species offshore (Table 4a). Inshore fishes were dominated by croaker, silver perch, silversides, pinfish, and sea mullet (Table 4b).

The abundance of most fish species had decreased by 4 February. This February sampling took place after a 3-week cold spell, the first prolonged cold weather of the winter of 1999-2000. The contents of these February 2000 samples (Table 5a,b) contrasted with those of November 1999 (Table 4a,b), showing an average reduction in catch by 81%. Catch in February from inshore stations was 41% and of offshore stations 3.7% of the corresponding catches in November. The abundances of two commercially and recreationally important species, spot and croaker, which made up 51% of the fall catch, dropped by 98.9% and 99.8% respectively. In February, pinfish, menhaden, and silversides made up 96.4% of the total catch. Spot, croaker, pigfish, sea mullet, and silver perch all showed large declines from November to February in both inshore and offshore areas. Pinfish catch in offshore areas was greatly reduced in February compared to November; however, inshore catches of pinfish were similar across dates. Two species of fish, menhaden and southern flounder (both found only in the inshore area), were more abundant in February than in November.

Our sampling on 11 May 2000 revealed higher total abundance of fishes in the inshore areas than we observed in either of our earlier samplings, but total fish abundance in the offshore borrow areas was intermediate between the December and February counts (Table 6a,b). Catch in May from the inshore stations was 1200% higher (Table 6a) than in February, largely due to increases in Atlantic silversides and Atlantic thread herring. In the offshore stations, catch in May was 1600% greater (Table 6b) than observed in February. Pigfish and scup largely accounted for this enhancement in total fish abundance in the offshore.

Examination of the stomach contents of the eight most abundant fish (croaker, gray trout, pinfish, pigfish, sea mullet, silver perch, silversides, and spot) taken from the November 1999 sampling demonstrated that many of the benthic invertebrates found in core samples and belt transects were major diet items of these fish (Table 7). Only about half of all stomachs examined were empty, with some variation among species. Major prey species for croaker and pinfish included polychaete worms, bivalves, and occasionally small shrimp (primarily grass shrimp, *Palaemonetes* sp.) and crabs (primarily pinnotherid crabs). Shrimp (both *Palaemonetes* sp. and penaeids) and to a lesser degree portunid crabs were the primary prey species found in the stomachs of gray trout. Sea mullet prey items were dominated by pinnotherid and portunid crabs and large polychaete worms. Small grass shrimp and other bottom-dwelling crustaceans (amphipods and isopods) were the dominant prey found in silver perch stomachs. Pigfish stomachs contained primarily polychaetes with an occasional grass shrimp present. Some polychaetes and small crustaceans (isopods, cumaceans, and amphipods) were found in the stomachs of spot, but stomachs were relatively empty compared to other species. Finally, silversides fed primarily on harpacticoid (benthic dwelling) and calanoid (planktonic) copepods.

Comparisons between stomach contents of fish collected from inshore and offshore locations were possible for six of the eight species that were caught in abundance in both areas (croaker, gray trout, pinfish, silver perch, silversides, and spot). Examination of the data revealed no consistent pattern in either the proportion of empty stomachs or major prey items between the two areas.

C. Sediments

Data are summarized in Table 8; individual size frequency curves and histograms are provided in Figure 10. With the exception of two treatment sites in Borrow Area A, sands comprised at least 90% of the bottom sediment by weight. In all cases, muds comprised less than 4% of the sediment by weight. Visual inspection of the samples revealed that the coarse fraction, typically less than 8% by weight, was comprised primarily of coarse shell fragments. Using the Wentworth size scale (Folk 1974), mean grain size in 80% of the samples was classified as fine sand and 20% as either medium or coarse sand. Values for standard deviation showed that 85% of the samples were moderately or moderately well sorted. Reed and Wells (2000) found similar sediment distribution patterns off Fort Macon, Atlantic Beach and Pine Knoll Shores, NC, in samples taken at 36 locations during each of two sampling periods, fall 1996 and spring 1997. Their samples showed muddier sediments occurring in the offshore areas but no significant seasonal variations in mean size or sorting.

Comparison of the grain size distributions taken in conjunction with the invertebrate coring and the analysis of grain sizes from the CSE Baird and Athena Technologies cores indicates finer sizes in the cores associated with the invertebrate sampling. This difference can be attributed to several factors: (1) the cores taken in association with invertebrate sampling covered only the uppermost surface layer only (2 cm), which is often covered by a thin mud drape; (2) this set of cores included Control locations outside the Borrow Areas, which were selected for their sand deposits, whereas the controls do not always match this level of coarseness; and (3) the cores associated with invertebrate sampling were collected by hand by divers in a fashion that involved minimal loss of fines during the sampling process.

4. Discussion

The benthic invertebrates occupying the bottom in both the inshore and offshore Borrow Areas represent species that are indeed being consumed by demersal fishes, such as spot, croaker, pinfish, pigfish, and sea mullets. Our gut examinations revealed that feeding was active and intense enough on the benthos in late November to yield gut contents in fishes with gut passage times of 6-12 hours. Compared to other gut data that we have taken from demersal fishes in the Neuse River and the Newport River in summer (pers. obs.), the percentages of empty stomachs in this data set are quite low. The densities of benthic invertebrates (6-16 individuals per 76.4-cm^2 core) are similar to those found occupying sandy bottoms in the Beaufort Inlet in December 1994 (Peterson et al. 1999), which were around 10 individuals per 76.4 cm^2 core (the same used in this study). The Beaufort Inlet samples were taken at a depth of 26-36 feet, similar to the inshore sites sampled in this study. Both surveys showed a general dominance by polychaetes. No other sampling of benthic invertebrates is truly comparable to these because of differences in sieve mesh size, water depth, reef proximity, geography, or sedimentology. Nevertheless, we present some benthic macrofauna data in Tables 9 (total macrofauna) and 10 (major taxa) from these other studies for contrast. Densities of benthic infauna in cores at the Borrow Areas in late November during our sampling period and in the earlier Beaufort Inlet study are lower than those observed near hard-bottom reefs off Wrightsville Beach (Posey and Ambrose 1994) and those observed by Van Dolah (1994) in finer sediments off Hilton Head, South Carolina (Table 8). For those taxa reported in Posey and Ambrose (1994), bivalves, gastropods, scaphopods, amphipods, isopods, polychaetes, and echinoderms, densities were higher than in our sampling of the Borrow Areas (Table 9).

Belt transects for larger invertebrates revealed a similar dominance by gastropod molluscs in our new data set from the Borrow Areas and in our earlier Beaufort Inlet study. These larger invertebrates were slightly more common in the Beaufort Inlet than in the study areas sampled here (Table 11). Greater echinoderm (sand dollar) densities occurred in the vicinity of the Beaufort Inlet. The only other analogous data set on larger invertebrates comes from Dahlgren et al. (1994), although they report only some taxa from belt transects near hard-bottom reefs off Wrightsville Beach. Dahlgren et al. (1994) reported belt transect data (Table 11) for several classes of echinoderms near the same reefs studies by Posey and Ambrose (1994). Dahlgren et al. (1994) observed higher densities of holothuroids (sea cucumbers) than we document in the Borrow Areas but similar densities of echinoids (sand dollars) and stelleroids (sea stars) (Table 11). The difference in sea cucumber densities is likely also a consequence of the finer sediments in the site studied by Dahlgren et al. (1994).

Our fish sampling revealed densities of many fishes as high in December as we routinely find during all the warm months in the vicinity of Beaufort Inlet immediately outside the estuary and as high as Van Dolah et al. (1994) found in the Folly River. The fish assemblage at the proposed borrow sites for the Bogue Banks project was dominated by species of substantial value to commercial and recreational fisheries of North Carolina and neighboring states. These fishes were actively feeding on the benthic macrofauna. Shrimp catches were low, although commercial shrimp trawling was being conducted in the immediate vicinity of all the Borrow Areas at the time of our sampling in late fall 1999. Many species of demersal fish of the estuaries of North Carolina and the Southeast generally are known to exit the sounds and estuaries in the fall on route to offshore sites for overwintering. The precise locations of these overwintering sites are not completely described, but our sampling indicates that this area off Bogue Banks is utilized in abundance during late fall by spot, croaker, pigfish, pinfish, silver perch, and sea mullet. Subsequent sampling during early February revealed emigration of these fishes to unknown locations as the weather became cooler. The only other conceivably comparable data on fish and crustacean abundances from trawl sampling come from Van Dolah et al. (1994). They reported average densities in the Folly River, South Carolina ranging across site and season from about 7,000 to 55,000 per km^2. These densities are similar to our average densities ranging from 500 up to 120,536 per km^2. The densities that we observed around the borrow areas in late November 1999 were judged by our boat captain, who has operated this trawl routinely for 25 years, to be similar to densities in spring, summer, and fall around Beaufort Inlet (J. Purifoy, pers. com.).

Dredging could impact the demersal fishes and crustaceans by direct removal and mortality during dredging, by causing emigration to other areas, where crowding could reduce growth and production, and by creating some unknown period of time when benthic prey abundances had not yet recovered and so growth and production were reduced. If sediment character in the borrow areas changes after sand mining, the new community of benthic invertebrates could differ dramatically from the existing community and could provide less of more food resources for demersal fishes and crustaceans. Van Dolah et al. (1994) demonstrated an effect of sand mining at the borrow area on species richness of demersal fishes and crustaceans that persisted through the first spring and fall after the cessation of the winter project; however, no effect was detected on total fish abundance.

Our sampling was designed to serve as the fall baseline data set for the Borrow Areas in contemplation of a monitoring scheme to assess impacts of and recovery from the sand mining for beach renourishment. This includes not only the benthic macrofauna and demersal fishes but also the sediments on the sea floor. Unfortunately, two sites in the offshore borrow area (A) possesses sediments that are much coarser with much higher shell content than any of the controls (Fig. 3b), so that we have no adequate control for this portion of the borrow area. Unless one of these sites is mined and one is not, any subsequent assessment of impacts of sand mining will be compromised by this sedimentological anomaly. Because the macrofauna is so closely tied to sediment character, the evaluation of any changes in surface sediment character after mining is critical to interpreting the impacts on and recovery of benthic invertebrates and probably also fishes. The limited amount of past literature on impacts of sand mining at borrow sites on the nearshore shelf gives mixed indications of whether recovery of benthic invertebrates will occur rapidly or slowly. Borrow areas in which sedimentation has not dramatically reduced the average size of surficial sediments have tended to show recovery of total benthic abundances in about a year, whereas borrow areas that experienced deposition of fine sediments exhibited recolonization by dramatically different benthic organisms and did not converge to reference or pre-dredge composition even after multiple (3 or more) years (Saloman 1974, Taylor Biological Company 1978, Van Dolah et al. 1992, 1994). There has been no definitive analysis of the conditions that lead to mud deposition in some but not other borrow areas, so no confident predictions can be generated for this specific Bogue Banks project. Presumably, rate of supply of suspended fine sediments and bottom shear stress help determine the degree of deposition of fine sediments.

Baseline sampling of the nourishment sites and control sites on the beach itself would also need to be conducted prior to sand mining, but during the warm months when the intertidal beach is used by macrofauna. We already possess a substantial amount of data on abundances of intertidal beach invertebrates from all along Bogue Banks from 1997-1999 from studies conducted by L. Manning (unpubl.: see Table 11 for an example data set). This information could conceivably be incorporated into an assessment design to evaluate the potential consequences of the renourishment on the beach system, allowing contrasts between the multiple summers before renourishment and the summer or summers afterwards as one means of assessing impact and rate of recovery. This previous sampling was not conducted in a design intended for evaluation of the Bogue Banks renourishment project, so it is unclear whether sufficient sites were sampled throughout the biologically active (warm) seasons in sufficient places to provide a set of replicated reference and treatment (renourished) sites sufficient to achieve adequately powerful tests of impacts on intertidal invertebrates. A review of past studies of the response of beach invertebrates to renourishment projects (Nelson 1989, 1993, Peterson et al. 2000) suggests that return of macroinvertebrates will be rapid if renourishment is restricted to months when invertebrates are largely absent from the intertidal beach and if a good match exists between grain size distributions of the natural beach and the new sands that are added. Finer particles are detrimental to suspension feeders, especially mole crabs (Bowman and Dolan 1985), and slow their recovery. In analyzing short-term effects of renourishment in Pine Knoll Shores on Bogue Banks, North Carolina, Peterson et al. (2000) documented virtual failure to initiate the recovery process by mole crabs and coquina clams, the biomass dominants of the Bogue Banks intertidal beaches, by mid July, 5-10 weeks after termination of the project. This renourishment grossly modified the beach sedimentology, changing average phi from 2.33 to 3.67 (Peterson et al. 2000). A previous renourishment project on Bogue Banks at Fort Macon studied by Reilly and Bellis (1983) documented a similar failure of coquina clams to return to the beach by the first July after project completion, but mole crabs did return with only a one-month time lag relative to the seasonal cycle at control beaches. No information on quantitative sedimentology is provided in that report, although there is a claim of a good match in grain size, which could explain why mole crabs were able to initiate recovery sooner than in the Pine Knoll Shores project studied by Peterson et al. (2000). Manning (unpub. data) also has shown that enhancing shell content on the intertidal beach has a strong negative effect on coquina clams by inhibiting normal rates of burrowing, thereby exposing them to transport off the beach into unfavorable and potentially inhospitable environments.

5. Conclusions and Recommendations

(1) Based on our benthic invertebrate sampling, fish trawling, and observations of fish guts, we conclude that demersal fishes of commercial and recreational value are using the invertebrates on the seafloor at the Borrow Areas as food during the late fall (and presumably also winter and spring). We recommend a targeted evaluation of the degree to which these fishes are food-limited during late fall through spring and the degree to which they rely in all seasons on the prospective Borrow Areas for feeding as compared to nearby bottom habitats and sites, so as to evaluate the significance of reduced abundances of benthic invertebrates in Borrow Areas. It is presently unclear in the absence of sampling other shelf habitats and sites whether the sand bodies proposed for dredging are preferred feeding grounds, relatively low-use feeding grounds, or used in proportion to the bottom area that they occupy.

(2) We conclude that demersal fishes are sufficiently abundant at the Borrow Areas to justify additional sampling at other seasons and in other habitats offshore so as to be able to quantify the importance of the Borrow Areas to the total fish populations.

(3) We conclude that benthic invertebrates are common enough during late fall in the Borrow Areas and important enough as food for demersal fishes as to justify benthic monitoring in other seasons of the year prior to and after mining activities to assess impact and recovery.

(4) We conclude that sampling of intertidal beach invertebrates is necessary to provide the baseline for impact assessment after the renourishment. Such baseline information could conceivably come from historical data, but only if a sufficiently powerful design can be created, based on knowledge of spatial and temporal fluctuations and the project plan.

(5) A review of limited information on recovery rates of sediments and benthic invertebrate resources in offshore borrow areas from other studies suggests that recovery rate is unpredictable, requiring times ranging from a year to indefinite (undetermined) numbers of years.

(6) Results of the most applicable and recent study of impacts of renourishment on beach invertebrates imply effects that could last throughout the warm season if sediments used in renourishment do not match those of the natural beach. We recommend that renourishment occur in winter (the period of low intertidal abundances of beach invertebrates, which is December through March) and that sands used in renourishment be treated to remove shell that exceeds the average on the untreated beach and be selected to avoid deposition of mud balls and silts and clays to minimize duration of negative impacts. It seems that enhancement of the phi size to 3.67 was inadequate to allow rapid recolonization in a previous renourishment of Bogue Banks, but what phi increase is possible without impact on recovery rates of beach invertebrates is unclear.

(7) We conclude that inadequate information exists to recommend one proposed Borrow Area over any other for this project. Sampling of benthic invertebrate resources on only a single date does not provide sufficient seasonal coverage to rank the proposed Borrow Areas by importance as prey for demersal fishes and crustaceans.

(8) We conclude that the Bogue Banks renourishment project could be conducted with minimal adverse ecological damage (a) if the borrow sites were dredged in a way that avoided complete excavation of the sand body and avoided changes in sedimentation processes, thus preventing their transformation into depositional muddy areas, (b) if the dredging were confined to periods of low abundance of demersal fishes and shrimps at the borrow areas (as determined by in situ monitoring prior to dredging), and (c) if the sands deposited on the intertidal beach matched the size distribution of natural sands on the beach with minimal muds and minimal shell and were deposited during the winter (December through March) when these invertebrates are largely absent. These requirements present technical uncertainties because (a) it is not clear that we understand the potential sources of fine sediments and the processes of deposition of fine sediments at the Borrow Areas well enough to have confidence in designing the sand mining in a way that will avoid transformation into muddy bottoms; (b) the costs of placing the dredge on hold while awaiting departure of demersal fishes in late fall may preclude using monitoring to determine exactly when fish impacts will be minimized; and (c) costs of providing a sand resource that matches the sedimentology of the natural beach may be high.

Table 2a. Mean (SD = standard deviation) of abundance of individuals by taxonomic family found in 76.4cm² core samples taken at sites in (Treatment) and adjacent (Control) to inshore and offshore proposed sand borrow areas for the Bogue Banks beach renourishment. Statistics are calculated from the average of 10 cores taken from each of 6 sites sampled both within and around the offshore area and 4 sites sampled both within and around the inshore areas.

Pinfish	Offshore	40%	0.019	0%	55%	3%	10%	25%	5%	0%
Sea Mullet	Offshore	40%	0.240	1%	37%	61%	1%	0%	0%	0%
Silver Perch	Nearshore	66%	0.002	0%	0%	0%	95%	0%	5%	0%
Silver Perch	Offshore	10%	0.005	0%	0%	0%	61%	0%	38%	0%
Silversides	Nearshore	nd	nd	0%	0%	0%	0%	0%	100%	0%
Silversides	Offshore	nd	nd	0%	0%	0%	0%	0%	100%	0%
Spot	Nearshore	56%	0.007	55%	20%	0%	0%	0%	20%	5%
Spot	Offshore	50%	0.010	5%	10%	0%	0%	65%	10%	0%

* Percentage calculated by dividing the number of fish examined whose stomach contents weighed 0.000 g by the number of fish examined.

** Percent of total diet made up by each group was calculated by summing the total stomach contents weights in that category of all fish examined and dividing that weight by the total wet weight of identifiable stomach contents off all fish within that species.

nd = not determined, stomach contents do not weigh enough to make a reasonable evaluation.

Day et al. (1971)[a]	Apr. 1965 - Jan. 1966	10m site	1005
	Apr. 1965 - Jan. 1966	20m site	936
Peterson et al. (1999)[b]	Dec. 1994	East Site	1597 (959)
		West Site	1170 (592)
Posey & Ambrose (1994)[c]	Jul.1990		3680 (900)
	Apr. 1991(1)		11030 (1281)
	Apr. 1991(2)		6880 (917)
Van Dolah et al. (1994)[d]	Winter 1990	Control site	2755
	Fall 1990	Control site	3527

[a] Day et al. (1971) took samples with a $0.2m^2$ van Veen grab and sieved them through a 1mm sieve. Infaunal abundances from samples taken from sites along a transect off Cape Lookout NC, were averaged over 5 sampling dates from Apr 1965 to Jan 1966. The two sites with depths closest to those of this study are presented.

[b] Peterson et al. (1999) present abundances of infauna (> 0.5mm) from 9.9cm diameter cores taken at sites about 1km SE (East Site) and SW (West Site) of Beaufort Inlet, Beaufort NC prior to any experimental disturbance. Replicate cores were taken from each of 9 stations on each side of the inlet.

[c] Posey and Ambrose (1994) present abundances of infauna (> 0.5mm) from 12cm diameter cores taken 12cm deep from stations along transects (1 & 2) perpendicular to "23 Mile Reef" 43.5km from Wilmington, NC. The 32m deep stations presented here are the stations 75m from the reef and least affected by the presence of the reef and associated fauna.

[d] Abundances of infauna (> 0.5mm) from 7.6cm diameter core samples 15cm deep taken by Van Dolah et al. (1994) are from an undisturbed control site 3km from Hilton Head I.

Table 10. Mean (SD = standard deviation) abundance expressed as number m^{-2} of infauna from major taxanomic groups from this study compared with abundances found in studies from nearby locations.

[a] Dahlgren et al. (1994) present abundances of benthic fauna (> 1.5cm) from $10m^2$ belt transects taken by divers from 32m deep stations along a transect perpendicular to "23 Mile Reef" 43.5km from Wilmington, NC. The means presented here average samples from 1, 10, 25, 50, and 75 m from the reef. Tests among the transect stations showed no statistical difference in abundances relative to reef proximity.

[b] Peterson et al. (1999) present abundances of benthic fauna from (> 1.5cm) from $10m^2$ belt transects taken at sites about 1km SE (East Site) and SW (West Site) of Beaufort Inlet, Beaufort NC prior to any experimental disturbance. At the West Site transect were sampled by divers using visual and manual examination. Visibility was insufficient at the East Site for diver counts thus samples were taken using a benthic sled.

Table 12. Mean counts (standard error) of major taxa per transect for sampling conducted at six sites along Bogue Banks, NC. Sampling at each site was conducted along three transects oriented perpendicular to shore and spaced 50 m apart. Organisms were collected using a hand-operated aluminum corer with an internal diameter of 10.2 cm taken to a depth of 20 cm. Two cores were taken, seived on 1 mm mesh and pooled to form a single sample. Cores were collected every three meters along each transect and extended from just landward of mean high water to approximately 1 m deep in the surf zone. All sampling was conducted in the Spring and does not reflect relative abundances that may occur in other seasons.

APPENDICES

Appendix 1. Number of individuals by taxonomic family found in 76.4cm2 core samples taken at sites in (Treatment) and adjacent (Control) to inshore and offshore proposed sand borrow areas for the Bogue Banks beach renourishment. Ten cores were taken from each of 6 sites sampled both within and around the offshore area and 4 sites sampled both within and around the inshore areas.

Appendix 2. Number of individuals by taxonomic family captured in a $10m^2$ tow of a benthic sled at sites in (Treatment) and adjacent (Control) to inshore and offshore proposed sand borrow areas for the Bogue Banks beach renourishment. Two tows were taken from each of 6 sites sampled both within and around the offshore area and 4 sites sampled both within and around the inshore areas.

APPENDIX D

APPENDIX D
BIOLOGICAL ASSESSMENT

BOGUE BANKS BEACH NOURISHMENT PROJECT
CARTERET COUNTY, NORTH CAROLINA

February 2000

1.00 INTRODUCTION

Bogue Banks is a barrier island with a southward facing ocean shoreline stretching some 26 miles between two large tidal inlets, Bogue Inlet to the west and Beaufort Inlet to the east. The Banks are surrounded by Bogue Sound on the north and Onslow Bay of the Atlantic Ocean on the south. Bogue Banks is an important resource to Carteret County, both economically and ecologically. From an economic perspective, the need for the proposed Bogue Banks beach nourishment project is to protect the largest portion of the county's overall economy; tourism. Environmentally, beaches, high dunes, and maritime forests harbor a wide range of wildlife resources. However, severe storms and associated erosion results in the increasing loss of this valuable resource. Therefore, this project proposes to nourish a large section of Bogue Banks with 4.5 million cubic yards of sand taken from borrow areas offshore. The project area includes the beaches reaching from the town limits of Pine Knoll Shores and Atlantic Beach to the western end of Emerald Isle, approximately 1 mile east of Bogue Inlet. The total project length is 16.8 miles of shoreline.

2.00 PROPOSED PROJECT

The Bogue Banks nourishment project proposes to widen the beach area from the town limits of Pine Knoll Shores and Atlantic Beach to the western end of Emerald Isle, approximately 1 mile east of Bogue Inlet. The total project length is 16.8 miles of shoreline. The sand will be supplied by dredging from one or more of four possible borrow areas and bringing this material to shore via hydraulic or hopper dredge. These proposed actions are planned to occur between November of 2000 and April of 2001.

3.00 PRIOR CONSULTATIONS

No previous Section 7 consultations exist for the proposed beach nourishment project. However, consultations have been performed for beach nourishment projects on nearby beaches such as Atlantic Beach and address similar issues as this biological assessment.

4.00 LIST OF SPECIES

Species to be considered in this biological assessment were provided by USFWS and the NMFS and are listed in the following table.

Common Name	Scientific Name	Status	Habitat present?	Known observation*
Mammals				
Eastern cougar	*Felis concolor couguar*	E	no	no
Finback whale	*Balaenoptera physalus*	E	no	no
Humpback whale	*Megaptera novaeangliae*	E	yes	yes**
Right whale	*Eubaleana glacialis*	E	yes	yes**
Sei whale	*Baleanoptera borealis*	E	no	no
Sperm whale	*Physeter catodon*	E	no	no
West Indian manatee	*Trichechus manatus*	E	yes	no
Birds				
Piping plover	*Charadrius melodus*	T	yes	no
Red-cockaded woodpecker	*Picoides borealis*	E	no	no
Roseate tern	*Sterna douglallii*	E	yes	no
Reptiles				
American alligator	*Alligator mississippiensis*	T(S/A)	no	no
Green sea turtle	*Chelonia mydas*	T	yes	yes**
Hawksbill sea turtle	*Eretmochelys imbricata*	E	yes	yes**
Kemp's ridley sea turtle	*Lepidochelys kempi*	E	ycs	yes**
Leatherback sea turtle	*Dermochelys coriacea*	E	yes	yes**
Loggerhead sea turtle	*Caretta caretta*	T	yes	yes
Fish				
Shortnose sturgeon	*Acipenser brevirostrum*	E	yes	no
Plants				
Rough-leaf loosestrife	*Lysimachia asperulaefolia*	E	no	no
Seabeach amaranth	*Amaranthus pumilus*	T	yes	yes

KEY

Status	Definition
E	A taxon "in danger of extinction throughout all or a significant portion of its range."
T	A taxon "likely to become endangered within the foreseeable future throughout all or a significant portion of its range."
T(S/A)	Threatened due to similarity of appearance - a species that is threatened due to similarity of appearance with other rare species and is listed for its protection. These species are not biologically endangered or threatened and are not subject to Section 7 consultation.

* According to NC Natural Heritage Program data.

** Species known to migrate along the coast of NC (Wynne, 1999).

5.00 SURVEY AND ANALYSIS METHODS

Impacts to the natural environment of the project area were determined by information obtained from literature sources and consultation with informed individuals.

6.00 GENERAL EFFECTS ON LISTED SPECIES

The presence of these species in the project area depends on the availability and abundance of appropriate habitat. Since the Bogue Banks nourishment project area does not contain any freshwater or forested areas, the eastern cougar, American alligator, red-cockaded woodpecker, and roughleaf loosestrife are not likely to be found at this site and will not be affected by the proposed actions.

Listed species that could potentially be located at Bogue Banks during the proposed action are the finback whale, humpback whale, right whale, sei whale, sperm whale, West Indian manatee, piping plover, roseate tern, green sea turtle, hawksbill sea turtle, Kemp's ridley sea turtle, leatherback sea turtle, loggerhead sea turtle, and seabeach amaranth.

7.00 SPECIES ASSESSMENTS

7.01 Right Whale, Finback Whale, Humpback Whale, Sei Whale, and Sperm Whale

a. Status and Natural History of the Species in the Project Area

These whale species all occur infrequently in the ocean off the coast of North Carolina. Of these, only the right whale and the humpback whale routinely come close enough inshore to encounter the project area. Humpback whales are often found in protected waters over shallow banks and shelf waters for breeding and feeding. They migrate toward the poles in summer and toward the tropics in winter and visit the North Carolina coast during seasonal migrations, especially between December and April (Conant, 1993). They eat schooling fish such as herring and can consume up to 1.5 tons per day of krill. Right whales swim very close to the shoreline and are often noted only a few hundred meters offshore (Schmidly, 1981). They feed primarily on copepods and euphausids. While it usually winters in the waters between Georgia and Florida, the right whale can on occasion be found in the waters off North Carolina. Sighting data provided by the Right Whale Program of the New England Aquarium indicates that 93% of all North Carolina sightings between 1976 and 1992 occurred between mid-October and mid-April (Chris Slay, 1993). The number of right whales documented in the vicinity of Morehead City during a single season ranges from 2 to 25 (USACOE, 1989).

b. Effect Determination

Of the five species of whales being considered, only the right whale and humpback whale would normally be expected to occur within the project area during the construction period. While some food resources may be initially affected by either dredging activities or burial associated with the beach nourishment, most invertebrates will quickly reestablish from adjacent unaffected areas or through recruitment processes. Furthermore, the presence of a dredge in this area should pose no more of a collision threat to migrating whales than normal commercial ship traffic. However, if hopper dredges are used, ACOE and NMFS hopper dredge protocol will be followed to reduce potential impacts to whales. A whale observer with at-sea large whale identification experience will be present on the hopper dredge from the beginning of hopper dredge use through March 31 to conduct daytime observations in order to reduce the potential for accidental collision. Since habitat conditions and food supplies will be maintained in their current states and the potential for accidental collisions with dredges will be minimized, it has been determined that the proposed project is not likely to adversely affect these whale species.

7.02 West Indian Manatee

a. Status and Natural History of the Species in the Project Area

The manatee is an occasional summer resident off the North Carolina coast. The species can be found in shallow (5 feet to usually less than 20 feet), slow-moving rivers, estuaries, saltwater bays, canals, and coastal areas (USFWS, 1991). The West Indian manatee is herbivorous and eats aquatic plants such as hydrilla, eelgrass, and water lettuce (USFWS, 1999). During winter months, the United States' manatee population confines itself to the coastal waters of the southern half of peninsular Florida and to springs and warm water outfalls as far north as southeast Georgia. They are sighted frequently in southeastern North Carolina with most records occurring in July, August, and September, as they migrate up and down the coast (Clark, 1993). However, scattered records of this species in the region span all seasons. Based on these data, the manatee is considered a year-round resident with a maximum population in the late summer months. Manatee population trends are poorly understood, but deaths have increased steadily. A large percent of mortality is due to collisions with water crafts, especially of calves. Another closely related factor in their decline has been the loss of suitable habitat through incompatible coastal development, particularly destruction of sea grass beds by boating facilities.

b. Effect Determination

Since the proposed dredging work is currently scheduled to occur during the time of year when manatee populations are expected to be minimal, it is unlikely that there will be any manatees in the project area during the proposed project. Therefore, it has been determined that the dredging of the borrow areas and the subsequent beach nourishment are not likely to adversely affect the West Indian manatee.

7.03 Piping Plover

a. Status and Natural History of the Species in the Project Area

The Atlantic Coast piping plover population breeds on coastal beaches from Newfoundland to North Carolina (and occasionally in South Carolina) and winters along the Atlantic Coast from North Carolina south, along the Gulf Coast, and in the Caribbean USFWS, 1996). Since being listed as threatened in 1986, the population has increased from approximately 800 pairs to almost 1350 pairs in 1995, although most of this increase may be attributable to an increase in surveying intensity. Piping plovers nest above the high tide line on coastal beaches, sand flats at the ends of sand spits and barrier islands, gently sloping foredunes, blowout areas behind primary dunes, sparsely vegetated dunes, and washover areas cut into or between dunes (USFWS, 1996). Feeding areas include intertidal portions of ocean beaches, washover areas, mud flats, sand flats, wrack lines, and shorelines of coastal ponds, lagoons, or salt marshes. Loss and degradation of habitat due to development and shoreline stabilization have been major contributors to the species' decline.

Most piping plovers at Bogue Banks have been observed at the west end of Emerald Isle as predominantly a migratory and winter resident (D. Allen, pers. comm.). During a 1991 U.S. Fish and Wildlife Service International Piping Plover Census (winter), 4 piping plovers were observed and during a 1996 winter census, 1 individual was observed. However, both Bogue and Beaufort inlets contain intertidal flats exposed at low tide that are prime feeding and roosting habitat for a variety of shorebirds and colonial waterbirds including pelicans, cormorants, terns, and gulls. These areas may be used by piping plovers as well.

b. Effect Determination

Within Bogue Banks, only the west end of Emerald Isle has been documented to support piping plovers. This area is not located within the project boundaries and will not be affected by beach nourishment or dredging activities. However, one proposed borrow area is located within Bogue Inlet, which contains feeding and roosting habitat for a variety of colonial waterbirds and shorebirds. If this area is chosen for dredging, potential plover feeding habitat may be lost. However, there is sufficient intertidal flat habitat elsewhere in the area to compensate for this potential loss. Therefore, the proposed project will not adversely affect the piping plover.

7.04 Roseate Tern

a. Status and Natural History of the Species in the Project Area

Roseate terns breed primarily on small offshore islands, rocks, cays, and islets. Rarely do they breed on large islands. They have been reported nesting near vegetation or jagged rock, on open sandy beaches, close to the waterline on narrow ledges of emerging rocks, or among coral rubble (USFWS, 1999). This species is primarily observed south of Cape Hatteras, particularly at Cape Point within Cape Hatteras National Seashore, during the months of July and August.

b. Effect Determination

The roseate tern has never been observed within the project site. Bogue Banks is most likely too large and too developed an island to provide appropriate habitat for the roseate tern. Additionally, when the tern is observed in North Carolina, it is mostly during summer months, when the project is not scheduled to occur. Therefore, the project is not likely to affect the roseate tern.

7.05 Hawksbill, Leatherback, Kemp's Ridley, and Green Sea Turtles

a. Status and Natural History of the Species in the Project Area

In North Carolina, the green sea turtle and the Kemp's ridley sea turtle are known from estuarine and oceanic waters, whereas the hawksbill and leatherback sea turtles are normally associated solely with oceanic waters (Schwartz, 1977; Lee and Palmer, 1981). All of these species are found in North Carolina waters throughout the year and can be present in inshore waters April through December (Epperly et al., 1995).

Neither the hawksbill or leatherback sea turtle is observed in North Carolina with much frequency. Their nesting is generally restricted to Florida and these species are only occasionally observed migrating through North Carolina waters. The Kemp's ridley sea turtle is commonly observed migrating within North Carolina inshore waters during the spring and fall, but has been documented to nest only once in North Carolina. The entire population nests on approximately 15 miles of beach in Mexico between the months of April and June (USFWS, 1991). Green sea turtle nesting is primarily limited to Florida's east coast (300 to 1000 nests reported annually) but has been observed as far north as North Carolina. Although turtle crawls have been documented at Emerald Isle Beach (R. Boettcher, pers. comm.), no nests have been observed within the project site and the green sea turtle is not considered to be a regular nester within the project area. Like the Kemp ridley, greens are commonly observed migrating within North Carolina inshore waters during the spring and fall. The principal food sources for these sea turtle species are crustaceans, mollusks, other invertebrates, fish, and plant material (Schwartz, 1977).

b. Effect Determination

The hawksbill, leatherback, and Kemp's ridley sea turtles do not regularly nest along North Carolina coasts. The green sea turtle nests sporadically in North Carolina but has not been observed nesting in the project area. Therefore, beach nourishment activities will not affect any of these sea turtle species. However, all of these species migrate within North Carolina waters throughout the year, mostly between April and December.

Hydraulic or hopper dredges will be used to dredge material from borrow areas located within these migratory waters and transport it to the shore. Although the majority of construction activities is planned to occur between November and April to avoid nesting and migrating turtles, dredging activities may begin as early as October and may continue into the spring months in order to complete the project in one season. Therefore, dredging activities may occur during moderate levels of sea turtle migration.

Hopper dredges move rapidly over the bottom sediments and can injure or kill juvenile turtles lying on the sea bottom. If a hopper dredge is used, the proposed project will follow NMFS and ACOE hopper dredge protocol to reduce potential impacts to migrating sea turtles. An observer will be present on the hopper dredge, except when water temperatures are cold enough to ensure that turtles will not be present (January and February) to document any takes of turtle species and to ensure that turtle deflector dragheads are used properly. If two sea turtle takes occur within 24 hours, work will cease upon a subsequent take, and will only resume if concurred in by the ACOE. If three takes occur, a risk assessment and appropriate risk management plan will be developed and submitted to the ACOE. Should a total take of five sea turtles occur, all work will be terminated. If a total of two endangered species of sea turtles are taken during a project, work will be suspended until further guidance from the ACOE has been given. Despite these precautions, the chance of impacting migrating sea turtles with a hopper dredge still exists. Therefore, it has been determined that the proposed project may adversely affect the hawksbill, leatherback, Kemp's ridley, and green sea turtles.

7.09 Loggerhead Sea Turtle

a. Status and Natural History of the Species in the Project Area

The loggerhead turtle utilizes the Bogue Banks upper beach for its seasonal (March-October) nesting events. Off the Carolina coast these turtles commonly occur at the edge of the continental shelf when they forage around coral reefs, artificial reefs, and boat wrecks. They feed on benthic invertebrates including mollusks, crustaceans, and sponges (Morrimen, 1982). They have also been found to eat fish, clams, oysters, sponges, jellyfish, shrimp, and crabs when near shore. Research has shown that the turtle populations have greatly declined in the last 20 years due to a loss of nesting habitat along the beachfront and by incidental drowning in shrimp trawl nets. It appears that the combination of poorly placed nests coupled with unrestrained human use of the beach by auto and foot traffic has impacted this species greatly. Eroding steep beach escarpments, lights, sand fences, and other physical barriers (debris) often cause the mature females to select poor nesting sites at the dune toes which causes higher nestling mortality rates. Loggerhead turtles are known to regularly nest from Bogue Inlet to Beaufort Inlet, including the entire stretch of the project site. Between 1995 and 1999, an average of 28 nests/year were recorded within the project area (Ruth Boettcher, pers. comm.). Like the Kemp's ridley and green sea turtles, loggerheads are known to frequently use coastal waters as travel corridors (Wynne, 1999) and have been observed migrating along the North Carolina coast (Epperly et al, 1995).

b. Effect Determination

The proposed project could potentially affect loggerhead sea turtles in two ways. First, dredging activities proposed to occur offshore may occur in areas used by migrating juveniles. The act of dredging material with a hopper dredge may adversely affect juvenile turtles. If a hopper dredge is used, NMFS and ACOE hopper dredge protocol will be followed to reduce these impacts (see Hawksbill, Leatherback, Kemp's Ridley, and Green Sea Turtles' Effect Determination). Second, nourishing the beach with the fill material may affect nesting activities by altering nesting habitat. If the beach becomes too hard through the compaction of deposited nourishment sediments by construction equipment, it could present a physical barrier to turtle nest digging. Furthermore, beach nourishment may influence physical characteristics of beaches such as sand-grain size and shape, silt-clay content, sand compaction, moisture content, porosity/water retention, gas diffusion rates, and color of sand grains which could alter the temperature of the beach. These factors could reduce reproductive success of nests laid in nourished areas (Crain et al., 1995; Ackerman, 1996). To alleviate impacts to nesting sea turtles in the project area, the following steps will be taken:

1. Only beach quality sand suitable for sea turtle nesting, successful incubation, and hatchling emergence shall be used for beach nourishment on the project site. Furthermore, sand of similar grain size to the existing beach will be used to reduce any changes in physical characteristics of the beach that may affect nest survival.

2. Immediately after completion of the beach nourishment project and prior to the next three nesting seasons, beach compaction shall be monitored and tilling shall be conducted as required to reduce the likelihood of impacting sea turtle nesting and hatching activities.

3. Immediately after completion of this project and prior to the next three nesting seasons, monitoring shall be conducted to determine if escarpments are present and escarpments shall be leveled as required to reduce the likelihood of impacting sea turtle nesting and hatching activities.

4. Carteret County will ensure that contractors doing the beach nourishment and dredging work fully understand sea turtle protection measures.

5. Beach nourishment and dredging activities are planned to begin after November 1 and be completed before May 1. If any filling occurs before March 1, the pipeline will be placed along the landward edge of the berm.

6. If any beach nourishment or dredging activities take place during the period from March 1 through November 15, a standardized nest monitoring and relocation plan will be implemented in addition to the monitoring that already occurs. The plan incorporates monitoring of the beach disposal area each morning from the beginning of the nesting season until all equipment is removed from the beach and the relocation of any nests laid within the project area. Using standard nest relocation

techniques, all nests will be located to a suitable nursery beach, agreed to prior to the start of relocation effort by the U.S. Fish and Wildlife Service and the North Carolina Wildlife Resources Commission. Hatching success of relocated nests will be monitored and reported.

7. Immediately after completion of this project and prior to March 1 for three subsequent years, sand compaction will be monitored in the area of restoration in accordance with a protocol agreed to by the Service, the State regulatory agency, and Carteret County. At a minimum, the protocol provided under 7a and 7b below will be followed. If required, the area will be tilled to a depth of 36 inches. All tilling activity must be completed prior to March 1. A report on the results of compaction monitoring will be submitted to the Service prior to any tilling actions being taken. An annual summary of compaction surveys and the actions taken will be submitted to the Service. This condition will be evaluated annually and may be modified if necessary to address sand compaction problems identified during the previous year.

   7a. Compaction sampling stations shall be located at 500-foot intervals along the project area. One station will be at the seaward edge of the dune/berm line (when material is place in this area); one station will be midway between the dune line and the high water line; and one station will be located just landward of the high water line. At each station, the cone penetrometer shall be pushed to a depth of 6, 12, and 18 inches three times (three replicates). Material may be removed from the hole if necessary to ensure accurate readings of successive levels of sediment. Replicates will be located as close to each other as possible, without interacting with the previous hole and/or disturbed sediments. The three replicate compaction values for each depth will be averaged to produce final values for each depth at each station. Reports will include all 27 values for each transect line, and the final 9 averaged compaction values.

   7b. If the average value for any depth exceeds 500 psi for any two or more adjacent stations, then that area will be tilled prior to March 1 of the following year. If values exceeding 500 psi are distributed throughout the project area but in no case do those values exist at two adjacent stations at the same depth, then consultation with the Fish and Wildlife Service will be sought to determine if tilling is required. If a few values exceeding 500 psi are present randomly within the project area, tilling will not occur.

8. Visual surveys for escarpments along the project area shall be made immediately after completion of the beach nourishment project and prior to March 1 for three subsequent years. Results of the surveys will be submitted to the Service prior to any action being taken. Escarpments that interfere with sea turtle nesting or that exceed 18 inches in height for a distance of 100 feet will be leveled to the natural beach contour by March 1. The Service will be contacted immediately if subsequent reformation of escarpments that interfere with sea turtle nesting or that exceed 18 inches in height for a distance of 100 feet occurs during the nesting and hatching season to determine the appropriate action to be taken. If it is determined that

escarpment leveling is required during the nesting or hatching season, the Service will provide a brief written authorization that describes methods to be used to reduce the likelihood of impacting existing nests. An annual summary of escarpment surveys and actions taken will be submitted to the Service.

9. From March 1 through April 30 and November 1 through November 15, staging areas for construction equipment will be located off the beach to the maximum extent practicable. Nighttime storage of construction equipment not in use will be off the beach to minimize disturbance to sea turtle nesting and hatching activities. In addition, all construction pipes that are placed on the beach will be located as far landward as possible without compromising the integrity of the dune system. Temporary storage of pipes on the beach will be in such a manner so as to impact the least amount of nesting habitat and shall likewise not compromise the integrity of the dune systems.

By planning to perform the majority of the project during off-season months, monitoring beach hardness, and relocating nests found in unsuitable habitat if project completion delays occur, impacts to nesting loggerhead sea turtles will be minimized. In addition, NMFS and ACOE hopper dredge protocol will be followed to minimize impacts to migrating loggerheads caused by dredges. However, because of the possibility of missing a sea turtle nest during the nest monitoring program, inadvertently breaking eggs during relocation, or injuring a migrating loggerhead with a hopper dredge, it has been determined that the project may affect the loggerhead sea turtle.

7.10 Shortnose Sturgeon

a. Status and Natural History of the Species in the Project Area

This species ranges along the Atlantic seaboard from southern Canada to northeastern Florida (USFWS, 1999). The shortnose sturgeon feeds on invertebrates and stems and leaves of macrophytes. From historical accounts, it appears that this species was once fairly abundant throughout North Carolina waters, however, many of these early records are unreliable due to confusion between this species and the Atlantic sturgeon (*Acipenser oxyrhynchus*). Because of the lack of suitable freshwater spawning areas in the project area and the requirement of low salinity waters by juveniles, any shortnose sturgeons present would most likely be non-spawning adults.

b. Effect Determination

It is unlikely that the shortnose sturgeon occurs in the project area (F. Rohde, pers. comm.). However, should it occur, its habitat would be only minimally altered by project construction and maintenance. This species feeds on a wide variety of invertebrates and while some food resources may be initially affected by either burial associated with beach nourishment or excavation in borrow areas, most invertebrates will quickly reestablish from adjacent unaffected areas or through recruitment processes. Although dredges have been known to impact shortnose sturgeons, this species is not likely to be present in the project area and, therefore, impacts from dredges are not anticipated to occur. Because of the unlikelihood of shortnose sturgeon being present in the project area and because of the precautions being taken with the dredges, it has been determined that the actions of the proposed project are not likely to affect the shortnose sturgeon.

7.11 Seabeach Amaranth

a. Status and Natural History of the Species in the Project Area

Seabeach amaranth is an annual herb that occurs on beaches, lower foredunes, and overwash flats (Fussell, 1996). Weakley (1986) found that in North Carolina the plant is most common on overwash flats on accreting ends of barrier islands. This species occupies elevations ranging from 0.2 to 1.5 m above mean high tide (Weakley and Bucher, 1992). Historically, seabeach amaranth was found from Massachusetts to South Carolina. But according to recent surveys (U.S. Army Corps of Engineers, 1992-1995), its distribution is now restricted to North and South Carolina with several populations on Long Island, New York. The decline of this species is caused mainly by development of its habitat, such as inlet areas and barrier islands, and increased ORV and human traffic which tramples individuals (Fussell, 1996). Seed dispersal of seabeach amaranth is achieved in a number of ways, including water and wind dispersal (USFWS, 1995). Between 1992 and 1995, annual surveys of amaranth were conducted at Bogue Banks (NCNHP, 1995). The results are as follows:

	# Plants Observed at Bogue Banks	**# Plants Observed within Project Area**
1992	2556	159
1993	3762	232
1994	1181	182
1995	14776	391

No survey was conducted in 1996 because of early summer hurricanes that washed away or buried most of the plants. In 1997, certain sections of Bogue Banks were surveyed, but were found to support very low numbers of amaranth. Because no survey has been conducted since 1997, the size of recent populations are currently unknown. Several hurricanes that hit the North Carolina coast in 1999 may have buried plants and seeds under sand or heavy winds associated with the storms may have dispersed seeds along the project area and into the ocean.

b. Effect Determination

Since dredging of the borrow areas will be done offshore, no impacts to amaranth plants will occur from this action. Furthermore, since beach nourishment will occur in winter months, when amaranth exists as seeds, immediate impacts from filling will be reduced. However, deeply burying existing seeds could negatively affect the amaranth population in later seasons. Assuming that seeds are located in the general position of former parent plants observed in past surveys, they may be covered by proposed beach nourishment activities. Research on the consequences of beach nourishment to amaranth seeds is somewhat inconclusive. The U.S. Army Corps of Engineers (1995) found that amaranth at Masonboro Inlet was more abundant in areas that recently received dredged material. In addition, 1995 survey data from the NC Natural Heritage Program found a section of Bogue Banks that was used as a disposal zone in 1994 had an increase in population from 100 to 7300 plants. Dredging activities could uncover buried seeds and allow them to germinate in deposited areas. (This benefit is unlikely to occur during this project if dredged material is supplied from areas offshore that do not contain amaranth seeds.) In contrast, Hancock (1995) concluded that amaranth seedlings generally do not emerge from depths of sand greater than 1 cm. Therefore, the added sand may be detrimental if placed on top of seeds. However, the beach nourishment that is to take place along the coast of Bogue Banks will occur on areas suffering from erosion and should ultimately expand potential habitat for the plant species.

The U.S. Army Corps of Engineers has instituted a long-term seabeach amaranth monitoring program at every beach in North Carolina which routinely receives dredged material from federally funded projects. The program is to be conducted until such a time that enough data are available to allow a reasonable prediction of the actual impacts of each planned disposal action on the species in the future. After this beach nourishment project is complete, the project area will be monitored by the applicant to see if and where seeds survived. Within a few monitoring seasons, these data will help predict ultimate impacts of beach nourishment on amaranth at Bogue Banks and will be made available to the Corps' monitoring program. Because known amaranth habitat will be filled, it has been determined that the proposed project may affect seabeach amaranth.

8.00 SUMMARY EFFECT DETERMINATION

This assessment has examined the potential impacts of the proposed project on listed species of plants and animals which are, or may be, present in the project area. Both primary and secondary impacts to habitat have been considered. Based on this analysis, it has been determined that the project may affect the hawksbill sea turtle, leatherback sea turtle, Kemp's ridley sea turtle, green sea turtle, loggerhead sea turtle, and seabeach amaranth.

9.00 SUMMARY OF PROTECTIVE MEASURES

To minimize impacts to nesting sea turtles and vegetative-stage seabeach amaranth, work is planned to occur during the winter months with contingencies in place for project completion beyond this period. Furthermore, sand will be placed in areas suffering from erosion, minimizing impacts to suitable sea turtle nesting habitat and expanding potential habitat for seabeach amaranth. All material will be monitored to determine beach hardness, and areas will be tilled where the postdisposal beach is harder than 500 CPUs.

If any work on the project occurs between May 1, a beach monitoring and nest relocation program for sea turtles will be implemented. This program will include daily patrols of disposal areas at sunrise, relocation of any nests laid in areas to be impacted by fill placement, and monitoring of hatching success of the relocated nests. Sea turtle nests will be relocated to an area suitable to both the USFWS and the NC Wildlife Resources Commission's Sea Turtle Coordinator.

If hopper dredges are used to dredge and transport material to the shoreline during the proposed project, NMFS and ACOE hopper dredge protocol will be followed to reduce impacts to whales, fish, and sea turtles that may be in the area. An observer will be present on the hopper dredge to document any takes of sea turtle species, except when water temperatures are cold enough to ensure that sea turtles will not be present (during January and February), to watch for and alert the dredge operator of whales in the area (from the beginning of hopper dredge use through March 31 for daytime observations), and to ensure that turtle deflector dragheads are used properly. Limits on take set by the ACOE will be strictly followed.

APPENDIX E

APPENDIX E — SEDIMENT SURVEYS

APPENDIX E1. PREVIOUS STUDIES

Numerous scientific studies address the geology, geomorphic history, and sediments of the North Carolina coast (Table E1). In contrast, relatively few reports present field data on these topics for the area of Bogue Banks and immediate offshore zone (Table E2). The salient points of these studies with respect to nourishment planning and identification of viable borrow areas include:

- Bogue Banks is a Holocene barrier island within the less exposed western "limits" of the Cape Lookout cuspate foreland with strikingly different topography and profile compared to the northeastern-limit barriers, Core Banks and Portsmouth Island (Heron et al., 1984).

- During Quaternary times, the shoreline off Bogue Banks was transgressive under the influence of deglaciation and rapid sea-level rise across the gently sloping continental shelf of the Carolinas.

- Whether or not Bogue Banks existed as a single or series of subaerial barriers prior to 4000 years ago, only a thin sediment cover remains offshore--most of the inner continental shelf consists of outcropping Tertiary hard bottom (Fig. E1) (Hine and Snyder, 1985).

- As sea-level rise slowed and approached its present elevation about 4000 ago, Bogue Banks began to accumulate sediment from reworked paleo-inlet deltas and littoral sources (Hine and Snyder, 1985).

- Bogue Banks became a "regressive barrier" accreting seaward and vertically via build-up of the shoreface for several thousand years up to this century.

- Accumulation of littoral sediments in the area of present-day Bogue Banks, infilled paleochannels (inlets), the most recent of which were (Fisher, 1962):

  - Prehistoric relict inlet near the causeway to Atlantic Beach.
  - Two relict inlets (noted on Fig. E-5 as #1 and #2) in eastern Emerald Isle, approximately 0.1 and 2.0 miles west of Indian Beach, respectively.
  - Relict Cheeseman Inlet (closed sometime between 1860 and 1886) along west Atlantic Beach about one mile east of Pine Knoll Shores.

- With the exception of a short-term breach in the low area of eastern Emerald Isle during Hurricane *Donna* (1960), Bogue Banks has existed as a contiguous ~25-mile-long barrier island for almost 150 years.

- Bogue Inlet to the west and Beaufort Inlet to the east constitute the primary boundaries of the Bogue Banks littoral cell.

- Bogue Banks's bounding inlets contain huge reservoirs of littoral sand in the form of ebb- and flood-tidal deltas.

- Bogue Banks' positional stability allowed accretion of high dune ridges--in some areas, exceeding 40 feet (ft) above sea level and along most of the shoreline reaching 20 ft. Relief and absolute elevations across Bogue Banks are much greater than Core Banks and Portsmouth Island.

- High relief along Bogue Banks inhibits formation of washovers. Low longshore transport rates lessen the rate of sand loss to the inlets compared to east-facing barrier islands in other parts of Carteret County. Average erosion rates have been low (0-5 ft/yr) since 1939 according to available published reports.

- Subaerial sediments range from medium to coarse sand along the upper beach to fine sand in the dunes to mixtures of sand, coarse shells, and mud in back-barrier areas. The foreshore sediments coarsen toward the step (inshore breakpoint), then fine to the inner trough and bar. Seaward of a shore-parallel bar situated about 400 ft offshore, sediments fine along the lower shoreface.

TABLE E1. Selected references providing background information on the geology, geomorphic history, and sediments of the North Carolina coast (not specific to Bogue Banks).

NOTE: While by no means a complete list, these references provide an excellent overview of geologic processes, landforms, and sediments along the North Carolina coast. Their authors tend to be the researchers who frequently appear in the literature. Many remain active in the profession and continue to offer new insights regarding shoreline evolution. The list focuses on publications having relatively wide distribution. We particularly recommend *Geology of Holocene Barrier Island Systems* (R.A. Davis, editor, Springer-Verlag, 1994) for its collection of synthesis papers under one cover.

APPENDIX E2. SURVEY DESIGN

Despite a limited supply of beach-quality sand offshore of Bogue Banks as inferred from the literature (see Table E2), more detailed confirmation was required before ruling out alternative borrow areas. The study team recommended a reconnaissance-level survey during initial planning of the Bogue Banks restoration project based on the following desirable criteria:

- Viable sand deposits closer to the project areas than Beaufort or Bogue Inlets could potentially yield very large cost savings for the project.

- Sediments that are somewhat coarser (on average) than the native beach and coarser than the material typically available from channel maintenance would improve the durability of the nourishment projects.

- Deposits with lower mud/fine-sand content than previously used in Corps disposal projects would reduce the rate of fill losses and minimize turbidity in nearshore waters.

- If broad, shallow areas (at least 1-2 ft thick) could be confirmed, hopper dredges or alternate equipment could be used for excavations, and the rate of environmental recovery might be more rapid based on experience elsewhere (Jutte et al., 1999).

The sediment survey encompassed the following field sampling over two phases between June and November 1999:

- **Beach sampling and textural analysis** (June 1999) to quantify native material — 20 samples divided among dune (2), berm (6), beach face (6), and low-tide terrace (6) at CSE-Stroud transect 10 (west Emerald Isle), transect 30 (central Emerald Isle), transect 50 (Indian Beach), transect 70 (Pine Knoll Shores east), transect 90 (Atlantic Beach), transect 110 (Coast Guard Station); spacing of transects was approximately 20,000 ft.

- **Phase I borrow source sampling** (June 1999)
  - *Offshore reconnaissance* — 53 short cores by divers in a regional grid pattern encompassing a 16-mile length of coast from central Atlantic Beach to central Emerald Isle and extending between ~0.25 and 3 miles offshore. Generally consisted of shore-perpendicular transects of 3-5 boring locations at approximate two-mile intervals in the longshore direction. Additional, more closely spaced cores were collected 0.5-1 mile from the most promising sites. Cores average about 2 ft long.

  - *Bogue Inlet* — eight surface grab samples at five stations over intertidal shoals in the middle of Bogue Inlet.
  - *Bogue Sound* — three diver borings at accessible back-barrier areas adjacent to access channels.
  - *Corps disposal area (Brandt Island)* — four supratidal grab samples.

- **Phase II confirmation** sampling (November 1999)
  - *Borrow area A (western half)* — 46 borings (averaging ~2.3 ft) at ~1200-1500 ft spacing; eight vibracores (3-9 ft) at ~3000 ft spacing.
  - *Borrow area B1* — four diver borings (~2.8 ft); three vibracores (7.5-11 ft).
  - *Borrow area B2* — seven diver borings (~2.9 ft); three vibracores (~9-10 ft).
  - *Bogue Inlet intertidal shoals, borrow area "C"* — six short cores (~4 ft).

CSE Baird performed all Phase I sampling and the diver sampling for Phase II. Athena Technologies, Inc. (Columbia, SC) performed the vibracore sampling under subcontract to CSE Baird. Positioning was via Garmin Model Map215 differential GPS navigation system which provided ~10-15 meter accuracy after considerations of boat swing over each coring site.

The only known borings prior to the 1999 survey in the primary offshore region (central Bogue Banks) were those collected in the early 1980s by university researchers (Dr. S.R. Riggs and Dr. A.C. Hine, principal investigators, as reported in Hine and Snyder, 1985) (Fig. E2). That regional survey of Onslow Bay included approximately 20 vibracores on the inner shelf inside the 20-meter depth contour off Bogue Banks. The Hine and Snyder (1985) borings generally describe a shore-parallel line about 3-3.5 miles offshore. Several borings were made closer to shore in presumed paleochannels off the western end of Atlantic Beach and western Emerald Isle (Fig. E2). Hine and Snyder noted for the area thin layers of Holocene sands and crushed shell overlying more heterogeneous Pleistocene sediments. Paleo-channels (Fig. E2) reportedly contained admixtures of mud, sand, shells, and phosphatic material.

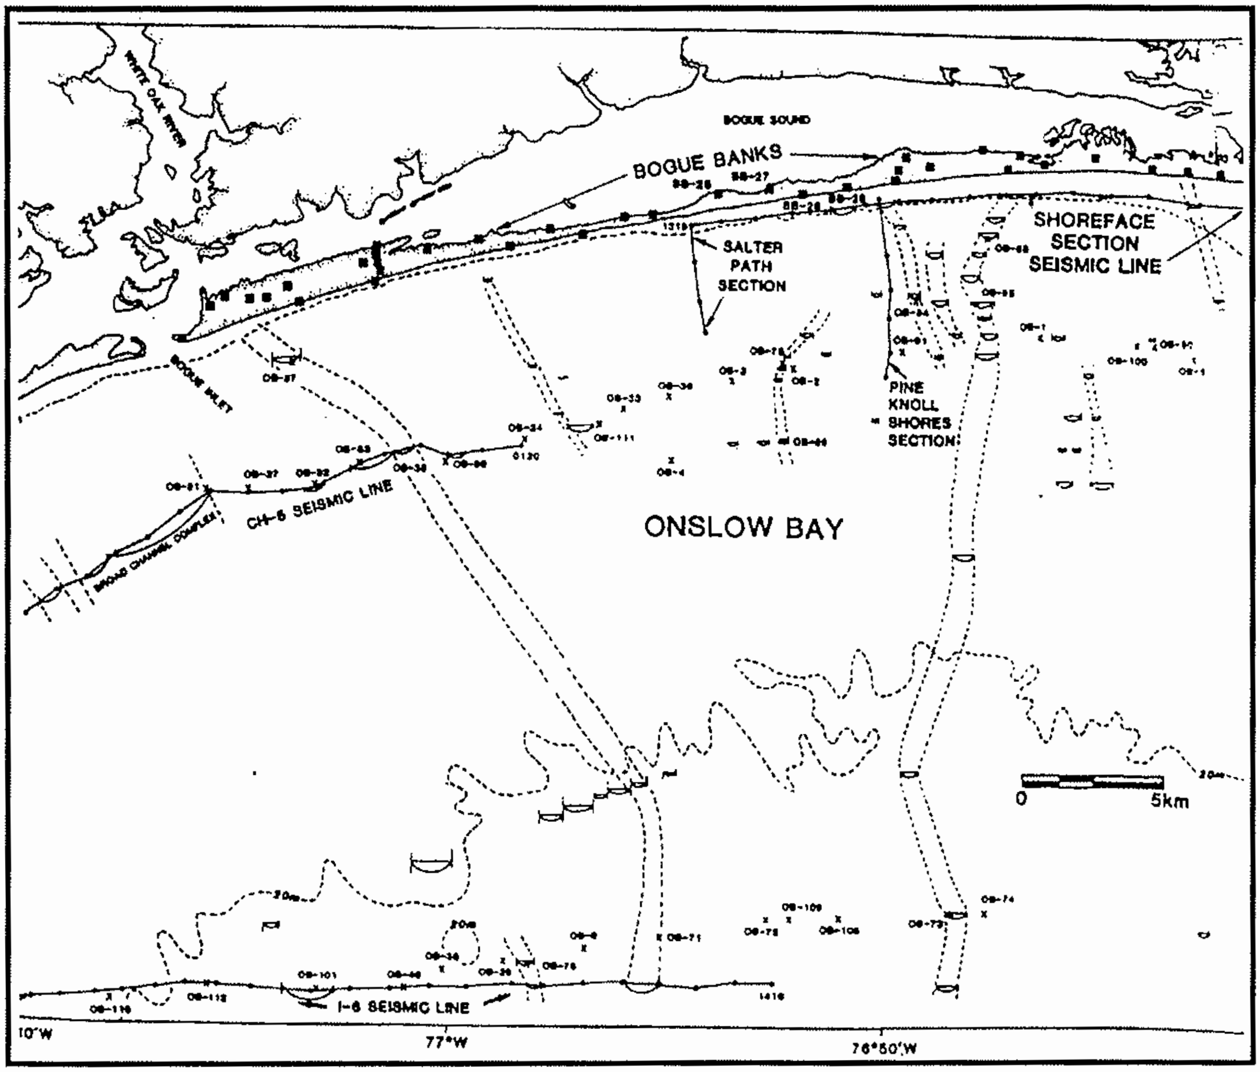

FIGURE E2. Vibracore locations and inferred positions of buried paleochannels (dashed lines perpendicular to the shoreline) offshore of Bogue Banks. Outer depth contour is 20 meters (~65 ft). [From Hine and Snyder, 1985; Fig. 2]

The present study focused on the uppermost ~2-3 ft layer for three reasons:

1) Preliminary evidence suggested that the "Holocene" section was more likely to contain beach-quality sediments.

2) Hopper dredges reportedly work most efficiently in borrow areas where the depth of cut is of the order 1-2 ft (E. Elefson, Aug. 1999, Weeks Marine, pers. comm.).

3) Given a fixed budget for offshore surveys, many more shallow borings could be obtained by divers working out of small craft compared to the number of vibracores possible using much larger equipment.

The study design provided for a two-phased search whereby preliminary borrow areas would be defined using a coarse regional grid of samples, then refined in Phase II by a more detailed search. Phase II also provided for a representative sampling of thicker sections using a large vibracore rig sufficient to recover ~10-ft samples.

In total, the 1999 surveys accomplished the following:

- Characterized the upper 2-3 ft of sediments in an approximate 50 square mile area off Bogue Banks.
- Identified potential offshore borrow areas representing approximately 10 square miles.
- Confirmed sediment in potential borrow areas in sufficient detail to develop isopach maps of textural properties.
- Obtained ~90 percent of the borings in the most promising six square miles, yielding an average 15 borings per square mile in the potential borrow areas.

The reader is also referred to sediment quality data from ten environmental sampling sites around the offshore borrow areas, reported by University of North Carolina investigators in Appendix C of this document. Those data apply to the upper 2 centimeters (0.07 ft).

APPENDIX E3. LABORATORY ANALYSIS

Sediment samples were collected and stored as follows.

Diver cores — two-inch aluminum barrels driven by hammer to refusal, cut, and temporarily capped in situ; then decanted, cut to sediment level, and recapped in the field noting penetration depth and recovery thickness; stored vertically for transport to the lab.

Vibracores — 2½-inch steel barrels driven remotely via large-scale vibrator to the depth of refusal; removed, cut, capped, and measured for penetration depth and recovery thickness.

Grab samples (beach) — hand samples from the upper three inches placed in sample bags.

Grab samples (Bogue Inlet)
- *Phase I* — hand samples in the upper six inches on the bar surface and in two vertical sections along steep slip faces adjacent to the channel.
- *Phase II* — on the subaerial bar surface by posthole excavations and short core tubes to achieve a representative 4-ft section; stored in plastic bags.

Samples were logged, split, and analyzed as follows.

1) **Diver and vibracore cores** — split by saw, logged, and one-half sampled as a single or multiple composite; the remaining core half was sealed in plastic in its half barrel and archived.

   Phase I samples — visual estimates of mud percentages; then washed, dried, and dry-sieved using 0.25 phi (ϕ) intervals from -1ϕ to 4ϕ – that is, granule (2 mm) to very fine sand (0.0625 mm); fractions retained >2 mm and <0.0625 mm were noted.

   Phase II samples — same handling and grain-size analysis procedures as Phase I samples except nearly all tested for percent mud and percent carbonate via subsampling.

   - *Percent mud* was determined by drying an undisturbed sample (composite from the length of the core), weighing it, rewetting and disagregating the sample, decanting the mud fraction until the water ran clear, redrying the sample, then reweighing it. Percent mud is computed from the difference in dry weight of the unwashed and washed samples.
   - *Percent carbonate* was determined from a 20-gram subsample that had been washed and dried, then treated with repeated quantities of 10 percent dilute HCL for several hours until all reactions stopped. Samples were redried and reweighed for comparison with the untreated sample weight, and the percentage of carbonate material is computed.

2) **Native beach samples, Bogue Inlet samples (Phase I and Phase II) and other miscellaneous samples** — representative splits were obtained, washed, dried, and dry-sieved at 0.25ϕ intervals. No mud analyses were performed because the grab samples were generally void of mud. Percent carbonate was determined via the same procedure for Phase II cores, for the Bogue Inlet (Phase II) samples, and groupings of native beach samples (i.e., physical composites of multiple berm, beach face, etc., samples).

Raw data were entered into spreadsheets and analyzed via custom software (CSE's BPAS system) which automates computation of standard statistical parameters [including moment measures and the graphic parameters of Inman (1952) and Folk and Ward (1957)]. Grain-size distributions (GSDs) were graphed as frequency and cumulative frequency distributions using phi (ϕ) and millimeter (mm) axes for cross-reference. To facilitate evaluation and comparison with other engineering sieve sizes, Figure E3 shows the general relationships of grain size (mm), phi value, sediment classification, and ASTM sieve mesh sizes.

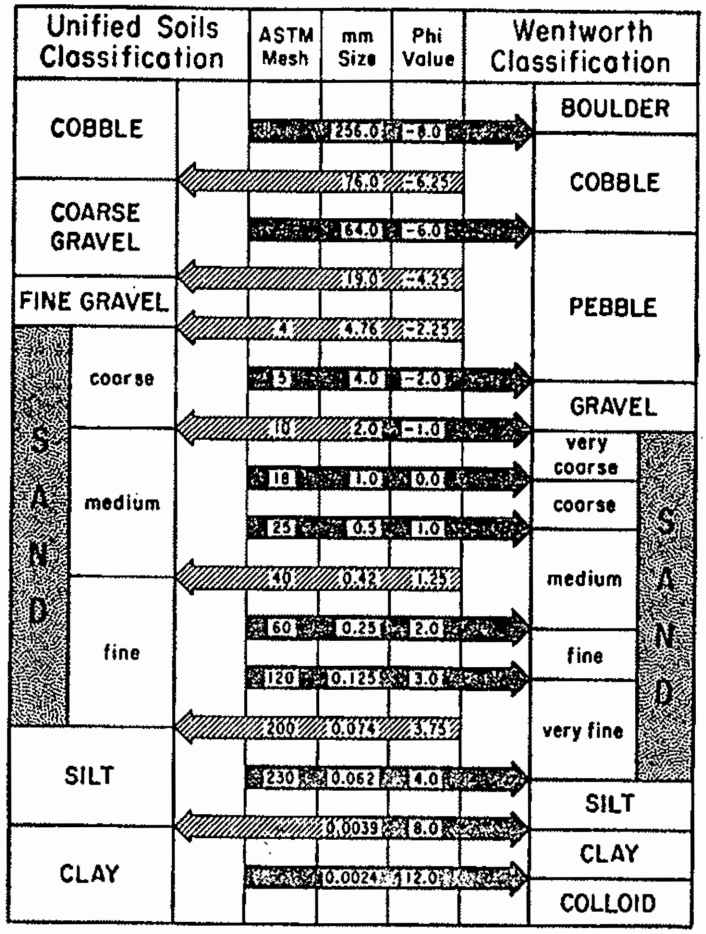

FIGURE E3. Grain-size scales (soil classification).

Sediment quality and compatibility for beach nourishment were based on the technique of James (1975) (CERC, 1984), whereby a population of potential borrow area samples is compared statistically with the native beach size distribution. James (1975) presents methodology for computing the "overfill ratio," R_A, which represents how similar a particular size distribution of sediments is compared to the native population of sediments. R_As of nearly 1.0 suggest the sample will perform more or less equal to the native population. Higher R_As represent the ratio of non-native "borrow" material required to perform as 1.0 unit of native material. Thus, an R_A equal to 2.0 suggests it will take twice as much material to equal 1.0 unit of native sediment.

The concept of overfill ratios is not a perfect predictor of nourishment performance, but it remains perhaps the most useful and proven technique for comparing nourishment sediments (NAS, 1995). The primary factors considered are mean grain size and sorting (standard deviation measure of the size distribution). Experience has shown that borrow sources at least as coarse as the native beach (Dean, 1991; CERC, 1984) or having significant coarse fractions (Kana and Mohan, 1998) perform equal to or better than native sediments (as measured by durability of the dry beach). Borrow sediments that are finer than native or that contain high percentages of fine material perform worse (NAS, 1995). This response is related to profile adjustment (function of wave energy and wave steepness) as well as the background erosion rate. Obviously, the concept of R_A as a predictor of performance assumes that the scale of the nourishment is relatively large and covers a reasonable length of shoreline. Short projects do no perform as well for another reason--because end losses cause spreading away from the nourishment "bulge" (NAS, 1995).

For purposes of the 1999 study, we determined R_As using the James (1975) nomogram in CERC (1984) (Fig. E4). The resulting R_As were revised based on the percent mud in each sample and reported as a revised overfill ratio. Mud is assumed to winnow out quickly, thus increasing the R_A in direct proportion to the mud percentage. Mud is defined as those sediments testing in the silt-clay range (mean size <0.0625 mm or >4.0ϕ).

Sediment quality and borrow area suitability was based on the R_As, mean grain size and sorting parameters, percent mud, percent carbonate, percent coarser than 2 mm (i.e., granule, or larger), and proximity to the project area.

Where data were sufficiently dense, we prepared isopach maps of various sediment size/quality parameters and R_As, and present them in the results section.

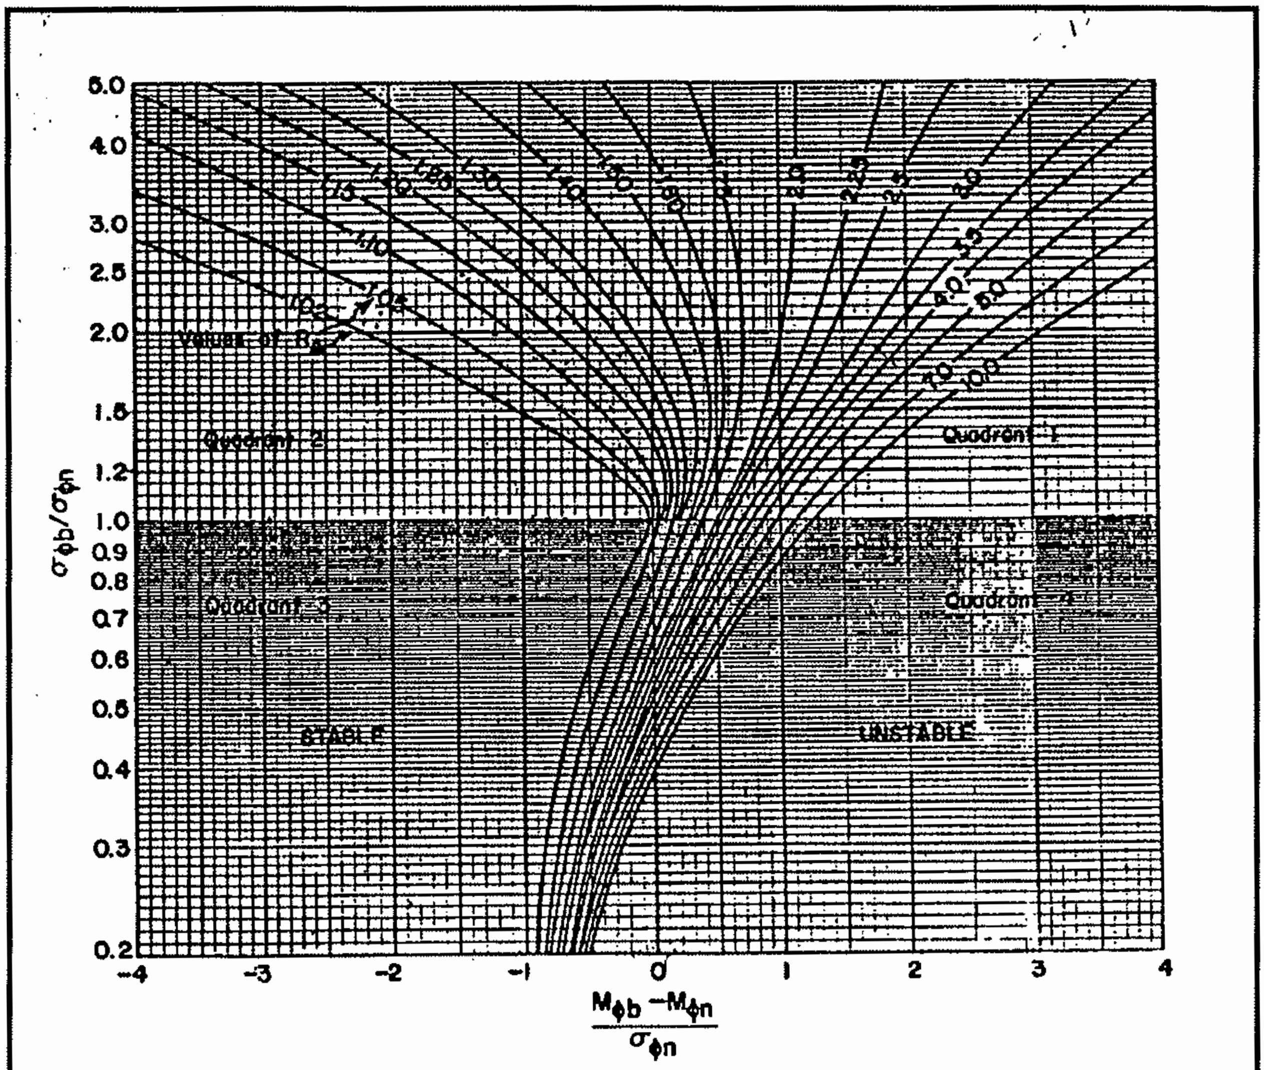

FIGURE E4. Isolines of the adjusted overfill factor for values of phi mean difference and phi sorting ratio (from James, 1975).

APPENDIX E4. SEDIMENT RESULTS

This section provides a summary of results and refers to data sets contained in Annex E1. Information on core and sample locations and summary statistics are given in Annex E1 as follows:

Table E1-A. Core locations in latitude/longitude and North Carolina State Plane System (NAD'83) (Phases I and II).

Table E1-B. Beach sample locations (CSE-Stroud transect numbers), grain-size statistics (mean, standard deviation, and skewness), sediment description.

Table E1-C. Bogue Inlet, Bogue Sound, and Corps spoil island samples — June 1999 Phase I sediment characteristics.

Table E1-D. Offshore core sediment characteristics — June 1999 Phase I samples.

Table E1-E. Offshore core sediment characteristics — November 1999 Phase II samples.

Grain-size distributions, size frequency curves, and textural classifications are contained in Annex E2. Because of the large number of individual samples, results are grouped by phase and sample area with divider pages between phases as follows:

Phase I	Beach	BB series	21 samples
	Bogue Inlet	BI series	8 samples
	Bogue Sound	BS series	3 samples
	Corps Disposal Area	BD series	4 samples
	Offshore Cores	C(MILE) series	53 samples
Phase II	Borrow area A	A series	59 samples
	Borrow area B1	B-1 series	7 samples
	Borrow area B2	B-2 series	13 samples
	Borrow area C	C series	6 samples

NOTE: Selected core locations were sampled by vibracore. These are given on sample sheets as ATH series or cross-referenced with A, B-1, and B-2 series. In some cases, two samples were processed for a core, in which case the samples are given as "S1" and "S2" in the suffix of the sample label. The sample thickness or interval (in the case of multiple samples) is given in Tables E1-D and E1-E. Core logs are given for the vibracores at the back of Annex E-2.

E4.1 Beach Composites

Native-beach size distributions were established using statistical composites of physical composite results of individual samples. Table E3 contains the individual sample results (primary statistics) from 21 dune/beach/low-tide terrace samples distributed in six transects along Bogue Banks. Of the three dune samples, only two were considered representative of natural dunes, which tend to have finer sediment than beach-face samples. At stations CSE-Stroud 30, CSE-Stroud 50, and CSE-Stroud 70, repeated dune scraping has introduced anomalously coarse sands from the berm. Therefore, these stations were not sampled at the dune. At station 110 (Coast Guard station), nourishment via Corps spoil projects has introduced a coarse sediment which similarly does not reflect native dune sands, therefore it was eliminated from the composites.

Mean=0.362 mm Std dev=.563 mm Skewness=-0.542

** Spoil Section   **Nourished Section

Sets of composites were computed as follows:

1) Composite "20" based on 20 samples (2 dune, 6 berm, 6 beach face, and 6 low-tide terrace).
2) Composite "12" based on 12 samples (6 berm and 6 beach face).
3) Composite "Dune" based on 2 dune samples.
4) Composite "Berm" based on 6 berm samples taken from the dry beach.
5) Composite "Beach Face" based on 6 beach face samples taken from the middle of the upper beach face.
6) Composite "LTT" based on 6 low-tide terrace samples.

The composite results are given at the bottom of Table E3 (statistics and frequency curves in Annex E3). Review of the results confirmed coarsest sediments tend to reside on the berm and beach face (medium sand, moderately sorted, coarse-skewed) with finer sediments occurring along undisturbed dunes and low-tide terrace (typically fine sand, well sorted). Composite "12" yielded a mean grain size of 0.362 mm along the beach face and berm, whereas composite "20" yielded a mean size of 0.302 mm. Considering that the proposed nourishment is designed to widen the recreational beach including part of the under-water profile, we elected to use the composite "20" as a "native" beach. This weights the composite toward the coarse sizes common along the beach face, berm. and low-tide terrace where the majority of the nourishment sand will be placed. We also elected not to include samples over the outer bar or further offshore (even if these areas are part of the littoral zone), because they tend to be much finer than the beach face and would weight the "result" toward less stable sediment sizes. Similarly, we elected to only include two dune samples in composite "20" because a relatively small percentage of nourishment sediments will be subject to aeolian processes or contribute to dune building after construction.

The "native" composite selected for a baseline in the 1999 study is considerably coarser than the native sediment distribution used by the USACE (1976) in planning for potential disposal projects along Atlantic Beach. The Corps sampled at 2 ft intervals from the berm to -30 ft mean low water (MLW) along four transects at the eastern end of Bogue Banks. Their statistical composites yielded a mean grain size of 0.17 mm (2.52ϕ) and standard deviation of 0.77ϕ. The Corps results confirm the fining of sediments offshore but tend to weight the result toward less stable material. The native composite we chose is much more conservative for beach nourishment planning because it eliminates from consideration certain fine deposits that characterize the area seaward of the bar. Use of a coarser "native" size distribution lowers the amount of potentially beach-compatible material in our search areas. At the same time, it better distinguishes good sediment from marginally acceptable sediment.

E4.2 Phase I Core Samples

The Phase I sediment test results are summarized in Figures E5 and E6. Figure E5 shows the general locations of diver cores (C## series) obtained in June 1999. The ## (i.e., 10a, 14b, etc.) corresponds approximately to the distance in miles west of Beaufort Inlet of a particular transect. The subscript "a" relates to whole-mile distances and "b" to one-half mile distances. Therefore, core C12a(#) is from a transect approximately 12 statue miles from Beaufort Inlet and C14b(#) is approximately 14.5 miles from the inlet. Also shown on Figure E-5 are the locations of shore profiles. Beach samples were collected at transects 10, 30, 50, 70, 90, and 110.

Grain-size isopachs developed for the Phase I cores are shown at the bottom of Figure E5. Also, superimposed are paleochannels inferred by Hine and Snyder (1985), largely from seismic records (limited number of cores as shown on Figure E2).

Figure E6 contains isopachs and sample data relating to the percentage of coarse material in each location (>2 mm mean diameter). The lower half of Figure E6 shows the approximate thickness sampled and confirmed, along with a visual estimate of mud percentages.

These preliminary results were used to identify three potential borrow areas: A, B1, and B2. Area A (Fig. E5, upper), represented by 12 cores, tended to contain the coarsest material and the least mud. Areas B1 and B2 were identified as promising because of their proximity to shore and reasonable uniformity of sediment with low mud content. B1 is represented by seven cores and B2 by four cores collected during Phase I.

E4.3 Phase I Sediment Compatibility

Groups of samples for each potential borrow area (including Bogue Inlet, Bogue Sound, and Corps spoil island samples) were compared with the native beach. Using the method of James (1975), borrow composites were compared with native beach composites to yield an overfill (R_A) factor for each borrow area (Table E4). The results--using beach composite 12 as well as beach composite 20--show a significant range with borrow areas A and C containing sediment that most closely matches the native beach. R_As for borrow area A were 1.10 on composite 20 and 1.13 on composite 12. Borrow areas B1 and B2 had finer sands on average, yielding R_As of 1.62 to 1.80 on composite 20. Samples from Bogue Sound yielded R_As >10, meaning only a small fraction of those deposits would provide stable nourishment sediments along the ocean beach. Most of the sediments in Bogue Sound are believed to be fine sand, silt, or clay.

On the basis of the preliminary results, CSE Baird recommended further sampling to refine borrow areas A, B1, B2, and C. Sediment quality and compatibility for nourishment as reflected by R_As in each deposit served as a basis for preliminary project formulation (CSE Baird-Stroud, 1999).

E4.4 Phase II Core Samples

The Phase II sampling strategy consisted of establishing a grid of closely spaced samples over the most promising section of area A and filling in gaps along areas B1 and B2. Approximately 60 additional borings were made by CSE Baird divers, and 14 vibracores were obtained by subcontract to Athena Technologies, Inc. (c/o Dr. Walter J. Sexton, P.G.). The western half of borrow A was targeted because of its slightly coarser sediments than the eastern half. Prior to sampling, we prepared a 15-second grid which yielded sampling "nodes" spaced ~1200x1500 ft apart in the longshore and cross-shore directions, respectively. Revised borrow area A (target) is an L-shaped grid ~12,000x12,000 ft (Fig. E7). Typical water depth is 45-50 ft, and its closest edge to the shoreline is ~2500 ft offshore. Because not every node was sampled (or was sampled during Phase I or by Athena Technologies in Phase II), station (sample) numbering is not in continuous sequence.

Revised isopach maps of various sample parameters were prepared over the target borrow areas where data provided relatively dense coverage. Figures E8 through E12 show the following:

Figure E8	Mean grain size (mm)
Figure E9	Percent mud
Figure 10	Percent carbonate
Figure E11	Percent coarser than 2 mm
Figure E12	Confirmed thickness (ft) based on the recovery length of cores or sample interval (as noted)

Table E5 contains sediment compatibility calculations (R_As) for all samples (Phases I and II) compared against the beach 20 composite. (Note: Sample statistics for skewness, percent carbonate, and percent coarser than 2 mm are given in Annex E1 through Annex E3.) Two R_As were computed during Phase II—the first on washed samples (mud eliminated) and the second factoring in the mud percentage. In the latter, mud adds an incremental volume of nonbeach-compatible material which increases each R_A in direct proportion to the sample mud fraction. This "revised" R_A is given on the summary map in Figure E13 and used as a basis for developing isopachs of sediment compatibility. Note that in some of the figures, nonlinear isopach spacing is used to simplify the graphic.

Table E6 summarizes the results for each borrow area and provides nonweighted averages for key sediment parameters. All values are approximate because percent mud for June samples was visually estimated. Nevertheless, the results reflect the typical character of sediments in each borrow area. During Phase II, the boundaries for borrow area A were revised to a much smaller area, and the boundaries for B1 and B2 were shifted to fit the sample distribution and to stay within the 30-40 ft depth contour.

The revised borrow areas yield revised R_As (factoring in mud percentage) of 1.16 at borrow area A, 1.57 at borrow area C, 1.97 at borrow area B1, and 2.19 at borrow area B2. Overall, borrow area A (revised) provides the deposit likely to perform the best for nourishment because its sediments are slightly coarser than the native beach. Carbonate material (mostly broken or crushed shell) comprises about 44 percent of the sediment in the confirmed section (versus 15-20 percent on the existing beach) and about 20 percent of the deposit is coarser than 2.0 mm. Mud percentage in borrow area A averaged ~4 percent in the applicable sections.

Borrow area C had the next lowest average R_A at 1.57, meaning ~35 percent more material would have to be placed to yield the same performance as borrow area A. Area B2, while averaging close to the native beach in mean grain size (composite 20), has areas of poor-quality material. As noted in Table E7, certain samples were omitted from the statistics under the assumption that these areas would not be dredged. Other sections of the EIS for the project provide refined borrow area criteria and suggest revisions in the areas to avoid marginal sections. The confirmed borrow volumes indicate borrow area A alone could potentially provide sufficient quantities for the present project. Similarly, borrow areas B1 and B2 could provide sufficient volumes, although 70-90 percent more sand would have to be pumped compared to borrow area A to yield comparable performance. Borrow area C is not sufficient by itself to provide the necessary project volume but could serve to supplement borrow areas A, B1, and B2. Further considerations addressed elsewhere in the EIS are the economics of borrowing from multiple areas based on proximity to the project sections.

Figure E13
Borrow area sediment capability based on revised overfill factors Ra (including mud%)

Table E6. Summary RAs and representative statistics for revised borrow areas A, B1, B2 & C.
Based on Phase II samples plus applicable Phase I samples.
See Figure E7 for Phase II revised Borrow Area Delineations.

Borrow Area	**# Samples**	**Mean Grain Size** (mm)	**Mean Grain Size** (phi)	**%mud**	**RAs** revised
A	61	0.51	0.974	4.0	**1.16**
B1	13	0.23	2.105	2.6	**2.19**
B2	17	0.30	1.729	4.1	**1.97**
C	8	0.42	1.255	<1	**1.57**
Native Beach	20	0.302	1.725	<1	**1**

Borrow Area	**Area** Acres	**%carbonate**	**% >2mm**	Confirmed **Thickness** (Ft)	Confirmed **Borrow Volume** (Cubic Yards)
A	2850	~44	~20.5	2.2	10+ million
B1	645	~20	~4.5	2.9	~3 million
B2	760	~22	~7.5	2.8	3+ million
C	370	ND	~5	~5	~3 million
Native Beach		~15-20	~5	NA	

Notes: Phase I & II samples omitted from the above statistics because they are outside the revised borrow area or represent sections below the confirmed thickness.
Area A: C10A4, C11A1, C12A3, C14B2b (lower unit below 1.8 ft), A-11s2 (lower unit below 3.3 ft), A-22s2 (lower unit below 3.0 ft), A-35s2 (lower unit below 2.4 ft), A-58, A-70B (below 1.25 ft).
Area B1: C7A2, ATH 9s2 (lower unit below 3.8 ft).
Area B2: C12A2, C17A1
Area C: Sample BI-4A, BI-4B, BI-3C, C-06

The confirmed borrow volume represents the potential maximum volume of material that could be obtained from the indicated borrow areas. In actuality, shallower cuts over a more select area will be planned during final design, with the idea of optimizing the area for best fill performance, and lowest cost of dredging. The final borrow areas will be revised to avoid any cultural artifacts, or unique biological habitats identified in other sections of the present EIS.

5 08-5 67 Silty, Mud High omount of intoct oyster shells
(OH) MU SH

5 67-9 0 Olive, soft Mud High woter content, moldoble Minor unidentifioble plont frogments present Some fine sond infilled burrows present Unit becomes silty down core (OH) MU

9 0-9 43 Fine groined well sorted Sond 3mm white corbonote lenses present Becomes finer with depth (SN) FX

APPENDIX F

ECONOMIC STUDIES

LIST OF TABLES

APPENDIX F

Supporting Computations for Section 4.3 "Retreat/Relocate Alternative"

The first three tables in this Appendix are the calculations for the summarized numbers in Section 4.3. Table F-1 breaks down the costs for relocating a house on the same lot, Table F-2 the same computations but for moving to a different lot (insufficient room remains on the same lot), and Table F-3 shows the cost breakdown by municipality.

In the analyses of the retreat/relocate alternative it is assumed that costs occur equally in each year of the 10 year study period; that construction costs escalate at 3 percent per year; that real estate costs escalate at 4.8 percent per year. Final costs for comparison with project costs are normalized to present value based on the discount factor for 30 year Treasury bonds as of February 24, 2000 as published in the Wall Street Journal.

The relocation costs used in the previous tables are supported in detail in Table F-9, showing the different relocation costs by community. The accumulation of these costs by year and type of relocation are further broken down in Table F-10. Thus F-10 feeds the supporting data into F-9, which then provides supporting data for the first three Tables F-1 through F-3.

Finally, the net present worth of all these relocation costs are summed in Table F-11 over the ten years.

Supporting Computations for Section 4.2 "Do-Nothing Alternative"

Impacts on Property Values

The number of oceanfront properties that will be lost under the 10-year project life are totaled in Table F-4 and the values totaled. The appropriate tax rates are then applied to determine the total property tax losses, broken down by community in each section of Table F-4. This is a government loss.

Table F-5 shows the lost property values by year and by community. These are losses to those in the special tax districts.

The present worth of the property tax losses are computed in Table F-6. **This value of $6.3 million is reported in the summary table in Section 4.2.**

In addition to the actual loss of property, there is a loss to the appreciated values, had the structures remained. The present worth of all lost properties, taking into account appreciation, are totaled by community in Table F-7. The listed property losses are losses in the Special Tax Districts, and the listed property tax losses are government losses.

All types of property loss are summarized in Table F-8. These include lost property, lost taxes, beach scraping, property repairs, and debris removal.

The relocation costs used in the previous tables are supported in detail in Table F-9, showing the different relocation costs by community.

Impacts to the Community (Carteret County) Economy

Tourist Expenditures -- Total revenues generated from domestic tourism in Carteret County has been estimated by Carteret County Economic Development Council to be $208.55 million (1998) in "Facts on Carteret County Tourism" based on statistics provided by NC Department of Commerce. The proportion of tourist revenues in Carteret County that are generated on Bogue Banks has been estimated by the same sources as 84 percent. The proportion of recreational beaches on Bogue Banks that this beach-nourishment project is planned to improve is the ratio of this project length to the total beach length or 78 percent. Thus the maximum tourist expenditures that are in jeopardy if there is no recreational beach over the proposed project length is 0.84 x 0.78 x $208.55 million = $136.64 million annually or $1,366.4 million over the ten-year lifetime of the project. The prime tourist attraction in Bogue Banks is the beach. It is difficult to estimate the percent of tourists who would not come to Bogue Banks if the proposed project beach has little or no beach above high tide. Some tourists who come to the area do not use the beach. Those who do use the beach will increasingly crowd onto remaining healthy beach areas such as Atlantic Beach. However, a range of possibilities can be considered. For inclusion in the high and low estimates in Section 4.2, we propose a low limit of 10 percent and a high limit of 25 percent proportion of tourist population that will elect to go elsewhere. Thus the total lost tourist revenues over ten years would range between $136.64 million and $341.61 million. For the purpose of ascertaining who will experience these losses, lost tourism is broken down into the following categories.

Occupancy Tax – There is a 3 percent occupancy tax on all short-term (visitor) rentals. In fiscal year 1998-99 this generated $1,706,788 in Carteret County. Using the numbers in Tourist Expenditures above, losses of occupancy tax for one year would be 10-25 percent of 0.84 x 0.78 x $1,706,788. So the loss range over ten years is $1,118,287 to $2,795,718. This is a governmental loss.

Sales Tax – There is a 6 percent sales tax on non-housing expenditures. The Economic Development Council (reference publication listed above under Tourism Expenditures) estimates $20.05 million of these annual revenues are generated by tourists in Carteret County. Using the numbers in Tourist Expenditures above, losses of sales tax for one year would be 10-25 percent of 0.84 x 0.78 x $20,050,000. So the loss range over ten years is $13,136,000 to $32,840,000. This is a governmental loss.

Payroll – The tourism industry is Carteret County's largest industry. The Economic Development Council estimates this annual payroll at $48.99 million. Using the numbers in Tourist Expenditures above, losses of payroll in one year would be 10-25 percent of 0.84 x 0.78 x $48,990,000. So the loss range over ten years is $32,098,000 to $80,245,000. This is a private loss.

Other Tourist Expenditures – The remaining tourist expenditures (total minus tax and payroll) over the project portion of Bogue Banks are annually 0.84 x 0.78 x ($208.55 - $1.71 - $20.05 - $48.99). So the range of possible losses (10-25 percent of this value multiplied over ten years) is $90.287 million to $225.718 million. This is a private loss.

Recreational Losses – Losses to the environment are more difficult to quantify than economic losses. However, the Corps of Engineers has established procedures for estimating the value of a recreational beach to the general public. Procedures outlined in Engineering Regulation 1105-2-100 were followed. Some choice of methods is allowed under the regulation, but most nourishment projects designed by the Corps use example surveys of the beach-going public that have resulted in "use curves" based on surveys conducted in Florida that were later updated in the Myrtle Beach, SC, project (USACE, 1993). These studies compute the number of beach visits annually by each person (P) as P = A exp (B x) where A and B are empirical coefficients determined by surveys, and x is the travel distance between a community and the beach. The Florida study generated values of A = 6.8 and B = -0.03, and Myrtle Beach updated these to A = 8 and B = -0.04. The A value represents the annual number of beach visits made by a resident who is within walking distance of the beach. Using these values the annual number of beach visits made by residents of Carteret County was computed in Table F-12.

The annual visits total 310,181. To translate this into a dollar value, procedures are available for assigning "point" values to various recreational experiences associated with the amenities at a particular beach. Rather than follow these complex procedures which tends to result in variation in the final number of only 10-20 percent, we simply used the value computed in another study for Folly Beach, SC (USACE, 1991) which produced a value per visit of $3.44. Multiplying the number of annual visits by this value results in an annual recreational value to County residents of $1,067,022. The portion of Bogue Banks represented by this project is 78 percent, so the annual recreational value to residents is 0.78 x $1,067,022 or $832,277. Following the same logic outlined above for Tourist Expenditures, we propose that 10-25 percent of these visits will not occur because of the degraded beach. Ten to 25 percent of the above value multiplied over the ten-year project results in value of $832,277 to $2,080,693. This is an environmental/quality-of-life impact to the county.

Impacts to Owners in Special Tax Districts

Beach Scraping – Since Hurricane *Floyd* (September 1999), an estimated 80 percent of oceanfront properties in the proposed project area have scraped the beach and restored the foredune. Scraping was continuing on 1 March 2000, nearly six months after *Floyd.* Typical dimensions of scraping are 10-15 cubic yards per linear foot. Scraping is performed by skimming the upper 2-4 ft of dry beach by bulldozer and pushing it into a steep sloping dune (typically 1 on 4 seaward slope). Elevation of the top of the scraped dune generally coincides with the backshore escarpment elevation (typically 15-20 ft NGVD). Typical range of expenditures per 100-ft oceanfront lot have been $500–3000 per incident. Some owners have scraped nearly every year since 1995. While the crest elevation of the scraped dune is well above the 10-year or 25-year surge elevation, the protection is not equivalent because the remaining beach after scraping is narrower and less able to absorb wave energy. As a result, the scraped dune is exposed at the toe and vulnerable to scarping. This, in turn, leads to mass wasting of the scraped dune and the need to rescrape. As erosion continues under the no action alternative, the frequency of erosion and undermining of the artificial dunes will increase. For purposes of cost estimating, we assume that 50 percent of the beach will require scraping in any given year. Scraping 50 percent each year results in an annual cost of $250,000. Escalating and normalizing to present value is $ 2.2 million over ten (10) years: (Table F-8).

Reconstruction of Dune Walkovers – An estimated 80 percent of existing dune walkovers in the project area have been rebuilt since Hurricane *Floyd.* Many of these same property owners had to replace their walkovers after *Fran* and the other hurricanes of the late 1990s. The nature of repairs ranges from replacement of just a few steps at the base to entire reconstruction of support piles, observation decks and handicapped ramps. A majority of walkovers extend from relatively high backshore elevations (typically 15–20 ft NGVD), thus the support systems are elaborate in many cases. With increasing frequency of runup to the base of structures, repaired walkovers are usually improved and more expensive compared to the destroyed walkover. We estimate a range of expenditures per property is ~$200 to $10,000 after *Floyd*, with a typical cost around $3000, or approximately $2.2 million. Thus, the ten-year cost of walkover replacement due to storm erosion has a present value of $19.1 million (Table F-8). This is an impact to oceanfront property owners.

APPENDIX G

APPENDIX G — LITTORAL PROCESSES

APPENDIX G1. PREVIOUS STUDIES

A substantial amount of literature exists on Outer Banks beaches, some of it specific to Bogue Banks. Generally there are two types of data that are fairly plentiful: monitoring studies of Beaufort Inlet by the Corps of Engineers and geological studies of the Outer Banks as student theses at various universities.

The Corps of Engineers studies on Beaufort Inlet are so numerous that Beaufort is used as the Corps' example of how to evaluate inlets in their Engineering Manual "Coastal Inlet Hydraulics and Sedimentation" (USACE, 1995). There is a substantial amount of bathymetric profile data for the inlet, and more recently, beach profiles for Atlantic Beach. What is generally missing are "coastal process" measurements, that is, waves, currents, tides, and sediment transport.

The student theses from Duke University, North Carolina State University, and University of North Carolina are rich in information about the geology of the islands themselves (hundreds of core samples taken on various barrier islands and sometimes profiles of the beach), but they are quite sparse in information for the underwater portion of the beach. Core samples and beach profiles generally end at the water line.

Many of the findings in the literature relevant to a Bogue Banks beach-nourishment project are listed in Table G1.

TABLE G1. Literature Summary — Historical Documents

Thesis on relict inlet locations — 1962. UNC. Fisher, J.J., Geomorphic expression of former inlets along the Outer Banks of North Carolina, 120 pp.

- Summary of former inlets in NC, as detected by geomorphology
- Distribution of relict inlets for entire outer banks shown in Figure 4
- Aerial photo of 3 Atlantic Beach relict inlets in Figure 5
- 1860 map of Atlantic Beach relict channels, Figure 6
- Opening history of Beaufort Inlet, p. 88
- Opening history of Bogue Inlet, pp. 88-89
- Opening history of Bogue relict inlet #1, pp. 89-90
- Opening history of Bogue relict inlet #2, p. 90

Study on hurricane impacts on Bogue Banks — 1966. USACE. Beaufort Inlet to Bogue Inlet, North Carolina. US House Document No. 479, 89th Congress.

- Survey of hurricane damages
- Recommends flood dike for west side of New River. Other protections not economically feasible
- 8 hurricanes listed, 1953-60, p. 16
- Hurricane surges, 1953-60, p. 17
- Hurricane tracks, 1953-60, p. 18
- Hurricane damages, 1953-60, p. 19

Dissertation on geologic history of Bogue Banks (UNC Chapel Hill) — 1967. UNC. Fisher, J.J. Development pattern of relict beach ridges, Outer Banks barrier chain, North Carolina, 247 pp.

- Maps of 300+ relict beach ridges on Bogue Banks, with 7 sequences (Fig. 53)
- Sequential development of Bogue Banks, Fig. 57
- Soil map for Bogue Banks, Fig. 58

NCSU study on North Carolina beach erosion — 1973. NCSU. Knowles, C.E., J. Langfelder, and R. McDonald. A preliminary study of storm-induced beach erosion for North Carolina. NCSU Rept. No. 73-5, 14 pp. + figs.

- Topographic surveys along each fishing pier
- Storm surge levels recorded and plotted as function of return frequency
- Design surge levels and breaking-wave depths, Table 1
- Estimated beach recession for 25 yr storm (21 ft), 50 yr (162 ft), 100 yr (220 ft) at Bogue Banks, Table 2
- Plot of storm surge versus return period (Fig. 1)

Thesis on Shackleford Banks geology and subsurface sediments — 1975. Duke. Susman, K.R. Post-Miocene subsurface stratigraphy of Shackleford Banks, Carteret County, North Carolina, 70 pp + app.

- Sediment-size statistics, radiocarbon dates, and fauna count for core samples within Shackleford Banks (Tables 1-3)
- Schematic cross-section of Shackleford, Fig. 4

Morehead City harbor general design memorandum — 1976. USACE. Morehead City Harbor, North Carolina, General Design Memorandum, USACE-Wilmington, 41 pp. + app A-F.

- Recommended increasing navigation channel depth to 40 ft in harbor and inlet and 42 ft in ocean approach.
- Proposed disposing of sediment along 4000 ft of Shackleford by hopper, initial disposal via pipeline dredge on the eastern 5000 ft of Atlantic Beach, and later disposal via pipeline for additional 25,000 ft west of the 5000 ft
- Inlet migration and throat width, pp. B2-3
- Table of dredging volumes through 1974, pp. B5-6
- Hurricane surge and winds for *Donna*, 1960, table, p. B8
- Table of tidal currents, p. B10
- Cumulative dune-line location for entire island, p. B17
- Hydrographic surveys since 1839 showing channel, plate B1
- 8 beach profile transect taken well offshore in 1958 and 1972, plates B6-B9
- Appendix C: longshore transport analysis from ship-based winds
- Attachment D1: boring logs
- D6-D7: grain-size information. **Reaches shown on Plate D-3. Reach P (inner harbor) has retention of 60% (Ra of 1.67); Outermost (ocean) Reach Hc has retention of 68% (Ra of 1.47); composite retention for all of H(a-c) is 80% (Ra of 1.25). Thus 1.25 is best estimate of beach-fill material Ra. Native material is rather fine, with mean of 2.52 phi (0.17 mm) and standard deviation of 0.77 phi.**
- Sediment transport conclusions: (1) transport is to the east (75%), (2) shoaling occurs more on the west side of the channel (68% of the channel shoaling), (3) bypassing efficiency of the inlet dropped from 52% to 28% after dredging, (4) net transport is about 14% of the gross

Thesis study of sediments and geology of Bogue Banks — 1977. UNC, Goff, W.T. Sedimentation in a modern tidal inlet: Bogue Inlet, North Carolina, 117 pp + app.

- Analysis of 244 bottom samples, 20 can cores, 9 trenches in Bogue Inlet
- Sketch of inlet geomorphics compared to Hayes' model, Fig. 2 and 3
- Mean tide range at Bogue (71 cm) and Beaufort (96 cm), p. 11
- Bathymetric map, Fig. 5
- Inlet migration maps, Fig. 7
- Sediment size-distribution map, Fig. 8
- Percentage shell content, Fig. 13
- Transport paths inferred from ripple/sand-wave geometry, Fig. 18
- Sediment environment map, Fig. 26
- Sediment environment vertical cross-section Fig. 28 (cross-shore)
- Fig. 29 (longshore)

Thesis on geology and sediments of Outer Banks — 1977. Duke. Moslow, T.F. Quaternary evolution of Core Banks, North Carolina, from Cape Lookout to New Drum Inlet, 171 pp.

- Analysis of many core samples from within Core Banks, nothing south of Cape Lookout
- Radiocarbon dating, macrofauna counts, and analysis of each depositional environment

- Comparison of relict and modern inlets, p. 108
- Rates of landward migration of Core Banks, 50-100 m/century, p. 102

Thesis on coastal process measurements in Beaufort Inlet — 1977. Duke. Sarle, L.L. Processes and resulting morphology of sand deposits within Beaufort Inlet, Carteret County, North Carolina, 152 pp.

- Storm frequencies, p. 14, 1.64 hurricanes per year for Bogue Banks
- Monthly wind roses, p. 19
- Data collected: surveys, fathometer, tidal currents, and grab samples
- Fathometer traverses all in Sound, locations p. 27, results, p. 98
- Tide measurement locations, p. 29
- Sediment sample locations, p. 31
- Tidal velocity data summary, p. 34
- Average curves for spring, neap, mean tides, p. 36
- Sedimentary structure flow-indicator classification, p. 40
- Tidal velocity curves for each station, p. 45-54
- Sketch of pre-dredging model of Beaufort Inlet, p. 57
- Western growth rate of Shackleford Spit, p. 66
- Morphological classifications of underwater topography: map p. 74, sketch p. 84
- Aerial photo with tidal current directions superimposed, p. 135
- Conclusion: tidal current velocities increased because of narrowing of inlet by stabilizing Fort Macon State Park and western growth of Shackleford, p. 139
- Conclusion: dredging causes sediment to be transported seaward and deposited in deeper water, where it is not available for beaches, p. 139

Thesis on geology and sediments for Core Banks — 1978. Duke. Herbert, J.R. Post-Miocene stratigraphy and evolution of northern Core Banks, North Carolina, 140 pp.

- Sediment size analysis, geological history, and inlet cross-sections, all north of New Drum Inlet

Thesis on sedimentation of Shackleford Banks — 1979. Duke. Berelson, W.M. Barrier island evolution and its effect on lagoonal sedimentation; Shackleford Banks, Back Sound, and Harkers Island: Cape Lookout National Seashore, 220 pp.

- Textural and size analysis of core samples throughout and landward of Shackleford, but no data offshore

Thesis on sediments in Bogue Banks — 1980. Duke. Steele, G.A. Stratigraphy and depositional history of Bogue Banks, North Carolina, 220 pp.

- 42 bore-hole locations on Bogue, p. 10 (none offshore)
- No prevailing longshore transport direction, except at eastern end, where sand accumulates on west side of jetty (p. 13)
- Monthly wind roses, p. 15
- Tide discussion, p. 16; maximum ebb in Beaufort 116 cm/s, flood 106 cm/s; tidal prism of Bogue Sound 80 million cubic meters
- Dune-line change along entire island, 1964-71, p. 18
- Sediment analyses: faunal counts, lithology, radiocarbon dating, size
- Detailed discussion of geologic history, by community, pp. 91-142
- Summary of Bogue Banks forming, pp. 165-167

Planning brochure on options for stabilizing Bogue Inlet — 1980. USACE. Planning Brochure for Bogue Banks Stage II Study, 21 pp.

- Summarizes Phase II study for inlet stabilization
- p. 20 summarizes plans; bottom line is that only channel deepening (by only 2 ft from 6 ft to 8 ft) is economically justified; all structural alternatives examined were not econonical

North Carolina erosion task force report — 1984. NCDNRCD. Coastal Resources Commission's Outer Banks Erosion Task Force Report, 29 pp.

- Evaluated the following alternatives for responding to coastal erosion: (1) hardening (seawalls), (2) trapping (groins), (3) nourishment, (4) dune building, (5) beach pushing (scraping), and (6) relocating threatened buildings. General cost comparisons were made:

Sandbags	$125-250/ft/yr
Bulkheads	$25-50/ft/yr
Revetments	$5-15/ft/yr
Groins	$12-25/ft/yr
Breakwaters	$60+/ft/yr
Beach pushing	$200/ft/yr
Nourishment	$240/ft/yr

- Determined that federal nourishment projects have taken 15-18 years to authorize, with a minimum of eight years.
- Conclusions: an unobstructed public beach is essential to the continued vitality of the tourism industry.
- Beach nourishment is the preferred response to erosion.

Sedimentation study of Shackleford Banks/Cape Lookout — 1984. Marine Geology. Heron, S.D., T.F. Moslow, W.M. Berelson, J.R. Herbert, G.A. Steele, and K.R. Susman. Holocene sedimentation of a wave-dominated barrier-island shoreline: Cape Lookout, North Carolina, Vol. 60, pp. 413-434.
- Process/response model of wave-dominated barrier islands in sand-rich environments with 5 parts of model in Fig. 8
- Per Nummedal et al. (1977) classification, area has relative to the rest of the southeastern United States: high waves, small tidal range, little ebb-tidal delta, and large inner shoal area
- Waves average 1.7 m height with 2 m exceeded 30% of the year, more than anywhere else in southeastern United States (Nummedal, Fig. 2)
- Bogue summarized in section lower-energy depositional limb with vertical sequence of sediments in Fig. 15

Vibracore data and interpretation for Bogue Banks — 1985. Marine Geology. Hine, A.C. and S.W. Snyder. Coastal lithosome preservation: evidence from the shoreface and inner continental shelf off Bogue Banks, North Carolina, Vol. 63, pp. 307-330.
- Analysis of Bogue shelf based on drill holes on Bogue Banks, 125 vibracores on shelf, and seismic data
- Much of sand deposits removed from shelf, but paleochannels with sand identified (fig. 2)
- Isopach map of Quaternary deposit thicknesses, fig 6, shows sands confined very close to shore and within the paleochannels
- Shoreface is narrow, generally 12 m deep and 500-800 m wide

Morehead City harbor improvement feasibility report and environmental assessment — 1990. USACE. Feasibility report and environmental assessment: Morehead City harbor improvement, Morehead City, North Carolina, App. A-F.
- Coastal engineering information in Appendix C contains:
  - Tides (IIB)
  - Changes in shoreline volumes (IID), including historical rates (Table 20) and recent (since dredging) rates (Table 21); Fort Macon recent erosion is explained as erosion of the large (1.2 million cy) nourishment placed in 1978
  - Longshore transport calculations in Section IIE and later are all based on wind hindcasts and are thus suspect
- Channel boring logs are in Appendix D

Morehead City general design memorandum (updated) — 1992. USACE. Design memorandum and environmental assessment: Harbor improvement, Morehead City, North Carolina, 50 pp. + App. A-M.
- Project encompasses deepening of outer harbor, extending ocean approach dredging, and enlarging harbor
- Proposed disposal for inner harbor is via pipeline to Brand Island, with pumpout to Atlantic Beach every 8-10 years; deposit outer harbor material on nearshore berm at 20 ft contour
- Disposal alternatives and their unit costs in Table 15, p. 37
- Analyzed potential for nearshore berm to move using Hands/Allison figure and WIS hindcast data to determine currents (p. C12); results suggest active motion; also applied LTD program, which also suggested active motion of berm (p. C13).
- Appendix D contains bore logs and sieve analyses, but no computation of composite size and overfill ratios

Shoreline erosion methods and maps — 1997. NCDEHNR. Benton, S.B., C.J. Bellis, M.F. Overton, J.S. Fisher, J.L. Hench, and R. Dolan. North Carolina long term average annual rates of shoreline change: methods report 1992 update, 20 pp. + app A-F.

- Uses both wet/dry line and vegetation line to estimate shoreline changes; latest update is 1992; previous updates in 1986 and 1980
- Bogue USGS maps are Q19-Q22 and SNC54-65; SNC photogrammetry available for Bogue in 1943, 1959, 1980, 1986, and 1992

Preliminary 111 evaluation on causes of erosion at Pine Knoll Shores — 1998. USACE. Preliminary Section 111 evaluation, Morehead City Harbor/Pine Knoll Shores, North Carolina, 15 pp. + figs.

- Lists dredging history in Tables 1 and 2
- Beach disposal volumes and locations, p. 3
- Pine Knoll Shores interests claim disruption of westerly LST by navigation channel and also increased flow (and thus sediment) into harbor because of increased tidal prism
- The results of the two previous LST studies are summarized below:
  1) The Corps of Engineers 1976 study compared two time periods relative to navigation-channel maintenance, before (1854-1936) and after (1960-1974) and concluded: (a) sediment transport is to the east (75%), (b) shoaling occurs more on the west side of the channel (68% of the channel shoaling), (c) bypassing efficiency of the inlet dropped from 52% to 28% after dredging, and (d) the net transport is about 14% of the gross.
  2) The Corps of Engineers 1990 study concluded that (a) the gross transport rate was about 600,000 cy/yr greater than shown in the 1976 study, but (b) the net transport proportion was about the same as in the previous study, in this case 78% of the total.
- The current study uses updated 1993 WIS hindcasts that show sufficiently changed wave-direction predictions from the past studies, that the transport direction may be from west to east. The use of the updated hindcasts in LST equations was not performed in this preliminary phase of the study, but postponed till the next phase.
- Tidal ranges increased 0.1-0.4 ft in the Sound after the 40 ft project deepening, thus increasing the tidal prism and flow rates.
- Analysis of Corps profiles uses both wet/dry line and vegetation line demarcations to examine shoreline erosion rates
- Conclusions: (1) Pine Knoll Shores has higher erosion rates than areas further west along Bogue. (2) WIS hindcast updates suggest the possibility of westward LST. (3) Tidal prism has increased, suggesting the possibility of increased sediment trapping in the inlet. These three factors plus annual removal of 325,500 cy by the harbor project suggest a possible impact on the beach. Further study was recommended.

Wave hindcast study on erosion impacts of Morehead City navigation channel maintenance — 1998. UNC. Roessler, T.S. Effects of offshore geology and the Morehead City Harbor project on Eastern Bogue Banks, North Carolina, 112 pp.

- General conclusion: dredging has increased the tidal prism, thereby increasing tidal velocities and ebb-tidal delta to move seaward. This increases gradients in longshore currents during storms and thus increases erosion.
- Maps of Beaufort Inlet channel since 1850, Fig. 2
- Inlet location now stable, since western side is jettied
- Dredging has occurred since 1911; inner harbor now dredged every two years, outer channel every year
- Dredging location and disposal sites, Fig. 4; volumes, Table 1
- Beach profiles collected monthly over two years on 13 transects in AB and PKS
- Longshore currents computed from offshore winds, RCPWAVE wave model, and Komar's longshore current equation
- Erosion for AB 1958-1972, Fig. 7
- Beach nourishment volumes changes, 1986 and 1994, Fig. 9
- Measured erosion rates of nourishment sand, 1996-1998, Fig. 10
- Volumetric and linear erosion rates from this study and NCDCM, Fig. 14
- Hurricane-induced erosion, Fig. 23
- Recent bathymetric map, Fig. 31; maps from 1854, 1925, and recent, Fig. 34

- Summary of effects of dredging, p. 860
- Conclusions:
  - Net longshore sediment transport is to the west
  - During hurricanes disposal area decreased longshore currents on beach
  - Progradation of ebb-tidal delta caused by dredging increases erosion at PKS
  - Dredging alters longshore currents from large storms and may increase erosion

Historical beach profile data set

- 1998. UNC. Bogue Banks historical beach profile data set; digital files provided by T.S. Roessler.
- 1978. USACE (Wilmington). Bogue Banks historical beach profile data set provided by Tom Jarrett

USACE/Pine Knoll Shores (PKS) — series of correspondence (various dates) — USACE. Correspondence between USACE-Wilmington, Pine Knoll Shores, Carteret County, and NCDEHNR contain the following relevant information.

- Cost-sharing documents provided by County show annual estimated cost of harbor-depth maintenance of $5,000,000 federal and $50,000 state. Sand is piped to Brandt Island, and is periodically pumped to nourish Atlantic Beach.
- Federal feasibility study is underway to determine whether federal navigation maintenance is eroding Bogue Banks (specifically Pine Knoll Shores). Expenditures on study to date total $54,000. Completion of study to cost $400,000 more, 50/50 federal/state cost split. Nourishment project estimated at $1,678,000 federal and $904,000 state costs.
- Proposed plastic pipeline plan for nourishing Bogue submitted by Bill Price to Carteret County. Feasibility of using small-diameter plastic pipe was evaluated by a rental company that has not performed beach nourishment. Phone check with a company specializing in beach nourishment confirms that the material and diameter would not withstand required pressure and stresses imposed by sand slurry.
- Series of correspondence between USACE-Wilmington, Pine Knoll Shores, and Sen. Helms provides the following information regarding possible use by PKS of sand dredged from the harbor and navigation channel:
  1) Option 1 is for direct pumping from Beaufort Inlet via ocean-certified dredge. Additional cost for 1 million cubic yards is estimated at $2.75-$4 million
  2) Option 2 is hoppers with direct pumpout capability with additional cost for 1 millon cubic yards at $4 million
  3) Option 3 is transport by pumpout hopper and later redistribution by dredge and pipeline, additional cost at $5-6 million
  4) Total available sand in harbor and range A (approach channel) is typically 1.6 millon cubic yards
  5) Corps says their surveys show stable or accretionary beaches for 6.5 miles west of Beaufort Inlet, since beach has been nourished
  6) PKS does not have full public beach access and is thus not currently eligible for 50/50 cost sharing of the additional costs under WRDA 1986
  7) Brandt Island disposal reaches capacity every 8-10 years and is not expected to be used as nourishment source again until 2002-4.
- State DEHNR cost-sharing with local governments for areas allowing public access can be up to 75% of non-federal costs for construction and 50% for preliminary studies and engineering. Typical state contributions in other NC beach nourishment projects ranged from $105,000 to $6,000,000. Detailed cost-sharing breakdowns with these other local governments are enclosed in the gathered materials.

APPENDIX G2. DIMENSIONS OF LITTORAL ZONE (Depth of Closure)

The dimensions of the active area of the littoral zone are of interest, since nourishment projects are supposed to move sediment from regions where it is not part of the beach system to locations where it will help build the active beach. If the nourishment sand were to simply be moved from one location to another within the beach system, then it is questionable whether such a project has a significant net value. To answer this question, standard coastal engineering practice is to determine the "depth of closure" where sequential beach profiles at the same location "close" to the same offshore location, indicating very infrequent motion.

Closure depth is sometimes erroneously referred to as the "depth of no motion" in some publications. The standard definition (Hallermeier, 1978) is the depth beyond which there is active seabed motion for an average of only 12 hours per year. This standard definition has been incorporated into the standard texts, such as the Shore Protection Manual (CERC, 1984).

To be confident of the results, we used several different methods of determining depth of closure. Described below are six methods, three of them computational methods using different wave databases, and three of them empirical geological evidence specific to this site.

1. From Nearshore Hindcast Wave Data

Closure depth is supposed to be computed from wave databases **nearshore**, that is in the general vicinity or depth at which closure is often found, typically in the 30 to 50 ft range. A de facto standard that has arisen is the 10-meter depth, for two reasons. The Corps of Engineers has its Phase III Wave Information Study stations at 10m depth. Also, the national field testing center for coastal engineering, the USACE Field Research Facility in Duck, North Carolina, has its permanent wave-measuring array at 10m depth. That station makes measurements of both waves and the resulting changes in beach topography, so tests of depth-of-closure methods are made with those data.

The data used in these computations were the Phase III 10m-depth hindcast waves at Stations 96 and 97 (USACE, 1983). Stations 95-97 are along Bogue Banks, with Station 97 for the western third, 96 the middle third, and 95 the eastern. Our project does not encompass nourishment for the eastern third. The 12-hour-per-year data were selected as the 80 highest readings out of the 58,440 predictions each year. This database averages all years during 1956-75, but does not include hurricanes. The 80th highest wave height was selected by interpolation between the tabulated bands and was determined to be 2.63m for Station 96 (mid-Bogue) and 2.47m for Station 97 (western Bogue). Wave periods were computed by weighting the periods in each height band by the number of occurrences in each band and produced 8.82 sec for #96 and 8.74 sec for #97.

There are two accepted equations for computing depth-of-closure:

(Hallermeier, 1978) $d_l = 2.28\ H_e - 68.5\ (H_e^2 / g\ T_e^2)$

(Birkemeier, 1985) $d_l = 1.75\ H_e - 57.9\ (H_e^2 / g\ T_e^2)$

where d_l is closure depth, H_e the extreme wave height (12 hrs/yr), T_e the associated wave period, and g the acceleration of gravity.

The latter method was determined from a study correlating measured waves with depth of observed motion at the North Carolina FRF site. Considering the proximity of that site to Bogue Banks suggests it is more appropriate for this project. Furthermore, the measurement methods were cruder and less accurate in the earlier study. The results from both equations in feet below MLW are:

Mid-Bogue:	Hallermeier 17.6 ft (5.38m)	Birkemeier 13.4 ft (4.08m)
Western Bogue:	Hallermeier 16.6 ft (5.07m)	Birkemeier 12.6 ft (3.85m)

2. From UNC Measured and Modeled Storm Waves

A University of North Carolina study (Roessler, 1998) shoaled the deep-water WIS database (Station 46, 1975-93) over bathymetry with the model RefDif. That work examined the resulting currents and potential sediment transport for the **average** wave conditions in that database. In addition to that main part of the study, certain storm wave conditions were modeled using brief visual measurements of the waves. The storm-wave input data were H = 3.0 m, D = 158 TN, and T = 15 sec. These storm waves were generated by the simultaneous combined distant departure of Hurricane *Bonnie* and approach of Hurricane *Fran*. Inserting these numbers in the two equations yields depth of closure of 21.5 ft (6.56m) (Hallermeier) and 16.4 ft (5.01 m) (Birkemeier).

3. From UNC Modeled Hurricane Waves

The same UNC study (Roessler, 1998) modeled the direct effects of Hurricanes *Bertha* and *Fran* for the conditions when they were in the immediate vicinity of Bogue Banks. These very brief extreme conditions produced results that varied somewhat along the study area, but which were fairly unvarying for the study area west of Atlantic Beach, with wave heights of about 7 m and period of 15 sec. (This result of 7m wave height is expected for the most extreme condition possible, because it is the highest wave that can possibly exist in the depths modeled, referred to as "depth limited".) The results from the two equations are 47 ft (14.44m) (Hallermeier) and 36 ft (10.96m) (Birkemeier).

4. Measured Closure Depths at Duck

The results presented thus far are predictions from equations, whereas measurements of both waves and resulting seabed motion were made at the reasonably close site of Duck, North Carolina (on the exposed open-coast Outer Banks close to the Virginia border). The results are reproduced here as Table G2-1 and Figure G2-1. Equation (1) in the table is Hallermeier and (2) is Birkemeier. Equation (3) is a simpler less accurate version of the Birkemeier equation. The results indicate a range of depths between 3.9 and 6.4m. These "ground truth" measurements appear to validate use of the Birkemeier equation results computed in Section 1 above for Bogue of 3.8 to 4.1m. It is expected that results for Bogue would be on the low end of the measured values at Duck, since Bogue is a south-facing beach protected from more of the wave climate than the east-facing Outer Banks site at Duck.

TABLE G2-1. Wave and limit depth data (from Birkemeier, 1985). [Note: 1 m = 3.281 ft]

Closure Estimate (1)	Wave Data: Date (2)	Wave Data: H (m) (3)	Wave Data: T (sec) (4)	Limit Depth (d_l) in Meters Below MLW: Measured (5)	Limit Depth: Predicted (Eq. 1) (6)	Limit Depth: Best Fit (Eq. 2) (7)	Limit Depth: Best Fit (Eq. 3) (8)
1	08/20/81	3.3	10.2	4.0	6.8	5.2	5.2
2	10/12/81	2.7	6.8	3.9	5.1	3.8	4.2
3	10/31/81	2.3	9.3	4.3	4.8	3.7	3.6
4	11/14/81	3.9	12.9	6.4	8.3	6.3	6.1
5	11/25/81	3.0	8.4	5.0	6.0	4.5	4.7
6	01/01/82	2.9	10.9	4.8	6.1	4.7	4.5
7	10/12/82	2.4	12.0	4.2	5.2	4.0	3.8
8	10/24/82	3.8	10.8	5.2	7.8	5.9	6.0
9	11/23/82	2.5	14.0	4.3	5.5	4.2	3.9
10	12/13/82	3.7	10.0	6.1	7.5	5.7	5.8

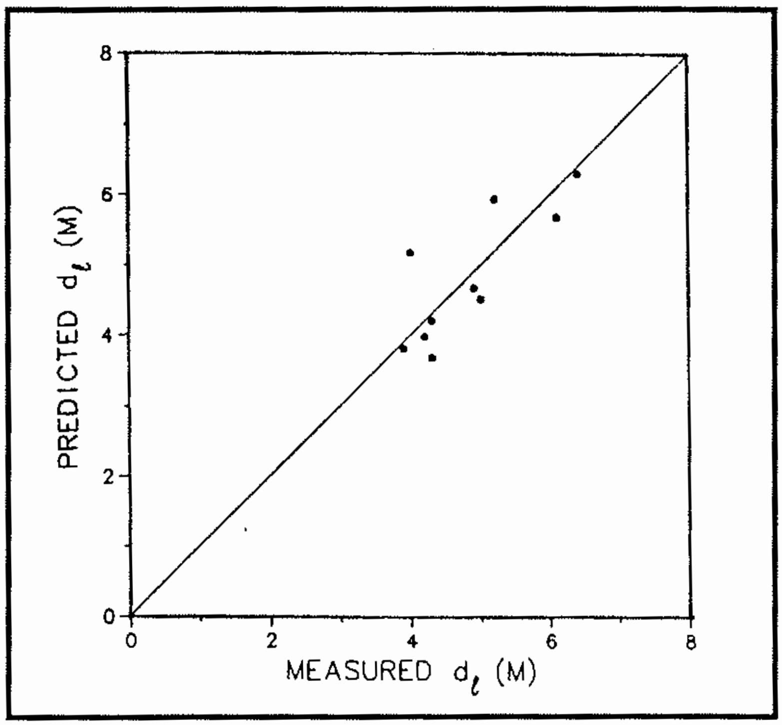

FIGURE G2-1. Best-fit comparison between predicted (Eq. 2) and measured d_l (from Birkemeier, 1985).

5. UNC Sediment Texture Study (Reed, 1997)

For this thesis, measurements were made of the color, texture, and size distribution of beach sand, shelf sand, and nourishment sand from Pine Knoll Shores to Shackleford Banks. The nourishment sand was from navigation-channel and harbor dredging projects by the Corps of Engineers. The excavation and delivery methods of the nourishment sand were similar to those proposed for this project, although the sand in the Corps project was significantly finer than that proposed in this project. Numerous surface grab samples enabled classification of sand type on the bed, and the results are reproduced here as Figure G2-2. The important point for this project is the solid line separating the native or replenishment sands from the shelf sands. The fact that the shelf sands are staying in place and not moving onto the beach in any quantifiable amounts suggests that the bounding line is one measure of the depth of closure.

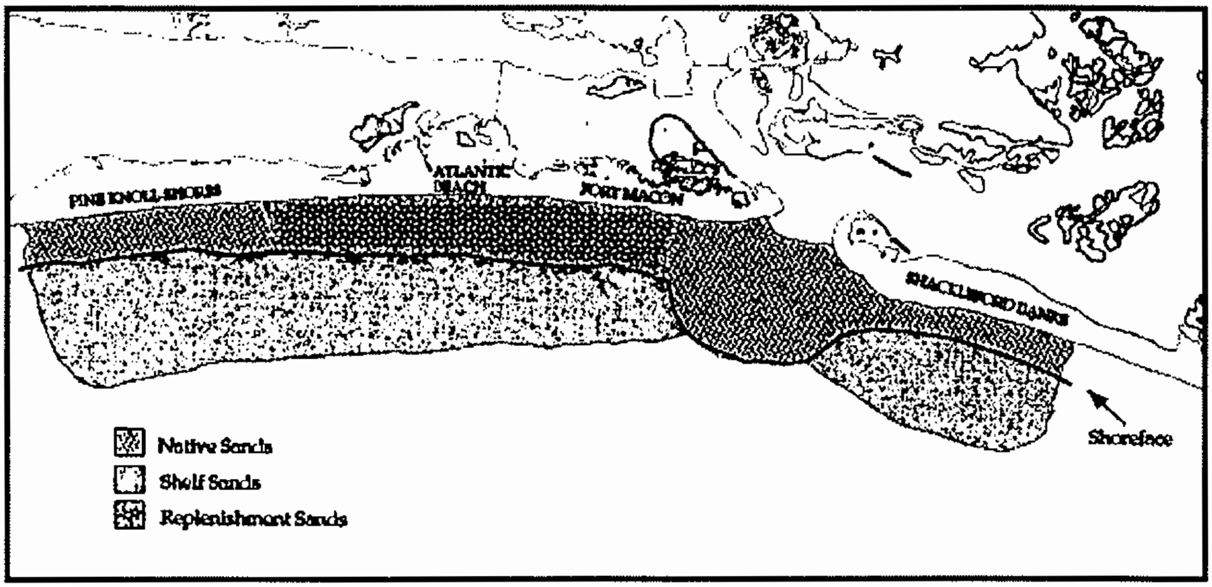

FIGURE G2-2. Interpretive map of offshore sediment distribution during the spring 1997 sampling period.

The figures in the thesis do not show bathymetric contours, so to estimate the bounding depths from the figures, we computed a scale conversion factor between the thesis figures and NOAA Chart #11543. Each 1.4 unit of distance on the NOAA chart equals 1 in the thesis figures, and this enabled us to determine depths of the solid bounding line at the following locations alongshore:

At the western end of the study area, d_l = 33 ft.
At the Pine Knoll Shores/Atlantic Beach border, d_l = 33 ft.
Along the line formed by the causeway to the mainland, d_l = 32 ft.
At the Atlantic Beach/Fort Macon border, d_l = 24 ft.

The latter two sites are east of and outside of the proposed project area.

The appropriateness of the contour data presented in Figure G2-2 for use in determining depth of closure is addressed in the thesis. Our professional opinion is that the data presented in the thesis are valid and useful and that the following opinions regarding their usefulness are incorrect and the result of misinterpretation of valid data (Reed, 1997, p. 66):

"The interpretive maps of offshore sediment distribution (Figures 17 A and B) may appear to indicate a closure depth, however this is only a result of the limitations of contour maps. . . . the stratigraphy of the cores (Cores #1-6), are better able to represent the history of sediment transport. Also, most sediment is transported offshore, past the designated "closure depth" during brief, but significant, storm events that are best recorded in the shallow stratigraphy and rippled scour depressions features."

In rebuttal to the three sentences above:

1) No evidence is presented in the thesis invalidating the results in the contour maps. Great care was taken in classifying the sediment types, and large numbers of grab samples allowed detailed delineation of sediment boundaries.

2) In three of the very small number of six cores taken, there are coarse shelly layers that are properly classified as to type of sediment, but their source is identified as "storm event" with no evidence to support that cause. Similar deposits were found in many of our core samples, which previous studies (Hine and Snyder, 1985) correctly identify as lag deposits from relict inlets and times of lowered sea level. No mechanism is identified in the thesis (e.g., computation of threshold velocities) for producing these deposits with current conditions.

3) The final sentence refers to sidescan sonar images collected by Thieler (1997), which identify linear ridges of coarser deposits. Those images of sand waves are consistent with the relict flows and conditions identified by Hine and Snyder (1985). Again, no mechanism is proposed in the thesis for causing these features under current conditions.

6. Non-motion of Nearshore Berm

The most conclusive hard evidence of the depth at which significant seabed motion occurs is the lack of motion of the Corps of Engineers' nearshore berm, a mound of dredged sediment disposed offshore of Atlantic Beach. The intended concept was to use the Beaufort Inlet navigation channel's dredged sediments for a beneficial purpose of feeding the beaches, rather than dumping the materials offshore in much deeper water where they would not move. Unfortunately, the originally intended placement depth of 18ft MLW was changed to 25-30 ft (USACE, 1994, p. 11), and the result from the monitoring survey is little motion, "little" meaning less than the error in survey methods. This confirms that **sediment deeper than 30 ft will not contribute to the beach system**.

Conclusions

1) Hindcast data of extreme (12hr/yr) conditions produce depths of closure between 13 and 18 ft MLW.

2) Measured storm conditions produce closure depths between 16 and 22 ft.

3) During the few hours that hurricanes are present in the immediate vicinity, closure depth has been computed as 36 ft.

4) The limit of sediment activity was measured at a nearby but more open-coast site at between 3.9 m and 6.4 m (13-21 ft).

5) Mapping sediment types by color, texture, and size result in a boundary between beach and shelf sands between 32 and 33 ft depths.

6) The Corps of Engineers nearshore berm off of Atlantic Beach in 25-30 ft depths has not exhibited significant motion and has not contributed sediment to the beach.

APPENDIX G3. WAVES

Databases of wave climate were utilized for the purposes of (1) characterizing the site, (2) use in final design of beach fill sections and berm heights, (3) use in computing potential longshore sediment transport (summarized in the next Appendix G4), and (4) changes in waves on the beach caused by dredging the borrow sites. Only the last item will be detailed here.

Several different estimates of the wave climate have been computed by the US Army Corps of Engineers over the years. All of these data have come from models relating offshore winds to the waves that they create. There is no wave database for the Bogue Banks area. As a measure of how inaccurate this method of computing waves from winds is, note that the resulting annual average sum of wave energy flux along the beach has changed direction, as the Corps uses different methods over the years for estimating the winds. Thus the current methods are incapable of resolving the question of total longshore wave-energy flux. Nevertheless, this database is thought to be somewhat more reliable for relative changes. That is, comparisons of percent changes in the same database under different scenarios are likely to be more accurate than the actual values of wave-energy flux.

The Corps' Wave Information Study data of waves computed from wind models is divided into separate data sets by: (1) location or "Station," (2) depth or "Phase," and (3) time period.

1) For the computations below, we used Station 45, which is the station directly south of Bogue (at 34° 15' latitude, 77° 00' longitude and 27 m depth). The next closest station, #46, is offshore of Atlantic Beach.

2) WIS data appear in three Phases. Phase I is in deep water. These waves are then refracted in to form the databases at the Phase II stations, typically in 20-30 m depths. Along some coasts data are refracted into Phase III stations at 10m depth. Up-to-date Phase III data for the Atlantic Coast do not exist. (The only Phase III data are in old reports using hindcast methods that are no longer used.) Thus we used the Phase II data for wave-energy computations.

3) Data have been hindcast for two time periods: 1956-75 and 1976-95. The two databases are not directly comparable, since different methods for estimating the winds and shoaling the waves were used. Furthermore, a statistical average of hurricane-generated waves were included in the 1976-95 database, but not in the earlier one. The wave-energy comparisons we made used the more recent 1976-95 database. We used this database to compare before-and-after dredging scenarios for the **relative** change in wave heights and energies. However, caution should be used in accepting the longshore energy fluxes computed from this database, since independent analyses (Reed, 1997; CERC, 1984, Table 4-7) suggest the longshore fluxes are unrealistically high.

The Automated Coastal Engineering System (ACES) program was used to shoal the waves from the offshore Phase II station 45 into the borrow areas. The subroutine "Linear Wave Theory with Snell's Law" was used. The main limitation of this program is that it assumes depth contours are straight and parallel. For the depths offshore of borrow area A this is a reasonable assumption, but is less so the closer to shore one approaches. The other main assumption is that wave data of different periods (or wavelengths) and direction can be shoaled separately and then recombined ("linear superposition"). Compared to the other assumption of parallel contours, this assumption is quite good for the depths we used in the model, since we did not shoal waves inshore of the innermost borrow area B. A graphical representation of the shoaling process is illustrated in Figure G3-1. Note that as the waves cross various depth contours as they approach the coast, the wave crests turn to become more parallel with the coast. As this happens, the wave heights (and energies), wave angles, and energy fluxes change.

Borrow area A is between depths 50 ft and 40 ft, and B is between 40 ft and 30 ft. Thus the first step was to shoal the WIS wave data from 27m (88.6 ft) to 50 ft. From CERC's website, the WIS datafile "au2percnt.045" was used as input. Only the directional bands from which it is possible for waves to approach Bogue Banks were used. WIS uses numbered bands to identify directions. Bands 6 through 12 produce waves that are within the half of the compass facing the beach. The angle of the shoreline for this application was measured as 171d for "shore normal" for the section of Bogue at borrow areas A and B-1 (approximately at the Salter Path/Emerald Isle border). Inputs into the shoaling model were the WIS statistics of mean wave height and period (Hmo and Tp), depth, wave directions, shoreline angle, and bottom slope from NOAA charts. Outputs for the wave conditions at the seaward side of borrow area A (depth of 50 ft) are shown in Table G3-1. As expected in these still relatively deep depths, wave heights decrease slightly, and energy flux remains constant.

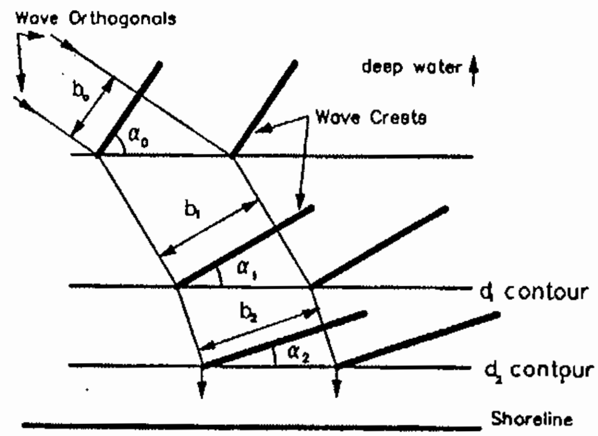

Figure 3-1-1. Snell's Law and Wave Refraction

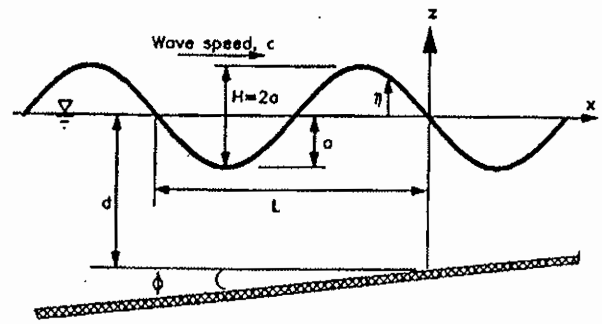

Figure 3-1-2. Progressive Wave on a Nearshore Slope

FIGURE G3-1.

The next step was to shoal waves over the existing topography in borrow area A. The results in Table G3-2 still show little change in total wave heights and energy flux.

The change in conditions if 6 ft of borrow area A is dredged is shown in Table G3-3. The results show a wave height increase of 0.2 ft, an increase in height of 2%, an increase in energy of 4%, and an increase in longshore energy flux of 9%.

The maximum dredging of borrow area A is not expected to be as large as 6 ft. That case was computed to show an extreme condition. The maximum anticipated dredging of the borrow area is 4 ft. The results for that scenario are listed in Table G3-4 and show a 1% increase in wave height of 0.1 ft, an energy increase of 2.5%, and an energy flux increase of 6%. Like the 6 ft scenario, this one should be viewed as unrealistically extreme, since the entire borrow area will not be dredged to this depth. Only localized areas within the delineated borrow area limits would experience this extreme of sediment removal.

The most realistic scenario for dredging is a 2 ft cut in borrow area A. The results in Table G3-5 show a 0.6% increase in wave height of 0.1 ft, a 1% increase in energy, and a 3% increase in energy flux.

To examine the effects of dredging the nearshore borrow areas B, the existing conditions in borrow area B1 were first computed and are listed in Table G3-6. Since the waves are now shoaling over shallower water, energy is being used in the shoaling process, and there are decreases in all relevant quantities of height, energy, and flux.

The maximum expected cut in borrow area B is 4 feet. The scenario of dredging B but not dredging A is investigated in Table G3-7. Results show less than 1% increase in wave height of less than 0.1 ft, a 1.5% increase in energy, and a 9% increase in energy flux.

The combined effect of dredging both borrow areas A and B is investigated in Table G3-8. The most likely scenario of dredging 2 ft in A and 4 ft in B was computed, and results show only 0.7% increase in wave height of less than 0.1 ft, a 1.5% increase in energy, and an 8% to 9% increase in energy flux. Note that the combined effect of dredging both borrow areas is **less** than the effect of dredging B alone. The reason for this is that the changes in topography caused by the dredging are spread out over a longer distance. The less abrupt change felt by the waves results in less change to the waves.

The final conclusions to this investigation are that:

1) Maximum anticipated dredging of the borrow areas will result in a **temporary** increase in wave heights at the landward edge of the borrow areas of somewhat less than 1% or less than 0.1 ft. The potential for longshore transport of sediment will also temporarily increase by several percent. The reason that these changes are temporary is that currents will smooth out the changes in topography by moving sand in the longshore direction to "even out" the changes.

2) Conclusions regarding the several percent increase in longshore sediment transport are suspect, because of the poor quality of the model wave data, illustrated by enormous changes in the wave database for different time periods and methods used by the Corps of Engineers in producing the Wave Information Study hindcast databases.

TABLE G3-1. Waves at the seaward edge of borrow area A (depth = 50 ft). Statistics for each directional band are listed, with the angle of wave approach shown as an azimuth (degrees clockwise of north). Statistics include wave height H, wave energy E, longshore energy flux P, the percent energy %E that each direction represents compared to the total energy, and the wave angle alpha (α). At the bottom right, the height H, energy E, and energy flux P are summed for the total values within the spectrum.

APPENDIX G4. LITTORAL TRANSPORT

Previous Transport Studies

Several studies have been performed by both the Corps of Engineers and the University of North Carolina to estimate the potential for longshore sediment-transport:

1) The Corps of Engineers 1976 study compared two time periods relative to Beaufort Inlet navigation-channel maintenance, before (1854-1936) and after (1960-1974). The results vary considerably over time, as shown in Table G4-1. But the overall results from the study concluded: (a) sediment transport is to the east (75%), (b) shoaling occurs more on the west side of the channel (68% of the channel shoaling), (c) bypassing efficiency of the inlet dropped from 52% to 28% after dredging, and (d) the net transport is about 14% of the gross. These results suggest that the dredged channel at Beaufort Inlet is blocking some (about half) of the longshore transport and that this impact should be felt more on Shackleford than Bogue, since net transport is to the east. The dataset used for these computations was a series of shipboard observations of winds, which in turn were used in models to predict the waves they create. The fact that this dataset was abandoned by the Corps several years later is an indication of its quality.

2) In 1990, the Corps of Engineers updated its previous study with a different set of wind data, but from the same time period of 1956-1975. That study concluded that (a) the gross transport rate was about 600,000 cy/yr greater than shown in the 1976 study, but (b) the net transport proportion was about the same as in the previous study, in this case 78% of the total or gross transport, and still to the east. Results are summarized below in Table G4-2.

TABLE G4-1. Results of the 1976 sediment budget analysis. [*Negative transport quantities indicate drift moving in opposite direction from assumed in the analysis. **Negative bypassing quantities indicate transport into the inlet by tidal currents. [From USACE, 1999]

1980-1988	1,130,000	328,000	898,000	-113,000

3) The Corps is currently performing an updated hindcast study, and results are not yet available.

4) Roessler (1998) performed a very similar study as the Corps, but used a very different set of wind data (the 1976-1993 Station 46 WIS dataset), a different wave-shoaling model (REF/DIF), and a slightly different set of digitized topographic data (UNC, 1998). He reached the following conclusions:

- "**Net longshore current velocity (and hence transport) in the study area is to the west.** Modeled fairweather and storm wave conditions based on USACE Hindcast Wave data indicated that the net longshore transport at eastern Bogue Banks is to the west."

- "**Although approximately 17 million cubic meters of sediment were removed from the active littoral system by offshore disposal, the offshore disposal area appeared to actually decrease both velocities and gradients in longshore current velocity during simulations of Hurricanes *Bertha* and *Fran* and potentially decrease erosion rates.** The offshore disposal area actually decreased longshore current velocities in some locations by up to 50 percent during Hurricane *Bertha* and up to 65 percent during Hurricane *Fran*."

- "**According to model results, the nearshore berm had a minimal effect on the refraction and diffraction of fairweather waves; however, during storm events the potential for cross-shore transport (perpendicular to the shoreline) was much greater.** REF/DIF results agree with USACE predictions that the nearshore berm will have a very limited effect on fairweather waves."

- "**Inlet orientation had only minor effects on wave refraction/diffraction processes during fair weather and storm conditions.**"

- "**Although the offshore disposal area decreased gradients in longshore current velocity, the overall effect of dredging Beaufort Inlet, which caused the ebb tidal delta to prograde seaward, was to increase gradients in longshore current velocity during simulations of Hurricanes *Bertha* and *Fran*.** REF/DIF results suggested that the progradation of the ebb tidal delta of Beaufort Inlet caused by dredging likely increases erosion rates in certain locations of the study area including Pine Knoll Shores. During storm conditions, steeper gradients in longshore current velocity were predicted for the recent bathymetry when compared to model runs for bathymetry from 1854 and 1925. These steep gradients in longshore current velocities were reflected in the erosion and accretion patterns following Hurricanes *Bertha* and *Fran*."

- "**Eastern Bogue Banks is susceptible to high erosion from storm waves approaching from the south, and longshore current velocities are altered by the progradation of the ebb tidal delta of Beaufort Inlet when simulated storm waves approach from the southeast.** When large storm waves (greater than 4.5 m) approach Bogue Banks from a direction less than 137 degrees, calculated longshore current velocities are altered throughout most of the study area which can potentially lead to higher erosion rates. When storms waves approach Bogue Banks from between 140 and 179 degrees, calculated longshore current velocities are changed in the vicinity of Atlantic Beach and Fort Macon State Park which can also potentially increase erosion rates especially at eastern Atlantic Beach and Fort Macon State Park."

Transport Computations for This EIS

We performed a similar type of analysis of potential longshore sediment transport along Bogue Banks to:

1) Investigate the variation of the transport along the entire island. (The Corps and UNC studies were for Atlantic Beach, Beaufort Inlet, and Shackleford Banks, since those were the areas being considered for Corps dredging and nourishment projects.)

2) Determine the sensitivity of the results to data source. We compared the variation in transport results for the different WIS time periods (1956-75 and 1976-95) and for different stations (45 and 46), by using exactly the same procedures for both time periods and both stations.

3) Determine the sensitivity of the results to wave shoaling method (i.e., simple linear shoaling vs. models such as RCPWave that account for the effects of nonparallel seabed contours).

We calculated potential for longshore sediment transport for both time periods and both wind-data stations. In addition, computations were performed at several different stations along the island listed in Table G4-3. The angle of "shore normal" was measured from NOAA charts for each location. "Shore normal" is the azimuth angle perpendicular to the beach, as illustrated in Figure G4-1. We did not perform wave-shoaling computations as a part of these longshore transport computations, since the Corps had already done so, and our intention was to determine how much the results depended on whether the waves were shoaled. Longshore sediment-transport theory says that if the seabed contours are straight and parallel, then no shoaling is necessary, because the longshore energy flux will remain the same. The transports were computed using the Longshore Sediment Transport module in the Automated Coastal Engineering System (ACES). The wave data inputs were in "CEDRS" format as obtained from the WIS datasets on the US Army Corps of Engineers' Coastal Engineering Research Center's website.

TABLE G4-3 Shore normal from NOAA chart 11543.

	Longitude	Normal Azimuth
West end of Emerald Isle west	77°04.5'	162°
Mid Emerald Isle west	77°02.0'	165°
Mid Emerald Isle central	76°59.0'	169°
Mid Emerald Isle east	76°56.0'	169°
Salter Path/Emerald Isle boundary	76°54.0'	169°
Mid Salter Path/Indian Beach	76°53.0'	171°
Salter Path/Indian Beach/Pine Knoll Shores boundary	76°52.0'	170°
Mid Pine Knoll Shores West	76°51.0'	172°
Mid Pine Knoll Shores East	76°49.0'	172°
Pine Knoll Shores/Atlantic Beach boundary	76°47.0'	173°
Mid Atlantic Beach	76°45.0'	180°
Atlantic Beach/Fort Macon boundary	76°42.0'	187°

The results for each combination of ten locations along the island, two time periods, and two WIS stations are listed as the 40 longshore transport rates in Table G4-4. Using the standard sign convention for transport, for an observer standing on the beach, transport to his right is positive, to his left negative. For Bogue Banks, this means positive transport is to the west. The **results** can be summarized as follows:

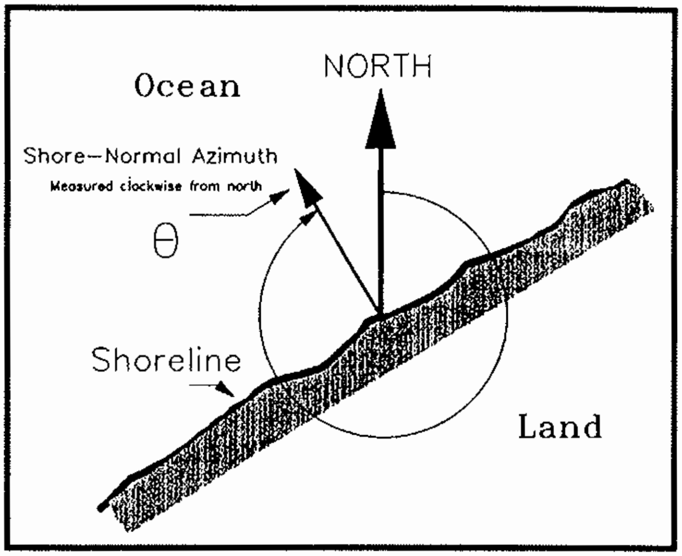

FIGURE G4-1. Definition diagram for shore-normal azimuth.

1) The results for the 1956-75 time period are directly comparable to the second Corps of Engineers study, which used the same input data. As found in the Corps study, the Station 45 data (directly south of Bogue Banks) generate longshore sediment transport **toward the east at every station** along the island. Numerical values decrease from a maximum 560,000 cy/yr at the west end of the island to 260,000 cy/yr at the eastern border of Atlantic Beach (next to Fort Macon).

TABLE G4-4. Longshore sediment transport rates from WIS hindcast data. Positive transport is to the west, negative to the east. Longitudes are in Table G4-3. [*No hurricanes. **Includes hurricanes.]

	Station 46		Station 45	
Location along Bogue Banks	**1956-1975***	**1976-1995****	**1956-1975***	**1976-1995****

Pine Knoll Shores West	-129,940	841,233	-471,172	670,450
Pine Knoll Shores East .	-7,927	934,084	-405,011	750,221
Pine Knoll Shores/Atlantic Beach boundary	285,997	1,186,473	-258,183	938,429

2) For the same 1956-75 time period Station 46 data (southeast of Bogue Banks) generate transport which has **somewhat smaller transport values (about 20% less)** until a point in the middle of Atlantic Beach is reached. At that point the transport is essentially zero. East of that point the data generate results that are geologically impossible: transport is to the west. This would require sediment to be piling up in the middle of Atlantic Beach, which it is not. Most likely, the model is generating unrealistic results for eastern Atlantic Beach and Fort Macon, because of the nonlinear bathymetric topography in that area, which violates the basic assumption of the shoaling model. For

this station, the values range from a high of 450,000 cy/yr at the west end of Bogue Banks to zero in the middle of Atlantic Beach. [For the record, the results that we do not believe show: to the east of that point, transport is back to the west, increasing from the mid-Atlantic Beach nodal point of zero transport to 286,000 cy/yr westward transport at the border with Fort Macon.]

3) The computations for the time period 1975-95 are directly comparable to the University of North Carolina study, which used essentially the same database. (Since that study, the WIS data were changed only slightly by adding two more years of data during 1994-95.) As found in the UNC study, transport is **to the west everywhere** along the island (although the UNC study was only for the eastern half of Bogue). Our values of longshore transport for Station 46 (the same as used by UNC) ranged from a minimum of 551,000 cy/yr at the western end of Bogue to a maximum of 1,186,000 cy/yr at the Fort Macon border.

4) The results for the 1975-95 time using Station 45, directly south of Bogue, were qualitatively similar to the Station 46 runs, but the values **(all transport to the west)** ranged from a minimum of 350,000 cy/yr at the west end of the island to 938,000 cy/yr at the Fort Macon border.

Conclusions which can be made from these results include:

1) Error in the wave data results in inability to predict even the direction of longshore transport, since opposite directions are predicted for all locations, depending on which datasets are used.

2) Because of change in beach orientation, transport necessarily becomes more and more westward-directed as one progresses to the east end of Bogue.

3) Results are far more dependent on input wave data than on what wave-shoaling model is used, or even if a shoaling model is used at all.

4) Although different methods were used to determine the WIS wave data for the two time periods, the only significant difference in which winds were "counted" in modeling the waves was the presence of hurricanes. The 1956-75 datasets do not include hurricanes, whereas the 1976-95 datasets do. This may account for the change in predicted net transport direction for most of the island from eastward (1956-75, no hurricanes) to westward (1976-95, with hurricanes).

5) Other independent methods of determining longshore sediment transport, such as measuring dispersal of nourishment sand (Reed, 1997) show small values of net transport in the Atlantic Beach area. This places doubt on all the WIS hindcast results, which tend to show high transports.

APPENDIX G5. EROSION RATES

Erosion rates are important in determining environmental impacts for the following reasons:

- Nourishment volumes are computed so as to counteract the natural erosion for a specified number of years. Erosion rates are used in computing the needed nourishment volumes.
- The severity of erosion is the most important indicator of how fast detrimental impacts will occur to the economy and infrastructure, if the "no action" option continues.
- The rate of erosion will determine how long beneficial impacts will last for both humans and plant/animals (e.g., increased dry beach width for turtle nesting).

Estimates of erosion rates have been obtained from two types of data analysis: linear retreat of shorelines seen in aerial photographs, and comparisons of profile surveys of the beach. The latter method is far more accurate, but also far more expensive. The available data from both methods on Bogue Banks will be described below, but the best method of determining erosion (a comparison of two comprehensive surveys) is not possible, since there have not been multiple surveys of most of the island.

Most of the studies described below are comparisons of "lines" on aerial photographs. Typically, there are two such lines that are identifiable: a high-tide or "wet/dry" line and a dune or "vegetation" line. Regardless of which line is identified and compared between successive photograph dates, this linear shoreline change (ft/yr) must then be translated into a volumetric erosion/accretion rate in cubic yards per year (cy/yr). There are various rules of thumb for doing so, but site-specific determination of the conversion factor is more accurate than rules of thumb. The site-specific conversions are computed by comparing the two types of rates (linear and volumetric) for that site and then dividing the results to determine the conversion factor. This exercise was performed by the Corps of Engineers (USACE, 1976, p. C-10), and for Bogue Banks 1 ft/yr equates to 1.3 cy/yr.

Long-Term Linear Erosion Rates (COE & NCSU)

Several recent studies of aerial photography have been performed to determine recent erosion rates, but for long-term erosion there are two important studies, one conducted by an agency of the Corps of Engineers called the Beach Erosion Board in 1948, and a study conducted by North Carolina State University. The BEB study determined erosion along the entire island between the dates 1854 and 1933. Of course, this study did not use aerial photography, but instead relied on surveys by the National Ocean Survey of certain topographic contour lines. Starting from the eastern end of Bogue at Beaufort Inlet, the BEB measured erosion averaging 0.14 ft/yr for the first mile, 0.90 ft/yr of accretion for the next two miles, and 1.14 ft/yr erosion for the remaining 7 miles. The Corps of Engineers uses different rates from the BEB study, depending on the location of the proposed project. But clearly the most appropriate number for this EIS is the 1.14 ft/yr erosion for the island west of Atlantic Beach. Using the USACOE conversion factor of 1.3 over our project length of 88,760 feet results in an **erosion rate of 132,000 cy/yr during 1854-1933.**

NCSU measured locations of vegetation lines and wet/dry lines on aerial photographs from 1939, 1953, 1958, 1964, and 1971. The vegetation or dune-line results (USACE, 1976, p. B-15) for the long-term period of 1939-71 were 4.2 ft/yr erosion for the easternmost 32,000 feet of Bogue and 2.9 ft/yr for the remainder. Multiplying the latter rate by 1.3 and our project length of 88,760 feet produces an **erosion rate of 335,000 cy/yr during 1939-1971.**

Beach Erosion from Aerial Photos (COE & NCDCM)

North Carolina's Division of Coastal Management updates shoreline erosion rates from aerial photographs about every 6 years. Erosion maps for Bogue Banks are available for 1980, 1986, and 1992. The resulting erosion rates are computed as changes from the baseline set of photos from 1938. So the results are averages from 1938 until the update. We tabulated the 1980 and 1992 erosion rates for each of our beach-profile stations along the island for comparison. The plotted erosion/accretion values for the two time periods (1938-80 and 1938-92) are shown in the upper half of Figure G5-1.

The Corps of Engineers performed similar analyses in a study of effects of their dredging projects (USACE, 1999). They measured the changes in both types of linear indicators: the wet/dry line and the vegetation line. We tabulated these results alongside our survey results for use in computing nourishment volumes. The Corps' rates are plotted in the lower half of Figure G5-1.

Beach Erosion from Comparison of Surveys (COE & CSE)

Repetitive beach surveys, encompassing the entire littoral zone, are the best means of determining how much sand is lost or gained along the beach (NAS, 1995). Bogue Banks, unfortunately, does not have an extensive data base of historical surveys. One island-wide survey by the USACE in 1978 allowed comparisons to low-tide wading depth (~−4 ft NGVD) with 60 of our profile lines. USACE profiles were superimposed on our present surveys and analyzed for changes. By extrapolating profile cross-sections over one foot of shoreline ("unit width") or from one profile to the next, a measure of the sand volume change can be obtained. The two sets of profiles, plotted for the entire island, are presented at the end of this appendix.

Figure G5-2 presents our summary of **estimated volumetric rates**, based on best-available data (bold-faced values in Table G5-1).

All five of the methods described above were tabulated for each profile line (1-111) shown in Figures G5-1 and G5-2. Starting with profile line 1 at the western end of Bogue Banks and working east, we tabulate below the results for each of the island "reaches" (separated by solid vertical lines on both figures). Since volumetric methods are considered more accurate, the numbers from that method were generally selected as most appropriate. When those values differed drastically from the other methods, the method which most closely matched the volumetric method, namely the Corps wet/dry line, was selected. The selected value for each reach is in boldface in Table G5-1.

Clearly there are large discrepancies between individual methods and reaches. However, there are some trends. Generally, the Volume Change method and the COE Wet/Dry Line methods were consistent. The two methods that used vegetation lines over roughly the same time period were also consistent: the NCDCM 1992 and COE vegetation lines. Some choice had to be made as to the most reliable estimates for each reach.

The computed **volumes on each of the 111 profile lines are in Table G5-2**. The volumes are all relative to the Stroud survey baseline. Each profile volume computation was started at the listed "offset" distance from the baseline and ended at the listed "cutoff" distance from the baseline.

Plots of each profile are included at the end of this appendix in Annex G1.

#53 & #62 & #67 Frt Stk Lost - Not Recoverable

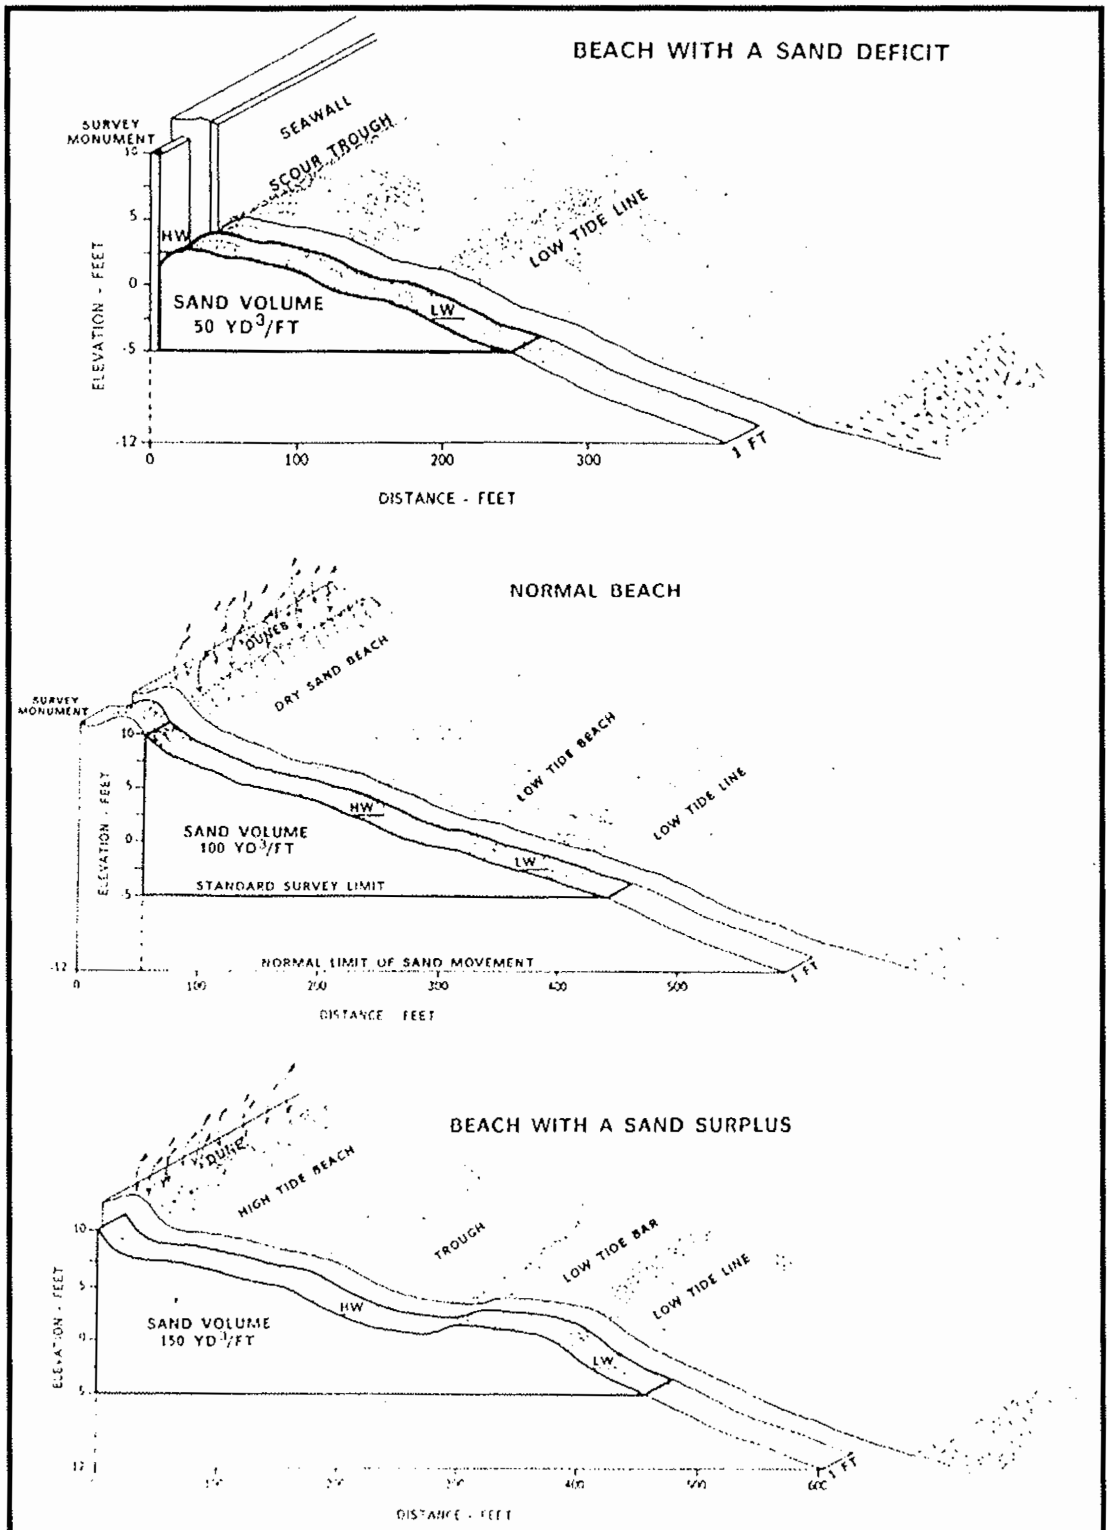

FIGURE G5-3. The concept of profile volumes (i.e., the sand volume contained in a unit length of shoreline between the dunes/seawall and representative underwater contours). In the absence of comparative data, profile volumes provide an objective measure of the beach condition from one place to another. [From Kana, 1990]

If profile volumes reflect the condition of the beach from place to place (assuming similar sediments and exposures to waves and currents), they can be used to quantify sand deficits with respect to some ideal beach condition. A number of analytical and numerical techniques are generally used to define a healthy beach/dune profile for a particular level of storm protection. Erosion models, such as S-BEACH used by the USACE, allow prediction of the expected sand volume losses or dune recession during storms of a particular size. While these models are important design tools and should be a part of any final analysis, they are limited by the availability of coastal process data which are needed to "drive" the models.

For this preliminary study, which was budget-limited, we used an empirical approach for estimating an ideal "minimum" profile volume. We located Bogue Banks profiles where there was more-than-average sand volume and reviewed the beach and backshore conditions for evidence of long-term stability, wide berms for recreation, and extra sand nearshore. We also obtained hurricane erosion data for *Bertha* (June 1996) and *Fran* (September 1996) which showed short-term sand losses to low-tide averaging ~8-15 cubic yards per foot (cy/ft). [Note: This range was also confirmed by re-surveys of 18 of our profile lines after Hurricane *Floyd* during the week of September 20, 1999.] Based on these criteria, we established a threshold minimum profile volume of 175 cy/ft (Fig. G5-5). While this is not a value based on determination of a particular level of storm protection, it is one that reflects the site-specific conditions of Boguo Banks. Based on experience elsewhere, it reflects a level which we believe will provide adequate protection for ~10-year return-period events.

Once a minimum profile volume is established, it is a straightforward procedure to compute the volume deficit at each point along the shoreline. Figure G5-5 shows that, on average, six reaches fall below the minimum volume--Emerald Isle-West, Emerald Isle-Central, Emerald Isle-East, Indian Beach/Salter Path, Pine Knoll Shores-West, and Pine Knoll Shores-East. Atlantic Beach, on average, presently contains nearly the minimum sand volume and can be used as a practical guide to what other reaches would look like if they were nourished as proposed in the present plan. By extrapolating the volume deficit over representative shore lengths, a measure of **initial** fill-volume requirement is obtained.

The actual amount of nourishment recommended consists of **three components**. It begins with the **volume deficit** and then takes into account the long-term **erosion** rate and the **quality of borrow area** sediment. For the present study, our team provided estimates of the additional sand needed over a 5-year, 10-year, and 20-year period to accommodate background erosion. These amounts were calculated by applying the site-specific erosion rates shown in Table G5-1 over the representative time periods. A final adjustment was made to account for variations in the quality of borrow material. For example, a borrow area with a fill ratio of 1.1 will require about 10 percent more nourishment than the volume requirement; a borrow area with a fill ratio of 2.0 will require twice as much nourishment. While these adjustments may seem confusing at first, they are important because of the wide differences in performance of various borrow areas. This last adjustment puts projects using alternate borrow areas on an equal basis and allows fairer comparisons of cost. For example, one million cubic yards of sand that have a fill ratio of 1.1 will perform much better than two million cubic yards that have a fill ratio of 4.0. Unfortunately, differences in borrow material quality are often ignored, leading to widely varying opinions regarding project performances.

In short, we developed a detailed beach condition survey, historical erosion rate data, and borrow area sediment quality data to establish:

- Initial profile volume deficit for six reaches.

- 5-year, 10-year, and 20-year volume requirements to accommodate the long-term background erosion.

FINAL
ENVIRONMENTAL ASSESSMENT

Bogue Banks
Beach Nourishment Project
Carteret County North Carolina

Submitted in Conjunction with the
National Environmental Policy Act and
Federal Review of Permit Application ID 200000362

APPLICANTS:

Carteret County
Town of Pine Knoll Shores
Town of Indian Beach
Town of Emerald Isle

US Army Corps of Engineers
PO Box 1890 Wilmington NC 28402-1890

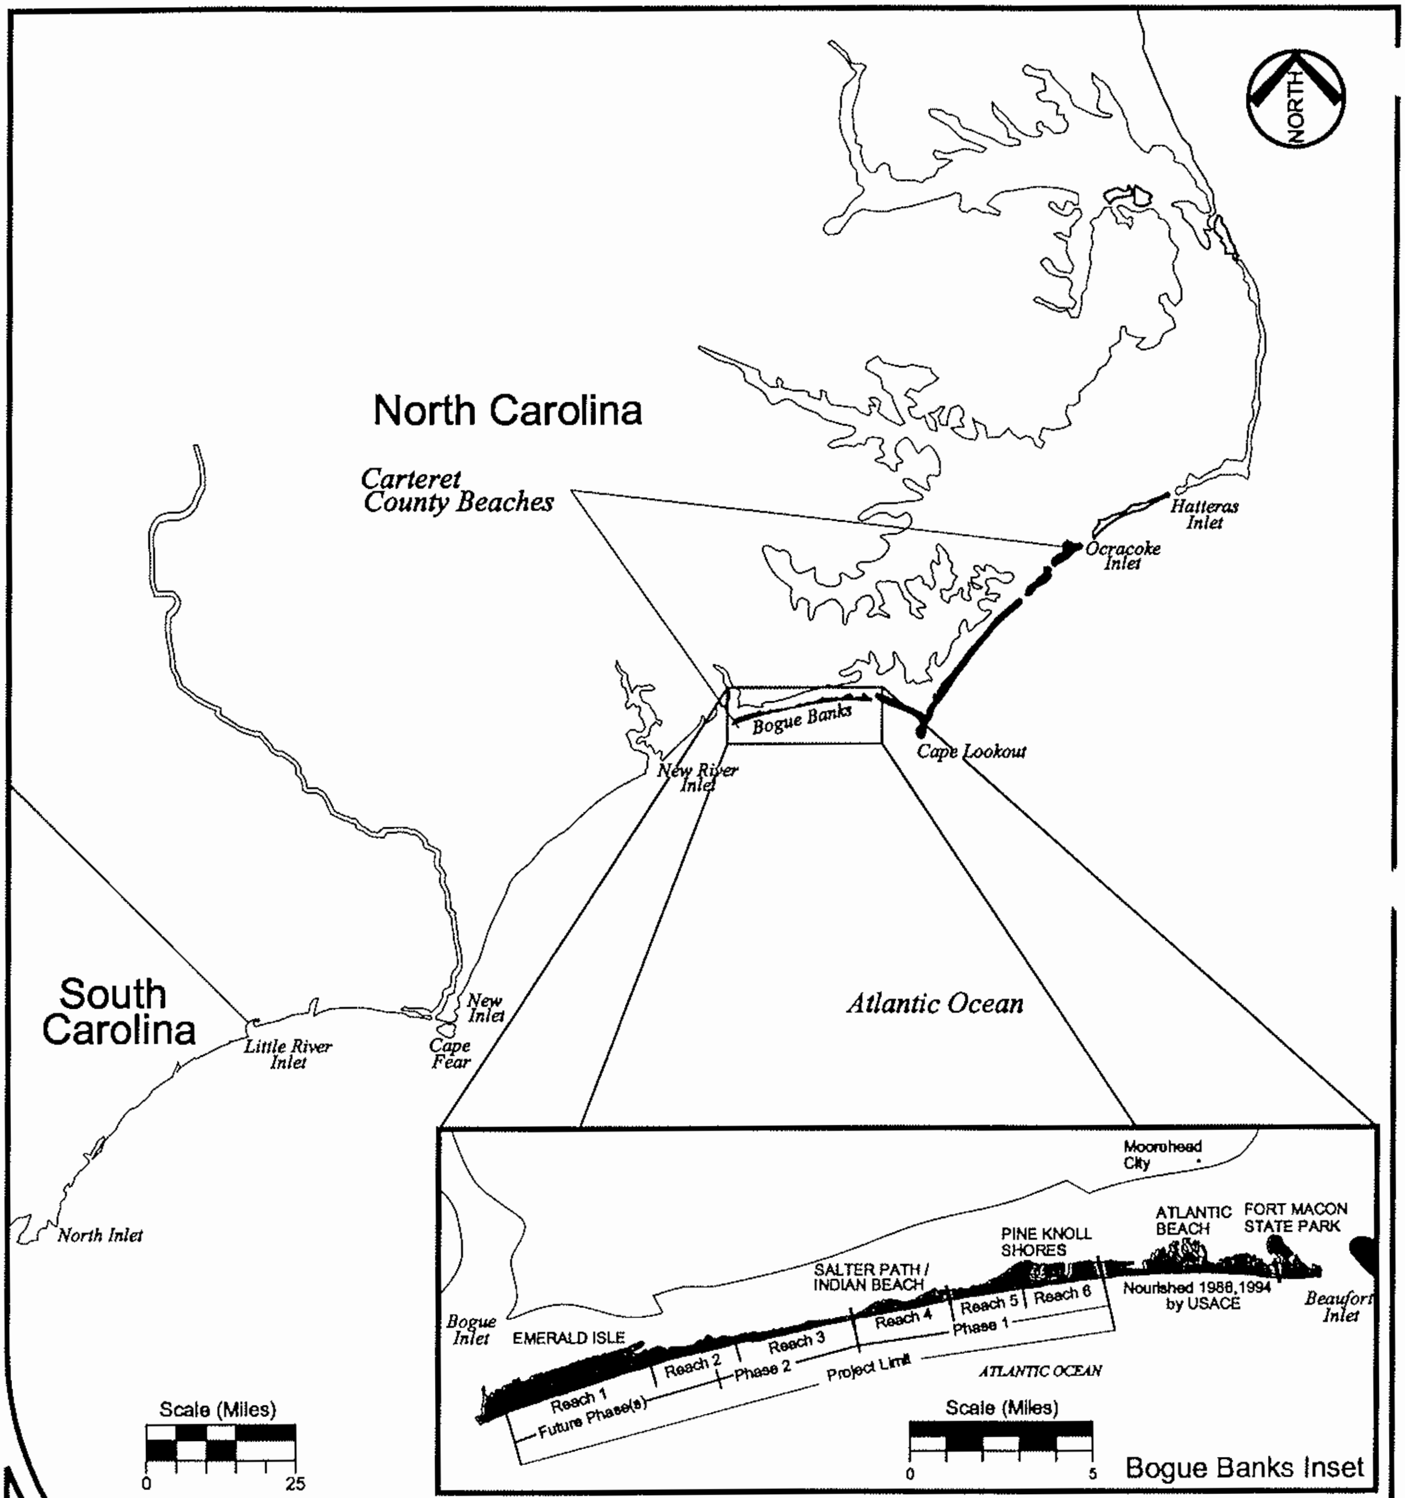
1.0 PURPOSE OF AND NEED FOR ACTION

This Environmental Assessment (EA) is prepared in accordance with the National Environmental Policy Act of 1969 (as amended) to address environmental concerns associated with a proposed beach nourishment project along Bogue Banks, North Carolina (Fig 1.1). The proposed beach nourishment project is being locally sponsored by Carteret County in conjunction with the Towns of Pine Knoll Shores, Indian Beach, and Emerald Isle. Funding is proposed by a combination of locally generated revenue sources.

Bogue Banks is one of the most stable barrier islands along the North Carolina coast (Pilkey et al 1998). However, it has sustained chronic erosion averaging about 2 feet per year (ft/yr) over the past 20-30 years (Benton et al, NCDEHNR 1992). Between 1996 and 1999, it was directly impacted by five hurricanes including *Fran* (1996) and *Floyd* (1999). The combination of chronic erosion and accelerated erosion associated with recent hurricanes has eliminated the dry beach along much of the island, caused erosion of the foredune, and damaged habitable structures.

During the past five years, an estimated 90 percent of the property owners in the proposed project area have scraped the beach and rebuilt their foredune at least twice. Many have scraped yearly including winter 2000 and winter 2001 when there were no major storms. A high percentage of property owners have rebuilt dune walkovers at least two or three times in the past five years.

The purpose of the proposed project is to restore the recreation beach and its associated habitats in the chronic erosion areas of Bogue Banks, eliminate the need for annual beach scraping, eliminate the need for frequent rebuilding of dune walkovers, allow foredunes to evolve naturally, and preserve property values and the tax base of Carteret County.



Site location map for Bogue Banks beach restoration project showing 16.8 mile project length, six (6) reaches defined in the SEPA EIS and Phases (for construction) as presently planned. Only Phase I is funded at this time (June 2001). There is no development or vehicular access to any other beach between Ocracoke Inlet and New River Inlet.

Figure 1.1

Coastal Science & Engineering, LLC

1.1 PROJECT SETTING

The project area includes the beaches reaching from the town limits of Pine Knoll Shores and Atlantic Beach to the western end of Emerald Isle, ~1 mile east of Bogue Inlet. Total project length is 16.8 miles of shoreline.

Bogue Banks is a barrier island with a southward facing ocean shoreline stretching some 25 miles between two large tidal inlets, Bogue Inlet to the west and Beaufort Inlet to the east. The Banks are surrounded by Bogue Sound on the north and Onslow Bay of the Atlantic Ocean on the south.

Of approximately 80 miles of barrier island shoreline located in Carteret County, Bogue Banks is the only developed area. The remainder, made up of Shackleford Banks and Core Banks to Ocracoke Inlet, will remain undeveloped in perpetuity as part of the Cape Lookout National Seashore. Bogue Banks is the only ocean shoreline in Carteret County with convenient vehicle access to all citizens.

1.1.1 Description of the Proposed Action

The proposed project consists of excavating by hydraulic dredge up to 6.7 million cubic yards of beach-quality sediment from ocean borrow areas situated 0.5 to 3.0 miles offshore of the project area. Sediment would be pumped onto the beach between the toe of the existing dune and the low water line and shaped by bulldozers into a profile that closely matches the contours and elevations of the natural beach. Approximately 50 percent of the excavations would be deposited by run-out from the discharge point between mean low water and the outer bar (~500 ft offshore). Typical fill sections would add ~44 to 113 cubic yards per linear foot (cy/ft) of beach and advance the shoreline 50 to 125 ft. The work would be performed in phases covering all or portions of each of six designated reaches according to the following schedule (subject to local funding availability).

- ***Phase I*** (funding approved) – Reaches 4, 5, and 6 – Towns of Pine Knoll Shores and Indian Beach – 7.2 miles – up to 3.1 million cubic yards* – November 2001 to April 2002.
- ***Phase II*** (subject to funding) – Reach 3 and eastern half of Reach 2 – Town of Emerald Isle – 3.0 miles – up to 1.7 million cubic yards* – November 2002 to April 2003.
- ***Phase III*** (subject to funding) – Reach 1 and western half of Reach 2 – Town of Emerald Isle – 6.7 miles – up to 1.9 million cubic yards* – November 2002 to April 2003 or November 2003 to April 2004 (or later environmental window).

[*Pro rata of base volume by reach given in permit application plus overfill volume up to 50 percent of base volume. Emergency nourishment is not planned but may be requested in lieu of or in addition to Phase III work in the event of major storm damage. Such work would be performed if it is associated with FEMA emergency recommendations and sponsorship under existing disaster assistance programs]

Three potential borrow areas (A, B1, and B2) have been sampled and delineated offshore of the project area, and have been tested for sediment compatibility (detailed results in later section of the EA). Sediments have been confirmed over an ~2.6 square-mile area to a section thickness averaging ~3 ft. This yields potentially ~9 million cubic yards of beach-quality sediment with overfill ratios (R_A's) averaging 1.2-1.3. Water depths in borrow areas are ~35-50 ft. The anticipated optimal equipment for excavations will be ocean-certified, self-contained hopper dredges. Such equipment typically excavates shallow trenches (~2-3 ft of section) in each pass (leaving narrow undisturbed areas at the margin of each cut), then travels to a buoyed pipeline anchored close to shore. Discharge to the beach is via submerged pipeline across the surf zone, then by way of shore-based pipe positioned along the dry beach.

The project will be built in ~1-2 mile sections, optimizing the disposition of pipeline. Sections will be pumped into place with the aid of temporary dikes pushed up by bulldozer in the surf zone. Daily operations will directly impact ~ 500-1000 ft of shoreline as work progresses in either direction from the submerged pipeline. Upon completion of a section, the submerged pipe and beach-building equipment will be shifted to the next section.

As construction progresses, sections will be graded to final contours, dressed to eliminate low areas, and opened for use by the community. Support equipment will be shifted out of completed sections as soon as practicable, such that construction activities in a given reach will disrupt normal beach use for only a month or so at any locality.

The finished sections will be allowed to adjust to natural processes for several months. Then in applicable areas, dune fencing and/or dune plantings will be installed.

1.1.2 Project History

The proposed project has been formulated over the past three years with input from state and federal resource agencies and concerned organizations and individuals. The plan results from:

- Coordination with the Carteret County Beach Preservation Task Force (1997-1999).
- A reconnaissance study of erosion prepared by CSE Baird-Stroud (September 1999 copy on file with USACE and federal resource agencies).
- A SEPA final EIS (first draft dated 6 March 2000 and final dated 6 April 2001).
- Permit application for the project (ID 200000362 dated 24 January 2001; public notice dated 16 March 2001).
- Interagency scoping meetings involving federal resource agencies on 12 October 1999 and 11 May 2001.

- Supplement to final SEPA EIS dated 8 May 2001 updating correspondence files, comments, and responses to the March 2001 public notice.

- Biological assessment report submitted to USACE and federal resource agencies on 5 July 2001.

- Community forums.

- Three funding referendums to date.

The applicants propose to perform the first phase of the work during the earliest environmental window for construction between 16 November 2001 and 15 April 2002. [These dates agreed upon 27 August in meetings with state and federal resource agency officials.] Work on subsequent phases would be performed 1-5 years later according to funding approvals within the applicant communities. The only previous nourishment in the project area was a March-24 May 1990 fill involving disposal of sediments dredged from the Atlantic Intracoastal Waterway by the USACE. An estimated 150,000 cy out of 278,000 cy were placed on the proposed project beach in the vicinity of the Ramada Inn in Pine Knoll Shores. The balance was placed along Atlantic Beach out of the proposed project area (USACE 1989, *Environmental Assessment and Finding of No Significant Impact, Maintenance Dredging of the Atlantic Intracoastal Waterway, Wilmington District*). Two other nourishment projects (in 1986 and 1994) have been completed by the USACE along Atlantic Beach involving disposal of >4 million cubic yards of sediment from various Beaufort Inlet navigation projects (USACE 1993).

1.2 SOCIAL AND ECONOMIC DEVELOPMENT

The oceanfront beaches and adjacent properties of Bogue Banks comprise a major social and economic resource for Carteret County. Tourism is the largest industry in Carteret County. The industry contributes ~$208 million annually to the economy of Carteret County, with a direct payroll of more than $38 million to over 3,400 workers. The majority of tourism in the county is centered on Bogue Banks, the only accessible barrier island along a 125-plus-mile length of the North Carolina coastline.

Bogue Banks represents less than 1 percent of Carteret County's land area but accounts for ~43 percent (over $2 billion of the county's $5.4 billion tax base) of Carteret County's ad valorem property tax base (1997). Approximately 61 percent of all locally generated revenues in the county derive from property taxes with the remainder from sales taxes, occupancy taxes, and fees. Nearly 80 percent of Carteret County's tax levy funds Carteret County schools. Out of 8,483 students in Carteret County schools, only 537 (6.3 percent) reside on Bogue Banks (1997-98). Thus, property owners on Bogue Banks provide almost half the funds for county schools but make up less than 10 percent of the school population. Any reduction of the effective subsidy derived from Bogue Banks property and economic activity would result in increased property taxes over the remainder of the county. Loss of the first row of oceanfront properties (which alone comprise nearly 10 percent of the county tax base) would result in a county-wide tax increase of ~$0.05/$100 (from $0.50/$100 to $0.55/$100) to make up for the reduced tax base.

Approximately 90 percent of Bogue Bank's oceanfront is developed, and an estimated 75 percent of remaining platted lots on the barrier island are developed. The island includes a mix of residential, commercial, and governmental development that supports a year-round population upward of 10,000 and a seasonal population exceeding 100,000. Much of the social fabric of the Carteret County and eastern North Carolina revolves around the tradition of renting houses and condominiums for a week or so every year and hosting family gatherings at the beach. This social tradition extends well beyond the county and draws visitors from many states and foreign countries. Generations of families living inland have been drawn to Bogue Banks for rest and relaxation. Tourism has grown exponentially along coastal North Carolina during the past century because of the coast's attraction, particularly along coastal counties such as Carteret which have and maintain the infrastructure, housing, and beaches to support the demand for access to the shore.

The beaches of Bogue Banks are a valuable ecological resource. Of nearly 80 miles of barrier island shoreline located in Carteret County, Bogue Banks is the only developed portion. The remainder, made up of Shackleford Banks and Core Banks to Ocracoke Inlet, will remain undeveloped in perpetuity as part of the Cape Lookout National Seashore. Bogue Banks serves to draw human activity away from the inaccessible beaches and ecosystems of Shackleford and Core Banks. Neighboring barrier islands to the west (such as Bear Island) include another 25 miles of inaccessible wilderness preserves, giving the Cape Lookout region the highest ratio (3:1) of preserved to developed barrier islands in North Carolina for any 100-mile reach. The health of the beach environment is essential to a positive experience for the beach visitor. The damage associated with severe storms results in the loss of high oceanfront dunes, scrub and maritime forests.

The sportfishing industry in Carteret County is second in size only to Dare County. The health of those activities (including fishing, boat building, and outfitting and supply) is dependent on the health of the marine environment.

Project Planning Objectives – In undertaking the beach nourishment project, Carteret County has several objectives that the project must meet. Those objectives are summarized as follows:

- Preservation of the environmental, cultural and aquatic resources of the county.
- Provide an easily accessible recreational beach available to all citizens of the county.
- Provide protection of oceanfront property as a resource of tax revenues to the municipalities of Bogue Banks and the county.
- Maintain the economic viability of tourism, the county's largest industry.

1.3 SUMMARY OF PROJECT NEED

Bogue Banks is the only developed, accessible beach in Carteret County, representing ~35 percent of the county shoreline and 1 percent of the county land area. Residential and business properties on Bogue Banks account for ~43 percent of the county tax base but receive a much lower percentage of county services and investments. Chronic erosion, while occurring at low rates compared to many shorelines, has accelerated recently as a result of five landfall hurricanes in quick succession since 1995. Loss of beach area and a general sand deficit have left nearly 17 miles of oceanfront vulnerable to damage during even minor storms. The most recent hurricane (*Floyd* 1999) caused upward of $30,000,000 damage in the county, largely concentrated along Bogue Banks' oceanfront, where the beach is narrowest. Little or no property damage occurred along Atlantic Beach, which had a much wider beach as a result of nourishment in 1986 and 1994.

Erosion poses an immediate threat to property, infrastructure, and the county tax base. Loss of oceanfront properties to erosion would result in tax increases ranging from $0.05 to $100 for all mainland residents to $0.31 to $100 for Indian Beach residents, with Pine Knoll Shores properties in between these amounts.

Tourism, the county's primary industry, will decline if the beach continues to erode. Presently, there is less recreational beach area for the public than five years ago. Property owners have increased the frequency of beach scraping to rebuild foredunes and protect imminently threatened homes. Associated with erosion and dune scraping has been a decline in beach habitats for nesting sea turtles and other organisms.

A citizens' Beach Preservation Task Force (meeting frequently between 1997 and 2000) determined that the only viable alternative is to rebuild the beach via nourishment. Over a ten-year period, nourishment results in lower costs compared to the "no-action" alternative or "property abandonment and retreat" alternative.

A ten-year nourishment project is estimated to require approximately 6.7 million cubic yards to restore the sand deficit and provide for average yearly losses over a decade or so and for differences in sediment quality between the existing beach and the borrow area. This level of effort would add 44-113 cubic yards per foot (cy/ft) along 16.8 miles of beach from Pine Knoll Shores to western Emerald Isle and widen the recreational beach 50-125 ft. The project would restore eroded areas to a similar condition as that of Atlantic Beach.

Viable beach-quality sand with composite overfill ratios around 1.15 to 1.50 exists in several strategic offshore areas close to the shoreline. Preliminary estimates indicate that these deposits can be excavated and placed on the beach via hydraulic dredge at a cost of approximately $25 million. Other potential borrow sources (including shoals in Bogue Inlet, Bogue Sound, and Beaufort Inlet, or existing spoil areas controlled by the USACE) are considered less cost effective because of their distance to the project area or their poorer quality material.

The proposed project (in total) will require ~14-15 months to construct if only one dredge is available. The applicants desire to complete the project at the earliest time and in the shortest time practicable, and will seek ways to complete construction during cold weather months when environmental impacts are expected to be lowest. The earliest period of construction for Phase I (Reaches 4, 5, and 6) is now estimated to be 16 November 2001 through 30 April 2002. Construction activities will directly impact a particular property for only a few days as nourishment proceeds section by section at an average rate of about 500-1,000 feet per day. The project will be monitored carefully after construction to quantify its longevity and document environmental change. As the first nourishment along most of Bogue Banks, it will necessarily serve as a prototype for future beach maintenance efforts.

1.4 AREAS OF CONTROVERSY

Beach nourishment, in general, involves three primary areas of controversy: (1) funding, (2) physical impacts, and (3) environmental impacts.

1.4.1 Funding

Funding for the proposed project will involve a combination of locally generated funds, derived primarily from increases in property taxes in the affected areas (ie, special tax districts on Bogue Banks). Local sales taxes will contribute a portion of the funds. For Reach 4 (Indian Beach-Salter Path), the State of North Carolina may contribute up to $950,000 to nourish an ~2,200-ft state-owned tract in Salter Path, such that the beach fill will be contiguous. These are the only state funds that are being considered for application to the project.

The Town of Pine Knoll Shores (Reaches 5 and 6) and the Town of Indian Beach (Reach 4, excluding the state property) have applied for and received approval for a US Department of Agriculture (USDA) loan under the Rural Development Act to finance local bonds for their reaches. The USDA has prepared a Class II

Environmental Assessment for Reaches 4, 5, and 6 of the project dated 6 June 2001 (Appendix A3). These funds plus interest will be repaid in their entirety by property owners within the affected communities. No federal grants will be used for the project.

1.4.2 Physical Impacts

Nourishment is the "only engineered shore-protection alternative that directly addresses the problem of a sand budget deficit . . . improves natural protection while also providing additional recreational area." (NAS, 1995, Beach Nourishment & Protection, pp. 1-2). While it has grown in acceptance in recent years, nourishment engenders polarization between proponents who consider it the preferred solution to erosion and opponents who consider it to be a temporary stop-gap measure against an advancing sea (NAS, 1995). Its success depends on the frequency of storms, but more importantly, on the background erosion rate and long-term processes controlling shoreline change at the particular site. Nourishment adds to the littoral budget a measure of sediment which will become subject to onshore/offshore as well as longshore transport. Just as a natural beach waxes and wanes between storms, a nourished beach will adjust to daily and seasonal variations in waves and tides.

Most of the controversy and debate regarding the success of nourishment relates to:

- Insufficient postproject documentation of physical changes.
- Wide disparities in background erosion rates and nourishment sediment quality, making extrapolations from one site to another misleading.
- Use of different criteria for evaluating success.

These controversies are anticipated to persist within the community until such time as there is physical proof of the effect of nourishment along Bogue Banks. Presently, 70 percent of Bogue Banks has little or no experience with nourishment and has little quantitative data on which to define the background erosion rate or project erosion rates after nourishment. Yet, certain factors suggest that Bogue Banks is a better candidate site for nourishment than many other East Coast beaches:

- Nourishment experience at Atlantic Beach (25 percent of Bogue Banks) provides physical evidence of a wider dry beach and reduced storm damage throughout the 1990s compared to similarly exposed beaches in the proposed project area.
- Several independent erosion estimates confirm that 20-year volumetric losses have averaged 1-3 cubic yards per foot per year (cy/ft/yr), a rate that is relatively low. This is comparable to Myrtle Beach (SC) (1.6 cy/ft/yr) but only a fraction of Hunting Island (SC) (~25 cy/ft/yr).

- Linear erosion estimates quoted by Pilkey et al. (1998) and most likely based on NC Division of Coastal Management erosion maps are <2 ft/yr for all Bogue Banks localities except Pine Knoll Shores and Indian Beach, which are estimated at 2-3 ft/yr.

- Bogue Banks is a south-facing beach, partially in the lee of Cape Lookout and less exposed to damaging waves which tend to be more frequent from the northeast.

- Rates of net longshore transport are relatively low along Bogue Banks because of its orientation and placement with respect to Cape Lookout and the prevailing direction of ocean waves.

- The proposed project length of 16.8 contiguous miles would make it one of the longest nourishments on the East Coast. Numerous studies have proven that nourishment longevity is proportional to the square of the length of the project (NAS, 1995).

- The proposed borrow areas (A, B1, B2) contain sediments that are a similar mixture and quality of sand and shell material found on the native beach and much coarser than the spoil sediments placed by the Corps along Atlantic Beach. Sediment containing coarser material tends to hold a wider dry beach and require less volume for the underwater portion of the profile (Dean, 1991; NAS, 1995).

- The proposed quantity of nourishment (44-113 cy/ft) incorporates (a) initial volume to replace the sand deficit and (b) advance nourishment equivalent to approximately ten years of background erosion. In addition, plans call for increasing the nourishment volume in proportion to the overfill ratio (R_A) of the borrow area sediments because a certain fraction will be unstable on the beach (~15-30 percent using the combination of borrow areas A, B1, and B2 specified later in this report).

- The proposed project will be surveyed yearly from the dune line to beyond the outer bar and compared against the prenourishment conditions using volumetric calculations. Performance will also be evaluated based on persistence of a dry beach. Success will be defined in relation to how closely the postnourishment volume erosion rate compares with the estimated prenourishment volume erosion rate.

Not all physical impacts are predictable prior to construction. It is widely recognized that isolated erosion "hot spots" sometimes develop after nourishment as "packages" of sediment accumulate in one area, leaving deficits nearby. Nearshore bars also evolve, form runnels and outlets, and create related nearshore cell circulation which may locally cause scour of the berm. Such features occur on unnourished as well as nourished beaches. Regardless of the cause of physical changes, the proposed project area is expected to undergo the same transformations as a natural beach, but to do so with the ocean displaced about 100 ft seaward. By artificially increasing the average separation distance between development and the ocean, private property damage will be reduced for any return-period storm, and the tax base of the county will be preserved for another decade or so. After a decade of monitoring, the community will reevaluate the cost and benefits of nourishment and determine at that time based on experience whether continued nourishment is preferable to doing nothing or abandoning property.

1.4.3 Environmental Impacts

The primary environmental impacts of nourishment relate to mortality of in-situ organisms, changes in habitat, mobilization of fine-grained sediments, and pollution due to accidental spills during construction.

1.4.3.1 ***Mortality of In-Situ Organisms*** – The project will result in the excavation of sediments and organisms in the upper 2-3 ft an approximate 2.58-square-mile area offshore of Bogue Banks. This area represents about 3 percent of the ocean bottom between Bogue Banks and the three-mile state jurisdiction limit. Most of the sessile organisms (predominantly polychaete worms) excavated will die. As fill is placed on the beach, some in-situ organisms (eg, amphipods, *Donax* clams, and *emerita* mole crabs) will be smothered. These are unavoidable impacts. Studies have shown that borrow areas and nourished beaches recolonize eventually. Natural recovery appears to be most rapid under the following conditions (all of which are applicable for the proposed project):

- Excavations by hopper dredge which tends to make shallow cuts and leaves undisturbed furrows from which rapid recruitment of organisms takes place.
- Use of beach-quality sediment comparable to the native beach.
- Construction during cold-weather months when biological populations are a small fraction of their summer densities.
- Minimization of fines in the borrow area and nourishment area, which elevate turbidity levels.

In a recently published study in New Jersey, considered the most intensive analysis of environmental impacts of nourishment to date, beach habitats recovered to prenourished conditions in 2-6.5 months. Offshore borrow areas recovered in 2-2.5 years based on the results of a seven-year Corps-sponsored study costing over $8 million (ref: Burlas, Ray and Clark 2001).

1.4.3.2 ***Changes in Habitat*** – The project will leave shallow cuts over the borrow area, exposing older sediments to the water column. These sediments will have been less reworked by organisms but contain similar sediment textures and nutrients as the removed sediments. As such, they will leave an unoccupied niche habitat that is expected to become recolonized at time frames comparable to the life cycles of various species. Some studies have demonstrated that recolonization of borrow areas occurs in a few months or less (eg, Jutte et al 1999b), while other studies show recolonization occurring over 1-2 year periods. The proposed borrow area and construction method will be similar to sites where recovery occurred rapidly (a few months). However, because the only way of confirming recovery is by systematic monitoring, the applicants have initiated benthic sampling before construction and plan to continue benthic sampling after construction to document the degree and rate of recovery at this particular site.

The beach fill will displace the shoreline and inshore topography about 100 ft seaward. This will create more beach habitat (expanded turtle nesting sites), reduce the frequency of dune scarping and associated vegetation loss, and eliminate many chronic escarpments in the foredune. It will also lessen demand by property owners for beach scraping and dune restoration. Frequent beach scraping is believed by some researchers to cause mortalities and population reductions in some surf-zone species (eg, Peterson et al 2000). It also introduces coarser sediments in the foredune and inhibits revegetation because of the poorer water retention compared to natural dune sands. Existing littoral habitats will be displaced seaward but will be maintained in similar proportion as the native beach. Nutrients introduced with the nourishment sediments will provide a food source to attract benthic organisms to the new foreshore. Recent studies have found that recolonization of the beach in similar settings as Bogue Banks may occur within one month or less (Jutte et al 1999a). Because it is uncertain to what degree or how rapidly recolonization will occur, the applicants plan to monitor benthic recovery along the beach after construction.

A prenourishment beach and borrow area sampling was completed in June 2001. A second prenourishment sampling is scheduled fo November 2001 (see Appendix A-4). In addition, the applicants sponsored a biological survey of offshore borrow areas by UNC's Institute of Marine Sciences in 1999-2000 which provides additional baseline information for the project (Appendix C).

1.4.3.3 ***Mobilization of Fine-Grained Sediments*** – The proposed project will mobilize silts and clays in the borrow area, raising turbidity in the immediate area of construction. Use of hopper dredges will return some of the silt and clay immediately to the borrow area by on-board drainage as the hoppers are loaded. Fine-grained sediments transported to the beach will be unstable and, during placement, will winnow by normal surf-zone mixing. These fines will raise turbidity levels around the point of discharge, then settle seaward of the longshore bar (lower foreshore). The increase in turbidity due to the project is unavoidable. However, turbidity during similar construction at other sites has been shown to be short-lived (hours to days) and below the natural variations in turbidity observed between storms and calm days. The proposed borrow area contains an average of ~4 percent fines (silts and clays) which is well below the state and USACE guidelines of 10 percent.

1.4.3.4 ***Pollution Due to Accidental Spills*** – Federal and state regulations place a high burden on contractors to prevent accidental spillage of fuel, grease, and related substances used in the operation of hydraulic or mechanical equipment. Zero releases are unattainable, but detectable discharges are rare. The applicants will monitor construction and insure that all federal and state requirements for discharge of contaminants are met by the contractors.

2.0 ALTERNATIVES

Under existing federal and state laws, there are only three alternatives for dealing with erosion along Bogue Banks: (1) no action; (2) abandon property, retreat, and relocate; (3) nourish the beach.

Structural shore protection involving seawalls, revetments, and bulkheads is not allowed under present North Carolina Coastal Area Management Act (CAMA) regulations. Semi-hard solutions involving sand-retaining structures, such as groins and detached break-waters, plus nourishment are not recommended in areas of low erosion rates away from inlets (NAS 1995).

Of the three primary alternatives, all have large costs associated with them as described below, and whether nourishment is the lowest cost alternative depends on a combination of four main factors:

- Existing sand deficit with respect to the desired scale of the beach.
- Average, long-term erosion rate at the site.
- Density and value of developed property at risk.
- Proximity of beach-quality borrow sediments and their cost of transportation to the project area.

> *Beach nourishment can provide protection from storm and flooding damage when viewed within human time scales (decades not centuries) in those situations where its use is technically feasible, provided that:*
>
> - *erosion rates are effectively incorporated into project design . . .*
> - *. . . engineering standards are used for planning design and construction, and*
> - *projects are maintained . . .*
>
> *. . . Beach nourishment may not be technically or economically feasible or justified for some sites, particularly those with high rates of erosion. Government authorities with responsibility for coastal protection should view beach nourishment as a valid alternative for providing natural shore protection and recreational opportunities, restoring dry beach area that has been lost to erosion. (NAS 1995, p. 3)*
>
> [NOTE: Signatories to this statement include Dr. R.J. Seymour, chair, Scripps; Dr. Robert G. Dean, University of Florida; Dr. Paul Komar, Oregon State University; Dr. Orrin H. Pilkey, Duke University; and Dr. Robert L. Wiegel, University of California Berkeley; among others.]

2.1 NO-ACTION ALTERNATIVE

The no-action alternative is evaluated based on whether the alternative considered meets the project planning objectives. In terms of those objectives, the no-action alternative is not a viable plan of action for Carteret County and the municipalities of Bogue Banks. Discussions of each objective are provided below.

Planning Objective: *preservation of the environmental, cultural and aquatic resources of the county*

The no-action alternative would not meet this objective given the current state of the beach. Continued erosion will increase the frequency of dune scraping. Forty acres of vegetation and its associated habitat will be lost. Turtle nesting habitat will be eliminated because of steep escarpments and unstable back beach areas subject to wave uprush.

Planning Objective: *provide an easily accessible recreational beach available to all citizens of the county*

The no-action alternative would not meet this objective. Significant recreational beach has been lost due to erosion of the shoreline. In many locations recreational use is limited to low tide periods. When structures are permitted to fail due to erosion of the beach, the costs of demolition and removal are often borne by the municipality. It is estimated, based on expenditures by municipalities and the county over the past four years, that without a substantial berm, costs for cleanup of debris on the beach will be $400,000 per year. Accounting for escalation and normalized to present worth, debris cleanup costs are $3,509,000. The costs associated with rebuilding beach access structures borne by homeowners, municipalities, the county and by homeowners associations is estimated at $2.1 million per year. A survey of the beach indicated that in excess of 80 percent of access structures either had been repaired or were in need of repair. It was observed that, in areas of Atlantic Beach and west Emerald Isle where a wide berm exists, few access structures were repaired. It is estimated that the average repair cost is $3000 per property. Escalating the costs and normalizing to present value results in costs for access structure repair of $19,161,950.

Planning Objective: *provide protection of oceanfront property as a resource for tax revenues to the municipalities of Bogue Banks and to the county*

The no-action alternative would not achieve this objective. Based on the number of oceanfront properties that it is estimated will be lost over the ten-year analysis period, the net present value of property tax revenues lost for the municipalities and the county is $6,332,889. This is present worth for a ten-year project period.

In addition to loss of revenue to municipalities and the county, there would be a negative economic impact caused by the retarded appreciation of all property on Bogue Banks. The precedent for this trend is Topsail Island in Onslow County. Property on North Topsail Island showed zero appreciation between the last revaluation conducted by Onslow County. It is unlikely that Bogue Banks would experience a zero increase over an assessment period. According to assessments conducted in 1989 and 1997, Bogue Banks property appreciated at approximately 4.8 percent annually. Real estate brokers contacted indicate an appreciation over the last five years of 10-15 percent annually. Just a lag of only 2.0 percent in the rate of appreciation would result in an economic loss of some $ 9 to 106 million with escalation over a 10 year period. With escalation and normalized to present worth, that represents over 1.25 billion dollars over a ten-year period. This value manifests itself in lost value to owners, lost revenues to real estate brokers and in reduced appreciation for purposes of tax revenues (estimated ~$8.6 million at the going rate over ten years).

These revenue losses would have to made up by each municipality (including those on the mainland) and the county by increasing ad valorem taxes on non-oceanfront properties and, in the case of the county by additional taxes levied on properties not located on Bogue Banks.

Planning Objective: *maintain the economic viability of tourism, the county's largest industry*
The no-action alternative would not meet this objective. Healthy beaches providing suitable recreational beach are the main attraction of the tourism industry. Loss or degradation of that attraction would have a significant impact on the tourism industry. Loss of oceanfront properties would eliminate indefinitely the rental income and associated economic activity generated by the income. Bogue Banks is the only accessible island for large-scale tourism over a reach of 100 miles of coastline in central North Carolina. All adjacent beaches are inaccessible nature preserves with no vehicle access.

In the past five years, there has been an increase in storm frequency, increase in dune scraping frequency, apparent decline in the rate of property value appreciation compared to other beach communities, and increased public perception of erosion. All of these factors contribute to economic impacts which can not be quantified precisely. However, it is possible to estimate a range of potential costs based on recent experience in Bogue Banks. Following are potential costs that will accrue over a *ten-year period* to the entire community and property owners on Bogue Banks if no action is taken in response to continued erosion.

A) Impacts to community (Carteret County) economy – government losses:	
- Reduced property tax revenues (see above)	$6.3 million
- Loss in occupancy tax due to lower beach use	$1.1 - $2.8 million
- Loss in sales tax due to lower beach use	$13.1 - $32.8 million
- Debris removal after storms (walkovers, decks, etc.)	$3.5 million
- Reduced property tax revenues (due to lower Bogue Banks property value appreciation)	$8.6 million
Subtotal	$32.5 to $55.9 million
B) Environmental Impacts to Carteret County:	
- Loss of 40 acres of vegetated dunes	not quantifiable
- Reduced turtle nesting area	not quantifiable
- Chronic impacts to beach fauna	not quantifiable
- Loss of recreational beach (computations given in Appendix F–Economic Studies)	$0.8 - $2.1 million
C) Impacts to Owners in Special Tax Districts on Bogue Banks	
- Beach scraping after storms	$2.2 million
- Reconstruction of walkovers and beach access	$19.1 million
Subtotal	$21.3 million
Poststorm repairs (foundations, sheathing, windows, etc.)	not calculated

D) Other Potential Private Losses:

- Reduction in payroll in tourism industry due to lower beach use	$32.1 - $80.2 million
- Reduction in other (nontax, nonpayroll) tourist expenditures	$90 - $226 million

Total Economic Costs for No-Action Alternative (10 Years)

Community/Governmental (A & B above)	**~$53.8 million – $77.2 million**
Private [C & D above]	**~$143 million – $327 million**

Estimates are present worth of escalated annual costs. Details of determination of costs are presented in Appendix F.

The above-listed estimates have been determined for the ten-year project life. Given the marginal condition of the beach today, it is likely that the cost of repairs will increase faster than the rate of inflation and faster than the above estimates because shoreline damage increases geometrically with decreasing distance to the waterline. Additionally, escalation rates for real estate used in the analyses is 4.8 percent annually compared to a historic appreciation in market value of 10 to 15 percent annually. Therefore estimates are considered conservative.

2.2 RETREAT/RELOCATION ALTERNATIVE

The relocation/retreat alternative involves moving oceanfront structures that are threatened by erosion of the shoreline. As of March 2000, the town building inspectors of Emerald Isle and Pine Knoll Shores had identified 173 oceanfront properties in Emerald Isle and 36 properties in Pine Knoll Shores that are threatened or, in many cases, condemned due to beach erosion.

Study of the retreat/relocation alternative involved identification of oceanfront properties that would be threatened over the ten-year study period. A survey was conducted to locate the toe of the naturally occurring dune along the project area. Using the long-term erosion rates developed in the Shoreline Assessment and Preliminary Beach Restoration Plan Report, a ten-year setback zone was determined for reaches of the beach that fall into one of the six erosion rate zones. Beach erosion rates for each of the six areas are shown in Table 2.1. [Note: These erosion rates are considered conservative with respect to the property relocation alternative. Higher erosion rates would impact more properties and result in substantially higher costs.]

A visual survey was made of the oceanfront properties to identify structures that fall into the ten-year setback zones for each reach. This included single family residential structures and condominium units.

TABLE 2.1. Erosion rates and 10 year retreat distances for project areas.

Location	Long-Term Erosion Rate (ft/yr)	10-Year Retreat Distance (ft)
West Emerald Isle	2.0	20
Central Emerald Isle	2.0	20
East Emerald Isle	2.0	20
Indian Beach/Salter Path	2.0	20
West Pine Knoll Shores	3.0	30
Central Pine Knoll Shores	2.0	20
East Pine Knoll Shores	3.0	30

Using tax maps, a count of properties was determined in each of two categories: (1) the properties with sufficient land area to allow relocation of the structure on site, and (2) those properties where erosion of the property and street setback requirements will require that the structure be relocated to another lot. Estimates of moving costs are based on discussions with house movers, on costs from R.S. Means Cost database, and on the project cost experience of Stroud Engineering in Carteret County. Detailed breakdowns of the costs for relocation on site, relocation to new lot, and total present day costs for each municipality are provided in Appendix F.

The retreat/relocation alternative is evaluated based on whether the alternative plan meets the project planning objectives. In terms of those objectives, the retreat/ relocation alternative is not a viable plan of action for the County. Discussions of each objective are provided below.

Planning Objective: *preservation of the environmental, cultural and aquatic resources of the county*
The retreat/relocation alternative would not meet this objective given the current condition of the beach. Continued erosion will increase the frequency of scarping. Forty acres of vegetation and its associated habitat will be lost. Turtle nesting will be eliminated because of steep escarpment and unstable back-beach areas subject to wave uprush.

Planning Objective: *provide an easily accessible recreational beach available to all citizens of the county*
The retreat/relocation alternative would not meet this objective. Significant recreational beach has been lost due to erosion of the shoreline. In many locations recreational use is limited to low-tide periods. Additionally, with the loss of oceanfront properties, there is loss of beach access areas. In Emerald Isle and Indian Beach, beach access is provided at locations where public street rights-of-way dead end at the back of the dunes. Loss of the oceanfront property will include loss of these beach access areas.

Planning Objective: *provide protection of oceanfront property as a resource for tax revenues to the municipalities of Bogue Banks and to the county*
The retreat/relocation alternative would not achieve this objective. The total economic loss associated with this alternative is evaluated. The total losses are evaluated and expressed here in terms of the net

present worth in year 2000. The evaluation includes annual escalation of construction costs and land values. The losses include the costs of property lost, costs of property that must be purchased to relocate a structure, and the costs of relocation. It is assumed in the analysis the condominiums located in the setback zone will have to demolished and reconstructed at another location on the development site. Costs are distributed equally over the 20-year study period with escalations included for real estate value and construction costs.

The present worth of retreat/relocation is shown in Table 2.2. The present worth of the retreat/ relocation alternative is $110,940,556 compared to the project costs for beach nourishment of $30,000,000. Both represent year 2000 costs. [Note: This does not count the costs associated with the no-action alternative, many of which will also apply under the retreat/relocation alternative.]

Planning Objective: *maintain the economic viability of tourism, the county's largest industry*
The retreat/relocation alternative will not meet this objective. Healthy beaches providing suitable recreational beach are the main attraction of the tourism industry. Loss or degradation of that attraction would have a significant impact on the tourism industry. As with the no-action alternative, loss of vacation rental revenues is not quantified. Loss of oceanfront properties would eliminate indefinitely some rental properties and reduce the remaining number of viable the rental properties thereby reducing rental incomes and associated economic activity generated in Carteret County and its municipalities.

TABLE 2.2. Net present worth of retreat/relocation alternative.
[Discount rate = 6.125%. Discount rate is yield on 30-yr treasury bond, latest auction reported in Wall Street Journal, 02/24/2000.]

	ANNUAL COSTS OF RELOCATION / RECONSTRUCTION				
Cash Flow Year	**Single Family Relocate On Site**	**Relocate Off Site**	**Condominiums Rebuild On Site**	**Rebuild MH Sites**	
1	$1,076,400	$ 8,991,000	$2,180,250	$156,000	
2	$1,108,692	$ 9,393,930	$2,245,658	$160,680	
3	$1,141,953	$ 9,796,860	$2,313,027	$165,500	
4	$1,176,211	$10,199,790	$2,382,418	$170,465	
5	$1,211,498	$10,602,720	$2,453,891	$175,579	
6	$1,247,843	$11,005,650	$2,527,507	$180,847	
7	$1,285,278	$11,408,580	$2,603,333	$186,272	
8	$1,323,836	$11,811,510	$2,681,432	$191,860	
9	$1,363,551	$12,214,440	$2,761,875	$197,616	
10	$1,404,458	$12,617,370	$2,844,732	$203,545	
Present Value	**$9,444,103**	**$82,357,407**	**$19,129,046**	**$1,368,711**	
				TOTAL NPV	**$110,940,556**

The applicants' economic analysis was evaluated by the USACE Planning Department on 18 May 2001and determined to be "adequate and thorough". USACE provided a list of differences between beach nourishment economic analyses prepared by the applicants for the proposed privately funded project and those required for federally funded projects. USACE stated that the differences "should not be considered deficiencies".

2.3 NOURISHMENT ALTERNATIVE

Beach nourishment may be performed at a continuum of levels but to be viable should fully restore the profile deficit with respect to a "healthy" beach and provide advance nourishment for approximately ten years to accommodate the background erosion rate. Nourishment is the only practicable solution that will offset the sand deficit, maintain the recreational beach, and protect developed property and community infrastructure. There are many ways beach nourishment can be accomplished. This section outlines the main implementation alternatives with respect to sand sources, beach fill design, methods of construction, construction schedule, and maintenance.

2.3.1 Alternate Borrow Areas

Based on previous practice along the US East Coast, the following classes of borrow sources have been used for beach nourishment (CERC 1984):

- Lagoon sediments
- Inlet shoals (inshore)
- Inlet shoals (offshore)
- Nearshore bars
- Offshore deposits
- Recycled spoil sediments
- Accreting spits/beach deposits
- Attached bar deposits
- Inland deposits
- Freshwater pond deposits
- Fillets at jetties
- Imported material

In general, economics favor the borrow source(s) that matches the native beach quality, involves the shortest transportation distance, and minimizes environmental impacts. Large-scale projects such as the present Bogue Banks restoration plan require large volumes of material which may not be available in only one deposit.

2.3.1.1 ***Unacceptable Sources*** – The following sediment sources are considered unacceptable for the project.

- *Lagoon deposits in Bogue Sound* – generally much too fine compared to native beach sand and would not provide sufficient quantities of beach-compatible sediment.

- *Nearshore bar(s) along the project area* – part of the active profile and important for wave energy dissipation, therefore inappropriate as a borrow source; sediments too fine for the dry beach in this setting.

- *Accreting spits/beach deposits* – Bogue Banks has insufficient quantities of sand in accreting spits or accreting beach zones (eg, western Emerald Isle) for the project. At least 20 times more sand is required than resides onshore as "surplus" near the ends of the island.

- *Attached bar deposits* – only very limited reaches near the inlets have any "surplus" sands in attached bars. This would provide only a tiny fraction (of the order 1-2 percent) of the material required for the project.

- *Inland deposits* – Most of Bogue Banks is developed or privately owned. Even if a large tract were available and suitable for sand mining, costs of land acquisition in this setting would increase the cost of the project well beyond other alternatives. Other inland deposits on the mainland may be beach quality, but transportation distances make them much more expensive than other alternatives.

- *Freshwater pond deposits* – There are no known freshwater ponds nearby that require maintenance excavations or could provide the quantities of beach compatible sediment required for the project.

- *Fillets at jetties* – There is insufficient excess littoral sand trapped in fillets along the jetties/ groins at the inlets adjacent to Bogue Banks.

- *Imported material* – Imported beach-quality sediment from sources more than 15 miles from Bogue Banks will be significantly more expensive because of transportation costs than the acceptable sources (listed below).

2.3.1.2 ***Acceptable Sources*** – The following sediment sources were evaluated in more detail because of their likelihood of providing acceptable material (see also Appendix E).

- *Offshore deposits* – A sand search over a 50-square-mile area off Bogue Banks revealed about six square miles of beach-quality sand in close proximity to the project area in the areas designated borrow areas A, B1, and B2 as detailed herein.

- *Inlet shoals (inshore)* – Review of aerial photos and ground-truth sampling confirmed the presence of extensive inlet shoals at Bogue Inlet which contain beach-quality sediment. Studies by the USACE confirm that beach-quality material exists in some inshore areas of Beaufort Inlet. Because of unresolved issues regarding certain conservation habitats, Bogue Inlet shoals are not considered feasible for the present project. Beaufort Inlet shoals are not as economic as the proposed borrow areas and, therefore, are also not considered viable at this time.

- *Inlet shoals (offshore)* – Studies by the USACE confirm that beach-quality material exists in offshore shoals of Beaufort and Bogue Inlets. Because of the above reasons, they are not considered economic for the proposed project.

- *Recycled spoil sediments* – Studies by the USACE confirm that beach-quality material resides in certain spoil areas, such as Brandt Island, which can be "recycled" to the beach. Upon further review (see EIS), these sediments were rejected as being too fine for the project beach.

The results of sediment sampling and review of published reports (see Section 3 and Appendix E) yield the following ranking of acceptable borrow areas with respect to quality (as measured by composite overfill factors, R_A):

1) Offshore area borrow areas B1 and A at 65:35 ratio.
2) Offshore area borrow areas B2 and A at 65:35 ratio.
3) All other potential sources.

With respect to transportation distances, the above-listed resources are ranked as follows (best to worst):

1) Offshore, areas B1 and B2, average distance <2 miles
2) Offshore area A, average distance ~5 miles
3) Bogue Inlet shoals, average distance ~10 miles
4) Brandt Island, average distance ~12 miles
5) Beaufort Inlet, average distance ~14 miles

The preferred borrow areas are A, B1, and B2 based on sediment quality and transportation distance (detailed in Section 3 and Appendix E).

2.3.2 Alternate Fill Profile

Beach nourishment may be performed at a continuum of scales, depending on the goals of the project, availability of borrow sediment, method of construction, and budget. Since the proposed project area has not been nourished to any extent, there are no site-specific data to use as a guide other than the existing natural profile and available erosion rate estimates. Nearby Atlantic Beach has been nourished twice, but its sediment characteristics (after nourishment) differ somewhat from those in the proposed project area.

As detailed later in the present report, CSE Baird-Stroud (1999) evaluated the condition of the beach and inshore zone along Bogue Banks, using the profile volume method (Kana 1993; Kana and Mohan 1996). This method establishes site-specific criteria by which volume deficits can be determined against an ideal or desirable profile volume (ie, one which contains sufficient dimensions to sustain daily, seasonal, and storm fluctuations of the beach without significant damage to the backshore). The profile volume method, if performed to the estimated depth of closure, integrates all cross-shore variations in profile geometry and is therefore insensitive to the timing of surveys.

The analyses (CSE Baird-Stroud 1999) demonstrated that there is a profile deficit averaging ~40 cy/ft along the 16.8-mile reach from western Emerald Isle to Pine Knoll Shores (profiles 8-76), compared to the existing profile volume along Atlantic Beach. Considering the fact that Atlantic Beach sustained Hurricanes *Dennis* and *Floyd* (1999) as well as *Fran* (1996) with only minor damage compared to other sections of Bogue Banks, its profile volume yields a rational minimum value for decadal planning.

The desired fill volume is one that restores the deficit (with respect to the criteria and goals of the project) plus adds "advance nourishment" to increase longevity. Advance nourishment is generally related to the anticipated average annual losses from the project area (ie, the background erosion rate). The Bogue Banks Beach Preservation Task Force evaluated projects which factored in 5-year, 10-year, and 20-year advance nourishment requirements based on best-available background erosion rates. It was the decision of the task force to formulate the project around the ten-year nourishment project (ie, initial deficit averaging ~40 cy/ft plus ten-year advance nourishment averaging 10 cy/ft). This provides a reasonable time period over which the first project can be evaluated and provides a project scale that is practical for dredging. Small-scale projects do not afford economies of scale during construction and result in more frequent nourishments and the associated disruption to normal beach use by people and animals.

The proposed fill will be placed by hydraulic dredge between the base of the foredune and the outer bar. Only the profile above high water is controllable in nourishment construction. Intertidal and underwater portions of the profile will be subject to natural adjustment by waves. Given the relatively high back-beach elevations along most of Bogue Banks and the issue of easements for construction, the majority of the fill will be placed no higher than +7 ft NGVD (the natural elevation of the berm) and seaward of the existing toe of the foredune and all development. Along portions of eastern Emerald Isle, a low dune (elevations <+12 ft NGVD) will be constructed as part of the project to prevent the dredge slurry from flowing landward across developed property (only in the event the predredge profiles show an absence of a foredune exceeding +9 ft NGVD at the time of construction — not a factor at present because all such properties have been scraped and contain a foredune as of June 2001).

Other fill profiles considered included:

- *Nourishment entirely below low water* – not the applicants' preferred alternative because it is more difficult to control sand placement, does not provide a safe working platform during construction, and does not provide immediate restoration of the dry beach and associated back-beach habitats.

- *Nourishment largely contained in a protective foredune* – not the applicants' preferred alternative because (1) a dry beach and healthy underwater profile are necessary prerequisites for a stable foredune; (2) nourishment sediments should be subject to wave action so material will sort naturally, bleach to a natural color, and winnow out fines; and (3) the project's primary goal is to restore a viable recreational beach for broad benefit to the community.

- *Smaller fill sections* – not the applicants' preferred alternative because they become more expensive per unit volume to construct due to economies of scale, they will not restore the minimum profile deficit, and they will leave more reaches vulnerable to storm damage.

2.3.3 Alternate Methods of Construction

There are two basic methods for nourishing beaches — via mechanical placement using land-based equipment and via hydraulic placement using dredges. In either method, mechanical equipment such as dozers, graders, etc., are used to spread the material in a controlled manner. Some projects involve combinations of hydraulic and mechanical transfer. The preferred method depends on the scale of the project, proximity of the borrow area, and type of borrow area. Hydraulic dredges involve high initial costs to cover the setup of discharge pipeline, etc. Land-based equipment such as trucks or scraper pans can be mobilized at low cost. After mobilization, the unit costs of sand placement depend on transportation distance. In general, unit costs of hydraulic fills are lower because of efficiencies in production and placement. Therefore, large-scale nourishments such as the proposed project tend to be more cost effective if constructed by hydraulic dredge.

2.3.3.1 *Methods Considered Unsuitable* – The following excavation and sand transfer methods are considered unsuitable for the present project.

- *Over-road trucks* – None of the designated borrow areas are situated inland, and none are directly accessible by road.
- *Mechanical conveyor belt* – None of the designated borrow areas are situated close enough to the project area for this technique to be economic.
- *Drag line* – None of the designated borrow areas are situated close enough to the project area for this technique to be economic.
- *SeadozerÔ* (c/o Cape Fear International, Beaufort, NC) – None of the designated borrow areas are situated close enough to the project area for this technique to be economic. The method would result in more ocean bottom being impacted because it involves "pushing" material by jets/prop wash from borrow areas to the beach, a minimum distance of 0.5 miles. Portions of the project area are situated >0.5 miles from the nearest borrow source. It is uncertain whether the SeadozerÔ is certified by the U.S. Coast Guard to work seaward of the open-ocean jurisdiction (COLREGS) line, a primary requirement for excavations in the offshore borrow areas (A, B1, and B2).
- *Traditional cutterhead suction dredges* – ocean-certified dredges are required by the U.S. Coast Guard for any excavations seaward of the COLREGS line. Generally, ocean-certified cutterhead suction dredges are the largest of their kind due to the certification requirements. Curtterheads are of the order 5-10 ft in diameter. Such dredges require a minimum operational depth of ~20 ft and work most efficiently if excavations remove at least 4-6 ft of section. Because the designated offshore borrow areas will be limited to excavations of ~2-3 ft for environmental reasons, cutterhead suction dredges will not be practical or efficient. They would result in deeper cuts and produce more variation in offshore substrate depth after construction.

- *Miscellaneous methods* – bucket dredging and transfer by barge are not cost effective for areas A, B1, or B2 and are generally not allowed seaward of the COLREGS line. Split-hull barges are not considered feasible because they require a minimum water depth of the order 20 ft for discharge. This depth would place the material too far seaward to achieve the project goals.

2.3.3.2 *Methods Considered Suitable*

- *Ocean-certified hopper dredge* – Self-propelled hopper dredges with built-in pump-out capability are feasible for borrow areas A, B1, and B2. Ocean-certified equipment typically requires ~25 ft minimum operational depth and is efficient for excavating shallow cuts of the order 1-3 ft. During excavation and loading, the slurry drains via scuppers discharging some fines in situ and leaving coarser material in the hopper compared to the excavated material. For example, contractors have noted 60-80 percent reduction of "fines" on the beach as a result of washing in situ. By fines, we mean sediments in the very fine sand, silt, and clay range (D. Hussin, Great Lakes Dredge & Dock Co, May 2001, pers. comm.). When loaded, the dredge travels to a temporary mooring and submerged pipeline near the project site. It hooks up to the pipeline and pumps the material from the hopper to the beach where it is spread mechanically by dozers.

- *Ocean-certified suction dredge equipped for shallow cuts* – one such dredge exists among U.S. companies which has been specially designed for shallow cuts. This "dustpan" dredge (so nicknamed) is presently owned by Weeks Marine, Inc. (NJ) and is used primarily for beach nourishment involving thin borrow areas offshore (P. Lamourie, Aug'99, pers. comm.). The dredge works most efficiently if the borrow area is close to the project area (e.g., excavations paralleling the beach less than one mile offshore). The slurry is pumped directly to the beach via submerged pipeline and distributed with the aid of dozers and other land-based equipment. In contrast to self-contained hopper dredges, the excavations are pumped only once and therefore transfer more fines to the beach according to the quality of the sediment in the borrow area. Unit costs may be substantially lower than all other methods if the pumping distances are short. This method is considered most feasible for borrow areas B1 and B2.

2.3.4 Alternate Construction Schedule

The proposed project involves a substantial volume of sand (up to 6.7 million cubic yards). Based on project experience elsewhere, one ocean-certified dredge can excavate and place on the order of 15,000-40,000 cy in a 24-hour period. The average production per day varies widely according to transportation distance and specifications of the project. In any case, a substantial period of time will be required to complete the project. For example, if production averages 15,000 cy/day, 400 calendar days (~13 months) will be required to excavate and place ~6 million cubic yards (4.5 million x 1.33 to account for overfill).

Preliminary discussions with environmental agencies indicate construction during colder months is favored because biological productivity tends to be lowest then. Construction during winter also avoids disruption of the peak tourism season.

The following general construction schedules were considered (including advantages and disadvantages).

2.3.4.1 *Construction Anytime Based on Dredge Availability and Lowest Bid*

- *Advantages* – Likely results in lowest construction cost and substantial financial savings to the community because the contractor controls the schedule around other workload and weather and only mobilizes once. Yields the earliest project completion and initiation of improved storm protection and recreational benefits.

- *Disadvantages* – Likely encroaches on high biological productivity periods, nesting seasons, and tourist season.

2.3.4.2 *Construction During Limited "Environmental" Windows Between ~November and ~April*

- *Advantages* – Direct environmental impacts occur during periods of lowest biological productivity. Avoids prime tourist season. Yields early benefits if the project can be initiated in fall 2001.

- *Disadvantages* – A five-to-six month construction window is insufficient to complete the entire project unless more than one dredge is used. Each dredge introduces large mobilization costs, increasing the total cost of the project. The narrower the dredging window, the fewer contractors will be willing to bid the project, further raising the cost of construction. Down time for weather is more likely during winter than summer. Delays project benefits for at least one year if the winter 2001-2002 construction window is missed and leaves properties and beach-dune habitats vulnerable to further erosion damage.

2.3.4.3 *Construction During Two or More Seasons Within Limited "Environmental" Windows*

- *Advantages* – The only viable schedule in the event only one dredge is available for the project. Generally similar environmental advantages but produces direct impacts over two seasons rather than one (not along the same project reaches).

- *Disadvantages* – Will require at least two mobilizations, increasing the project costs. Postpones project benefits (wider beach, improved storm protection, etc.) for the areas uncompleted during the first window. Causes disruption to habitats over two seasons instead of one.

Other schedules considered but found not acceptable were:

- *Yearly fills for limited reaches* – result in much higher construction costs because of multiple mobilizations and repeated environmental impacts and disruption to normal beach use; delays project benefits along reaches constructed last.

- *Multiple, smaller scale fills* – result in much higher construction costs because of multiple mobilizations and the additional labor required to place "thin" nourishment sections; produce repeated environmental impacts and delay natural recovery of biological populations; do not fully restore the deficit, leaving property and backshore habitats insufficiently protected during storms.

- *Medium-scale fills* – essentially the same disadvantages as multiple, smaller scale fills.

Nourishment at the scale proposed (base volume ~4.5 million cubic yards or ~50 cy/ft, and volume with advance/overfill nourishment ~6.7 million cubic yards or ~75 cy/ft) over a 16.8-mile reach will restore the sand deficit. Addition of 50-75 cy/ft compares favorably with the estimated maximum volumetric erosion during Hurricane *Floyd* (<15 cy/ft). This means that the profile will generally have sufficient volume to allow cross-shore adjustment during storms. The proposed project will not eliminate all dune recession during major storms whenever the surge overtops the berm. However, the need for and frequency of beach scraping after the project due to major storms is expected to decline to a fraction of what it was during the 1990s. This has been proven for the site by the experience of Atlantic Beach over the past five years. Dune fencing and revegetation will be used to promote gradual improvement of the foredune after the project and after storms.

Requested Construction Schedule – From the above list of options, we propose 2.3.4.2 and 2.3.4.3 – namely, construction during environmental windows which may extend into the fall and spring. Specifically, the applicants seek authorization to commence construction as early as 16 November and continue construction as late as 30 April during multiple years. The applicants anticipate performing biological monitoring and environmental sampling as required in permits before and after construction.

2.3.5 Alternative Plans and Costs by Reach

Six reaches and multiple alternatives are outlined in Tables 2.3.1-2.3.7 (preliminary project alternative sheets) for the reaches as listed below:

- Pine Knoll Shores – East
- Pine Knoll Shores – West
- Indian Beach/Salter Path
- Emerald Isle – East
- Emerald Isle – Central
- Emerald Isle – West

The upper half of each sheet gives dimensions and fill volume requirements (no adjustment for borrow fill ratios) and nourishment requirements (adjusting for specific borrow fill ratios). This is why different nourishment volumes are indicated for each alternative.

Unit costs are given as the estimated pumping cost (excluding dredge mobilization) for a particular borrow area, distance, and equipment type. The applicable unit costs range from \$2.75/cy to \$7.00/cy based on current market conditions. The low range applies to pipeline dredges equipped to excavate thin borrow layers of fine sand and pump over distances of about 0.5 mile (typically \$2-\$3/cy; E. Elefson, Weeks Marine, August 1999, pers. comm.). The higher range applies to self-propelled hopper dredges equipped to excavate thin layers, then travel to and pump out via short, buoyed pipelines close to shore in water depths of 20 ft or more (typically \$3-\$7/cy). The inshore water depths off Bogue Banks are favorable for ocean-going hopper dredges. The anticipated equipment assumes that excavations will be restricted to shallow cuts (~2-3 ft thick) for environmental reasons.

Unit costs per foot of shoreline and per foot per year are given along with a probable range of pumping costs (exclusive of engineering and dredge mobilization). The indicated cost range applies to each "10-year" alternative ±15 percent. The bottom of each project plan sheet gives a range of expected "soft costs" including dredge mobilization, engineering, permitting, and surveys. In each case, the low-range soft-cost estimate assumes at least four reaches are executed around the same time under a single design service and a single dredge mobilization procurement. Without these economies of scale, the soft costs for individual reaches will be close to the high range.

NOTE: Tables 2.3.1-2.3.7 were prepared in September 1999 prior to additional surveys of borrow area sediment quality. They reflect early estimates of overfill ratios and include alternate borrow areas such as Bogue Inlet (area C) and the Corps' Beaufort Inlet maintenance projects which are not being considered for the present project under permit 200000362.

The *Preliminary Project Alternative – Summary-Bogue Banks* (Table 2.3.7) summarizes the lowest cost alternative for each reach and provides totals for the six reaches (ten-year alternatives only).

The estimated total cost for six reaches (ten-year projects) is approximately $24.25 million to $26.75 million. This averages $273-$302 per linear foot of shoreline in the nourishment areas, or ~$27-$30/ft/yr if considered over 10 years (without interest). Because of variations in sediment quality in each borrow area, the nourishment volume requirement is higher than the profile volume requirement. For the assumptions made in unit cost estimates and borrow areas, the nourishment volume for the 10-year plan (six reaches) would be ~6.7 million cubic yards (~75 cy/ft). A fill of this magnitude will initially widen the dry beach by ~100 ft.

As can be seen in the preliminary project alternatives (Tables 2.3.1-2.3.7), the "20-year" plan is incrementally more costly than the "10-year" plan, based on the anticipated cost of replacing erosion losses during the period. The Emerald Isle-East reach was found to have the highest average annual erosion rate at ~3.2 cy/ft/yr. This yields a "20-year" nourishment cost of ~$6.9 million versus a "10-year" cost of ~$4.8 million (ie, 44 percent higher). The difference was substantially less for other reaches with the average around 25 percent higher. Based on this, a 20-year project using today's prices has a total cost of ~$31 million, which suggests average annual costs of longer duration projects will decline over time. However, given the limited database of historical surveys for the project area, the Beach Preservation Task Force recommended planning around a "10-year" project. Detailed monitoring over the life of the project will confirm the fill losses and allow calculation of the average annual cost of nourishment. The task force considers the cost of the "10-year nourishment" alternative substantially below the cost of the "no-action" alternative or the "abandonment/relocation" alternative, even if the costs are extrapolated out several decades and include periodic renourishment to restore erosion losses.

TABLE 2.3.7

Summary - Bogue Banks	Preliminary Project Plan	September-99
	Emerald Isle-West to Pine Knoll Shores East	
Beach Condition	Fair to Poor	
Reach Length (ft)	**88,761**	Applicable Profiles: **8 - 76**
Longterm Vol Erosion Rate cy/ft	-1.15	*Slow to Moderate Erosion*
Profile Volumes (cy/ft)		*Dry Beach to +2.5 ft: 9.17 cy/ft*
(Base Dunes to -10 ft NGVD):	**136.63**	*Wet Beach to -5.0 ft: 47.30 cy/ft*
Estimated Average Sand Deficit:	38.37	*Underwater to Bar (-10 ft): 80.17 cy/ft*

Note: Averages are weighted for the applicable shoreline length

Fill Volume Reqmt - No Overfill	Unit Volume (cy/ft)	Net Volume (cy)
Initial Deficit	38.37	3,405,750
Deficit Plus 5 yr Advance	44.11	3,915,129
Deficit Plus 10 yr Advance	*49.85*	***4,424,508***
Deficit Plus 20 yr Advance	61.32	5,443,266

Note: The fill volume requirement is less than the nourishment volume for a particular borrow area because of differences in sediment quality. Borrow Area A will require ~10% greater nourishment volumes; Borrow Area B1 will require ~62% greater volumes; Borrow Area B2 will require ~80% greater volumes; and Borrow Area C will require ~ 15% greater volumes to provide equivalent project performance and longevity. Unit dredging costs vary with distance between the Borrow area and the beach, type of equipment used, and quality of the sediments.

Lowest Cost Alternative (Borrow Area)	**Nourishment Volume (cy)**	**Pumping Costs**
	10-yr Project	*10-yr Project*
*1 Pine Knoll Shore - East (**B1**)*	1,465,965	**$4,031,405**
*2 Pine Knoll Shore - West (**B1**)*	777,962	**2,139,394**
*3 Indian Beach/Salter Path (**B2** or A)*	989,933	**2,722,316**
*4 Emerald Isle - East (**B2** or A)*	1,744,983	**4,798,703**
*5 Emerald Isle - Central (**A**)*	843,654	**4,218,268**
6 Emerald Isle - West (C or A)	865,964	**4,329,822**
Totals	6,688,461 cy	**$22,239,908**

Note: Similar costs are likely for Projects 3,4 & 5 using alternate borrow areas. The indicated nourishment volume requirement and unit pumping costs will vary according to which Borrow Area is chosen. See individual project sheets for details.

For The 10-yr Project	*Rounded*
Net Costs (per ft)	**$250**
Annual Unit Costs (per ft/yr)	**$25**

Probable Cost Range - 10-yr Project	
Plus 15%	25,500,000
Estimated Pumping Cost	**$22,250,000***
Minus 15 %	19,000,000

* Possibility for federal/local cost sharing @ 50/50 for some of the projects using Corps borrow areas in Beaufort Inlet and Bogue Inlet. See individual project sheets for details.

Estimated Soft Costs	*Low Range*	*High Range*
Dredge Mobilization	$800,000	$2,000,000
Engineering, Permitting and Surveys	1,200,000	2,500,000
Estimated Total Soft Costs	**$2,000,000**	**$4,500,000**

Note: The low range cost estimate assumes at least four projects are designed, permitted and constructed under a single procurement and a single dredge mobilization so that costs may be shared. The high range assumes two dredge mobilizations will be required because of different equipment requirments for each borrow area.

2.4 APPLICANTS' PREFERRED ALTERNATIVE

The applicants' preferred alternative is beach nourishment using offshore borrow areas A, B1, and B2 in close proximity to the six project reaches (Fig 2.1).

Following development of the preliminary plan (CSE Baird-Stroud 1999) (Section 2.3.5 of this report), additional surveys were performed and reported in CSE (2000) and CSE Stroud (2001). The project has also been revised based on comments from state resource agencies under the SEPA EIS review (final environmental impact statement published 6 April 2001) and from federal resource agencies through the public notice and subsequent meetings.

Based on the involvement of three municipalities and the present timelines for funding, the proposed project will be constructed in two or three phases over at least three years (ie, three environmental windows). Three borrow areas (A, B1, and B2) will be used, but excavations will be limited to specific areas within A, B1, and B2 (described in Section 3). Fill sections will involve up to the indicated volumes given in the permit application and in this report but may be less depending on final construction bids because the project funding will be fixed. Representative fill sections are given in the permit application (Appendix A-2). The fill sections shown in the permit application indicate a base fill volume (based on the ~4.5 million cubic yard volume deficit) and an additional "overfill" volume representing the additional quantity needed to match the performance of the native beach. The final project volume and section volumes cannot be known with certainty until bids are received and compared with the budget available for each phase. Based on best-available information, the proposed project will now be executed as follows.

2.4.1 Phase I

Reaches 4, 5, and 6 – Towns of Pine Knoll Shores and Indian Beach (transects 48-77). See sheets 3d, 3e, 3f, 7, 8, and 9 of the permit application (Appendix A-2).

Requested dates for construction: 1 November 2001 through 30 April 2002

Negotiated dates for construction (27 August 2001): *16 November through 15 April 2002*

Borrow areas: B1, B2, and A within the revised areas and sections (described in Section 3). Approximately 65 percent of the fill will be obtained from B1 and B2, and 35 percent will be obtained from A.

Estimated Phase I volumes:	Initial Base Volume (cy)	Advance Nourishment Plus Overfill Volume (cy)	Total Volume (cy)
Reach 4	550,000	440,000	990,000
Reach 5	480,000	240,000	720,000
Reach 6	905,000	445,000	1,350,000
Phase I Total			3,060,000

Phase I dimensions:

	Depth of Cut (ft)	Volume Cubic Yards (%)	Areas (acres / mile²)
Borrow area A	~2	1,071,000 (35)	332 / 0.52
Borrow areas B1 and B2	~3	1,989,000 (65)	411 / 0.64
Phase I Total		3,060,000 (100)	743 / 1.16

Beach Area	Length (ft)	Avg Unit Volume (cy/ft)	Estimated Added Dry Beach Width (ft)	Estimated Added Dry Beach (acres)
Reach 4	13,400	73.9	82	25.2
Reach 5	8,800	81.8	91	18.4
Reach 6	15,400	87.7	97	34.3
Phase I Total	35,600 (~7.1 miles)			77.9

Inshore (Surf Zone) Areas	Average Width Impacted by Direct Filling (ft)	Area (acres)
Reach 4	525	161
Reach 5	510	103
Reach 6	525	186
Phase I Total		450

Time required for construction: ~153 days (at 20,000 cubic yards per day average)

Average production per day: ~250 ft

Fill sequence (anticipated):

Begin Phase I in Reach 5 – Pine Knoll Shores West to avoid November surf fishery in Atlantic Beach
Fill Reach 5 @ ~1,800 ft per week (impacted areas)
Fill Reach 6 – Pine Knoll Shores East
Fill Reach 4 – Indian Beach
End Phase I

Type of equipment and construction sequence: Hydraulic dredge

There are an estimated 20 self-propelled hopper dredges and one shallow-cut suction dredge certified to perform work of this type in the U.S. Therefore, there is a 95 percent probability that the type of equipment used will by a self-propelled hopper dredge. (Such dredges are described in Section 2.3). Hopper dredges excavate borrow areas, then travel to an inshore site about 1,000 ft offshore where they connect to a temporary pipeline. From there, a slurry of sediment and water is pumped to shore and distributed in sections along the beach. Sediment is discharged parallel to the shore and semi-contained by low berms. The slurry runs alongshore and down-profile, carrying finer grained sediments into the surf where it is mixed and sorted by waves. Clay-sized particles dissipate beyond the surf zone and silts and very fine sands tend to settle beyond the outer bar. The balance settles in the trough or in the new berm. After completion of ~1-2 miles, the landing pipe from offshore is moved to a new locality. The area just filled is graded to the final slopes (matching the natural beach elevation and slopes above high water) and then left to adjust naturally. Typically, a given 1-2 mile reach is only impacted by construction activities for approximately one month, and then the operation moves to another reach.

Phase I (Reaches 4, 5, and 6) represents ~42.4 percent of the total project length and ~45.7 percent of the total project volume. Phase I has been approved by the municipal sponsors, and a funding plan is in place for construction at the earliest time.

2.4.2 Phase II

Reach 3 and portions of Reach 2 – Emerald Isle East and Emerald Isle Central (ie, Indian Beach/Emerald Isle town line at transect 48 to ~30th Street at transect 34). See sheets 3b, 3c, 5, and 6 of the permit application (Appendix A-2).

Anticipated dates for construction: 16 November 2002 through 15 April 2003.

Borrow areas: B1, B2, and A within the revised areas and sections (described in Section 3). Approximately 65 percent of the fill will be obtained from B1 and B2, and 35 percent will be obtained from A.

Estimated Phase II volumes:

	Initial Base Volume (cy)	Advance Nourishment Plus Overfill Volume (cy)	Total Volume (cy)
Reach 3	970,000	485,000	1,455,000
Reach 2 (east part)	150,000	75,000	225,000
Phase II Total	1,120,000	560,0000	1,680,000

Phase II dimensions:

	Depth of Cut (ft)	Volume Cubic Yards (%)	Acres (acres / mile²)
Borrow area A	~2	588,000 (35)	182 / 0.285
Borrow areas B2 and B1	~3	1,092,000 (65)	226 / 0.353
Phase II Total		1,680,000 (100)	408 / 0.638

Beach Area	Length (ft)	Avg Unit Volume (cy/ft)	Estimated Added Dry Beach Width (ft)	Estimated Added Dry Beach (acres)
Reach 3	12,900	112.8	125	37.0
Reach 2 (east part)	2,800	80.4	89	5.7
Phase II Total	15,700 (3.0 miles)			42.7

Inshore (Surf Zone) Areas	Average Width Impacted by Direct Filling (ft)	Area (acres)
Reach 3	575	~170
Reach 2 (east part)	475	~30
Phase II Total		200

Time required for construction: ~112 days (at 15,000 cubic yards per day average)

Average production per day: ~140 ft

Fill sequence (anticipated):

Begin Phase II at east end of Reach 3 (Indian Beach/Emerald Isle town line at transect 48)
Fill Reach 3
Fill eastern 2,800 ft of Reach 2 ending at 30th Street (~transect 34)
End Phase II

Type of equipment: Hydraulic dredge (see Section 2.4.1 for information on construction sequencing)

Note: Phase II is not presently approved and funded by the applicants. However, the indicated reaches have been designated by community leaders as the priority areas (Mayor B. Harris, March 2001, pers. comm.).

Phase II (Reach 3 and part of Reach 2) represents 17.9 percent of the total project length and 25.1 percent of the total project volume.

2.4.3 Phase III

Remainder of Reach 2 from 30th Street (transect 34) to Ebb Tide Drive (transect 25) and all or portions of Reach 1 (Ebb Tide Drive to Shipwreck Lane, transect 8) – Central and Western Emerald Isle.

Anticipated dates for construction: 16 November 2002 through 15 April 2003 **or** 16 November 2003 through 15 April 2004

Borrow areas: B1, B2, and A within the revised areas and sections (described in Section 3). Approximately 65 percent of the fill will be obtained from B1 and B2, and 35 percent will be obtained from A.

Estimated Phase III volumes:

	Initial Base Volume (cy)	Advance Nourishment Plus Overfill Volume (cy)	Total Volume (cy)
Reach 2 (west part)	617,000	308,000	925,000
Reach 1	753,000	282,000	1,035,000
Phase III Total	1,370,000	590,000	1,960,000

Phase III dimensions:

	Depth of Cut (ft)	Volume Cubic Yards (%)	Acres (acres / mile²)
Borrow area A	~2	686,000 (35)	212 / 0.33
Borrow areas B2 and B1	~3	1,274,000 (65)	263 / 0.41
Phase III Total		1,960,000 (100)	475 / 0.74

Beach Area	Length (ft)	Avg Unit Volume (cy/ft)	Estimated Added Dry Beach Width (ft)	Estimated Added Dry Beach (acres)
Reach 2 (west part)	11,700	79.1	88	23.6
Reach 1	23,700	43.7	49	26.7
Phase III Total	35,400 (6.7 miles)			50.3

Inshore (Surf Zone) Areas	Average Width Impacted by Direct Filling (ft)	Area (acres)
Reach 2 (west part)	425	114
Reach 1	425	231
Phase III Total		345

Time required for construction: ~130 days

Average production per day: 270 ft

Fill sequence: To be determined upon review of conditions around time of construction

Type of equipment: Hydraulic dredge

Note: Phase III is not presently approved and funded by the applicants. However, the indicated reaches have been designated by community leaders as the remaining priority areas for restoration.

Phase III may be further subdivided or reduced in scope if future conditions show favorable trends in sand volume gains. Phase III (Reach 1 and the west part of Reach 2) represents 39.9 percent of the total project length and 29.3 percent of the total project volume.

2.4.4 Summary

2.4.4.1 Phase I: Reaches 4, 5, and 6 — 3,060,000 cy — Nov 2001 – Apr 2002
Transects 48 to 77 (Pine Knoll Shores and Indian Beach town limits)
37,600 linear feet (7.1 miles)

2.4.4.2 Phase II: Reach 3 and 2,800 ft of Reach 2 — 1,680,000 cy — Nov 2002 – Apr 2003
Transects 34 to 48 (eastern Emerald Isle, 1st Street to 30th Street)
15,700 linear feet (3.0 miles)

2.4.4.3 Phase III: Reach 1 and remainder of Reach 2 — 1,960,000 cy — Future
Transects 8 to 34 (western and central Emerald Isle, Shipwreck Lane to 30th Street)
35,400 linear feet (6.7 miles)

2.4.4.4 Totals: Reaches 1 through 6 — 6,700,000 cy
Transects 8 to 77 [Shipwreck Lane (Emerald Isle) to Atlantic Beach town line)
88,700 linear feet (16.8 miles)

See Appendix A-2 for detailed maps and cross-sections of the proposed project.

Summary:

Length: ~88,760 ft - 16.8 miles

10-Yr Nourished Volume Required: ~6,700,000 cy

Incorporates first cost volume, 10 year advance nourishment plus overfill (Ra).

NOTE: Nourishment volumes are based on a computed profile volume deficit to the outer bar, background volume erosion rate, and overfill ratio for the indicated borrow area. Use of alternative areas will result in revised nourishment volumes and unit construction costs. The low-end cost estimate assumes shared engineering, permitting, and construction mobilization costs. The high-end cost estimate assumes independently formulated and executed projects. Details are given in CSE Baird/Stroud (1999); CSE - Stroud 2000 and present report.

Drawing Title:

Fig 2.1

3.0 AFFECTED ENVIRONMENT

3.1 LAND USE

3.1.1 Character of Bogue Banks

Bogue Banks is a barrier island with a southward facing ocean shoreline stretching some 25 miles between two large tidal inlets, Bogue Inlet to the west and Beaufort Inlet to the east. The area of Bogue Banks is surrounded by Bogue Sound on the north and Onslow Bay of the Atlantic Ocean on the south. The island is made up of the Fort Macon State Park; the Towns of Atlantic Beach, Pine Knoll Shores, Indian Beach, and Emerald Isle; and the unincorporated area of Salter Path.

Of almost 80 miles of barrier island shoreline located in Carteret County, Bogue Banks is the only developed area. The remainder, made up of Shackleford Banks and Core Banks to Ocracoke Inlet, will remain undeveloped in perpetuity as part of the Cape Lookout National Seashore. Bogue Banks is the only ocean shoreline in the county with direct vehicle access.

Topography on Bogue Banks varies from the salt marsh flats and flood prone drainage areas along the island's northern shoreline on Bogue Sound to dune ridges on the island interior and along the ocean shoreline. Dune ridge elevations reach 40 feet (ft) above sea level at some locations.

Bogue Banks' soils vary with Newhan sandy soils in the nearshore, beach and dune zones; Duckston, Corrolla and Newhan soils in the scrub zones; Duckston, Corrolla, and Fripp soils in the maritime forest zones; and Carteret soils in the salt marsh zones. Corrolla soils are fine sands, moderately to poorly drained that occur behind the frontal dune line. Fripp sands are excessively well drained and make up the interior dune ridge areas. Duckston fine sands are poorly drained and are in the troughs between dune ridges and on flats between dunes and marshes. Newhan fine sands are excessively well drained and make up the dune ridges that parallel the ocean shoreline. Carteret soils are the fine organic muck found in the salt marsh environment.

Vegetation on Bogue Banks reflects elevation and the amount of exposure to salt spray. As distance from the shoreline increases, sparse beach grasses merge with dense scrub vegetation. Maritime forests thrive in areas where the island is wide enough to provide sufficient protection from salt spray for forest growth. Maritime forests generally occur on lands that have been stable for at least 50 years. Vegetation typical of freshwater wetlands and tidal flats populate flood prone areas and natural and manmade drainage ways.

3.1.2 Typical Development

Development of Bogue Banks ranges from the densely developed portions of Atlantic Beach to the Theodore Roosevelt Natural Area in Pine Knoll Shores. Oceanfront development is, for the most part, residential with pockets of commercial hotels and campgrounds, multi-family condominium developments, and high-density mobile home parks. It is estimated that development of oceanfront lots has reached 90 percent build out.

Setbacks for oceanfront construction are established by regulations of the NC Division of Coastal Management (DCM). Residential construction setbacks are 30 times the long- term erosion rate as established by maps prepared by DCM. Maps currently in use were updated in 1992. The setback for large commercial or permanent structures in excess of 5000 square feet is 60 times the long-term erosion rate. The minimum setback is 60 ft in areas with long-term erosion rates less than 2 ft. The line for measurement of setbacks is the first line of stable vegetation. In locations where vegetation is sparse, the line is interpolated from adjacent areas where vegetation exist. The measurement line is typically established in the field by DCM personnel as part of the CAMA permitting process.

3.2 WETLANDS

There are no areas of 404 wetlands or coastal wetlands identified in the project area.

3.3 AGRICULTURAL LANDS

No agricultural land is in or adjacent to the project area. Low water retention capacity of the sandy barrier island soils preclude establishment of agricultural crops.

3.4 LITTORAL PROCESSES AND EROSION

Existing data on the littoral processes and erosion on the oceanfront side of Bogue Banks include:

- Historical, but not recent tidal statistics.
- Several versions of wave conditions as outputs from wind/wave models, but no wave measurements.
- Estimates of wave and current energy fluxes along the beach as outputs from different wave-shoaling models, but only brief visual measurements of waves and currents.
- Estimates of longshore sediment transport, especially at Atlantic Beach, from (1) wave-shoaling model studies performed by the Corps of Engineers (USACE) and the University of North Carolina (UNC), and (2) qualitative measures of diffusion/advection of the Atlantic Beach nourishment sand from UNC studies.
- Extensive sets of topographic surveys (beach profiles) for Atlantic Beach (only) from both USACE and UNC, with profile sets for the entire island available from 1978 (USACE) and 1999 (CSE Baird-Stroud).

3.4.1 Tides

Tides have been measured at Duke Marine Lab in Beaufort on the **sound** side of the islands continuously since 1973. Tidal measurements at other locations were made only during brief studies in 1960 and 1973 and show (USACE 1999):

Tide Gauge Location	Mean	Tide Range in 1960 (ft) Spring	Tide Range in 1973 (ft) Mean
Atlantic Beach (ocean side)	3.6	4.3	3.6
Morehead City	2.8	3.4	2.9
Duke Marine Lab (Beaufort)	2.5	3.0	2.9
Shell Point (Harkers Island)	1.3	1.6	1.6

The more recent 1973-1989 data set at Duke Marine Lab shows a tide range of 3.0 ft and a spring tide range of 3.5 ft. (http://www.opsd.nos/noaa.gov/cgi-bin/websql/ftp/staqry.pl)

3.4.2 Hurricanes

Tidal surges from storms add to the astronomically produced tides for a total stillwater superelevation. Frequency of occurrence of hurricanes is highly variable (Barnes 1998). One estimate of hurricane frequency made in the 1970s was 1.6 hurricanes per year for Bogue Banks (Sarle 1977). North Carolina hurricanes increased in frequency in the 1990s. With respect to beaches, the most important effect of hurricanes is the surge. Surge levels do not necessarily correlate with hurricane strength or "category," since categories are determined by wind and pressure, not surge. For example, surge levels at Atlantic Beach were estimated for *Hazel* (1954, Category 4) at 7.0 ft mean sea level (MSL), for *Ione* (1955, Category 3) at 7.2 ft MSL, and *Donna* (1960, Category 3) at 10.6 ft MSL (USACE 1966). *Donna* may be an appropriate "design" hurricane for Bogue Banks, since it is the only recent hurricane to have breached the island (near the location of a relict inlet in eastern Emerald Isle).

NCSU (Knowles et al 1973) estimated surge levels for different return periods of storms, along each section of the North Carolina coast. For the section that includes Bogue, stillwater surge levels in feet above MSL are 7.63 ft for a 25-year storm, 9.33 ft for 50-year, and 10.95 ft for 100-year. These surges were then translated into estimates of resulting dune retreat, using empirical data from several storms. Dune retreat is a function of surge, height and massiveness of the dune, and distance between the dune and the mean waterline. In the 70s Bogue's average dune reached 16 ft above MSL and had a toe 8.9 ft above MSL that was 158 ft from mean high water. Estimates of dune retreat were 21 ft for a 25-year storm, 162 ft for 50-year, and 220 ft for 100-year. Bogue's beaches are currently much narrower than in this study (the dunes are closer to the water). However, site-specific measurements after *Floyd* (1999) showed that dune retreat averages somewhat less than these model predictions--about 15 ft.

3.4.3 Waves

Wave heights, frequencies, and directions have been estimated for this area by various sources over the years. However, all such studies are based on observations or estimates of offshore winds, which models then convert into the resulting waves. In some studies these waves are then shoaled into breaking-wave depths using wave-refraction models. Estimating waves in this manner results in large errors compared to wave measurements. Early estimates of wave heights include Nummedal et al (1977) who used Navy shipboard wind observations to determine offshore wave heights for the area of 5.5 ft, with a 7 ft height exceeded 27 percent of the time. The Corps of Engineers Wave Information Study's 1956-75 data set of waves (Jensen 1983) modeled from winds shows mean wave height for the area in 10 meters (m) of water (Phase III dataset) of 4.3 ft (USACE 1992). Summary wave statistics (from USACE CERC's website) for the deeper (20-27m) Phase II stations are:

Station	Dates	Depth (m)	Mean Height (ft)	Mean Period (sec)	Mean Direction (azimuth degrees)
#45 (25 nm south ofEmerald Isle)	1956-75	27	3.9	6.2	112.5
	1976-95	27	3.9	7.4	112.5
#46 (7 nm southeast of Cape Lookout)	1956-75	20	3.6	6.4	112.5
	1976-95	20	3.9	8.2	90.0

Using a 1976-93 version of the Station #46 WIS data set, a University of North Carolina study (Roessler 1998, Fig 25) found wave heights shoaled all the way into the breakpoint varied considerably depending on the direction of approach, but averaged about 3.9 ft, except at the easternmost end of the island where Bogue is sheltered somewhat by Beaufort Inlet's ebb-tidal delta and the Corps' offshore dredging disposal areas.

The applicants have installed an offshore wave gauge about 8 miles off Pine Knoll Shores and an inshore wave gauge adjacent to the Iron Steamer pier for purposes of obtaining a site-specific record of incident waves between November and May.

3.4.4 Dimensions of Littoral Zone (Depth of Closure)

The depth offshore to which there is active interchange of sediment with the beach is of consequence to beach nourishment projects. The goal is to avoid taking sediment from within the active system, since that sediment is already, to some extent, helping to maintain the beach. The depth of closure is defined in standard texts, such as the Shore Protection Manual (CERC 1984), as the depth beyond which there is active motion of the seabed for an average of only 12 hours per year. Six different methods and sources of information were utilized in determining this depth for Bogue Banks, and the results are detailed in Appendix G2. Those calculations produce the following conclusions:

1) Hindcast data of extreme (12 hr/yr) conditions produce depths of closure between 13 ft and 18 ft MLW.

2) Measured storm conditions produce closure depths between 16 ft and 22 ft.

3) During the few hours that hurricanes are present in the immediate vicinity, closure depth has been computed as 36 ft.

4) The limit of sediment activity was measured at a nearby but more open-coast site at between 3.9 and 6.4 m (13-21 ft).

5) Mapping sediment types by color, texture, and size result in a boundary between beach and shelf sands between 32 and 33 ft depths.

6) The Corps of Engineers' nearshore berm off of Atlantic Beach in 25-30 ft depths has not exhibited significant motion and has not contributed sediment to the beach.

3.4.5 Littoral Transport

Studies of the potential for longshore sediment transport are detailed in Appendix G4. All of the quantitative studies used waves that are part of the USACE Wave Information Study, which is a compilation of wave predictions as modeled from the offshore winds that generate waves. Various versions of these databases have been produced over the years, but no measurements have been made of the directional wave field.

Hindcast studies of waves predict different magnitudes and opposite directions of sediment transport along Bogue Banks, depending on which database is used. Early studies (USACE 1976) predicted net transport eastward. Updated versions of the winds for the same time period (1956-75) produced significantly greater transports, but still to the east. Recent studies (USACE 1999) show westward transport, using winds from a different time (1976-95). Other studies (Roessler 1998) also show westward transport. However, our studies detailed in Appendix G4 show that the magnitudes and direction of transport are solely a function of which wave database is used. When we used the same databases as the above studies, we confirmed their results, even though our wave-shoaling methods were different. Thus, the qualitative results (net direction and rough magnitude) do not depend on the different wave-shoaling methods and topographic data used by different investigators.

More reliable than computation of transport from waves modeled from winds are geological indicators of net sediment accumulation. These indicators allow some qualitative conclusions to be reached regarding longshore sediment transport along Bogue.

Net longshore transport rates are low along Bogue Banks. Evidence includes:

1) Erosion rates measured from aerial photos and beach profiles do not vary dramatically along the island. The change (divergence) of transport rates along the beach is what causes net erosion/accretion.

2) There are no large accumulations of sand at the end of the cell (western end of Emerald Isle). Although that area is currently accreting, it is not doing so rapidly, and over time the area cycles back and forth between erosion and accretion.

3) A study (Reed 1997) examined the differences in texture and color between the Corps' nourishment sand at Atlantic Beach and the native sand. These differences allowed tracking of nourishment as a "tracer" and determined that the net transport was quite low, much lower than wave hindcast studies suggest.

3.4.6 Historical Erosion Rates

Rates of erosion/accretion were estimated for all sections of Bogue Banks using both volumetric measures of change, where previous data existed, and linear rates of shoreline change from aerial photography. [The methods are detailed in Appendix G5 and the results tabulated in Table G5-1 in Appendix G5. Final classifications of erosion rates are illustrated in Figure G5-2 in Appendix G5.] There is considerable variability in the results between very different methods, but all methods show an overall slow erosion. The bottom line is that most communities on Bogue Banks have slow but continuing erosion rates (on the order of 1 ft/yr shoreline retreat). However, the erosion does not occur at a steady rate, but in episodic events during storms. The net result of storm erosion (average of 15 ft retreat during Hurricane *Floyd*) and the following recovery is a slow retreat of the shoreline.

3.4.7 Beach Surveys

No island-wide surveys are available prior to 1999 that measure representative profiles from the foredune to the lower foreshore. One set of wading-depth profiles is available from a USACE survey (unpublished) in 1978. As part of the Corps planning for disposal of sediments from navigation projects in Beaufort Inlet, they have completed detailed profile surveys along Fort Macon State Park and Atlantic Beach out to the ~30-ft contour (USACE 1992).*

*[*In early 2001, the Corps initiated a feasibility study of erosion and contracted for surveys encompassing the entire Bogue Banks oceanfront in April 2001. These data were not available in time for inclusion in the present analysis.]*

Given the dearth of surveys along the entire island for volumetric erosion analyses, the applicants contracted with CSE Baird-Stroud (1999) to establish a network of 111 transects at ~1,000-ft spacing along Bogue Banks. These were first surveyed from the foredune/ backshore to the outer bar (800-1,100 ft offshore) in June 1999. Figure 3.1 shows the general location of survey lines, and Figure 3.2 illustrates eight representative profiles. These data were juxtaposed with USACE 1978 wading depth profiles for purposes of computing volumetric changes over the 21-year period (1978-1999, Fig 3.3). The results confirmed low rates of change along most of the island. An important implication of this result for the proposed project is that low background erosion rates improve the chance of success of nourishment and reduce the frequency of damaging erosion along backshore habitats.

Soon after completion of the county-sponsored shoreline assessment, Hurricanes *Dennis* and *Floyd* impacted Bogue Banks. CSE-Stroud (2001) resurveyed 18 profiles in September 1999 and all lines in June 2000. Representative profiles are given in Figure 3.4. *Floyd* caused average recession at the toe of the foredune of ~14 ft. In contrast, the mean high water contour (~+2 ft NGVD) shifted seaward by ~25 ft immediately after the storm (Fig 3.5). Between September 1999 and June 2000, the toe of the foredune (+9 ft NGVD contour) shifted seaward (mainly as a result of dune scraping), and the mean high water contour shifted landward. The net result on average was a restoration of the dune volume by artificial means and return of the recreational beach to its prestorm (eroded) condition along most of the island. Overall, between June 1999 and June 2000, there was negligible net change in the average contour position or in the total volume of sand in the littoral zone along Bogue Banks.

Survey Lines and Reach Boundaries

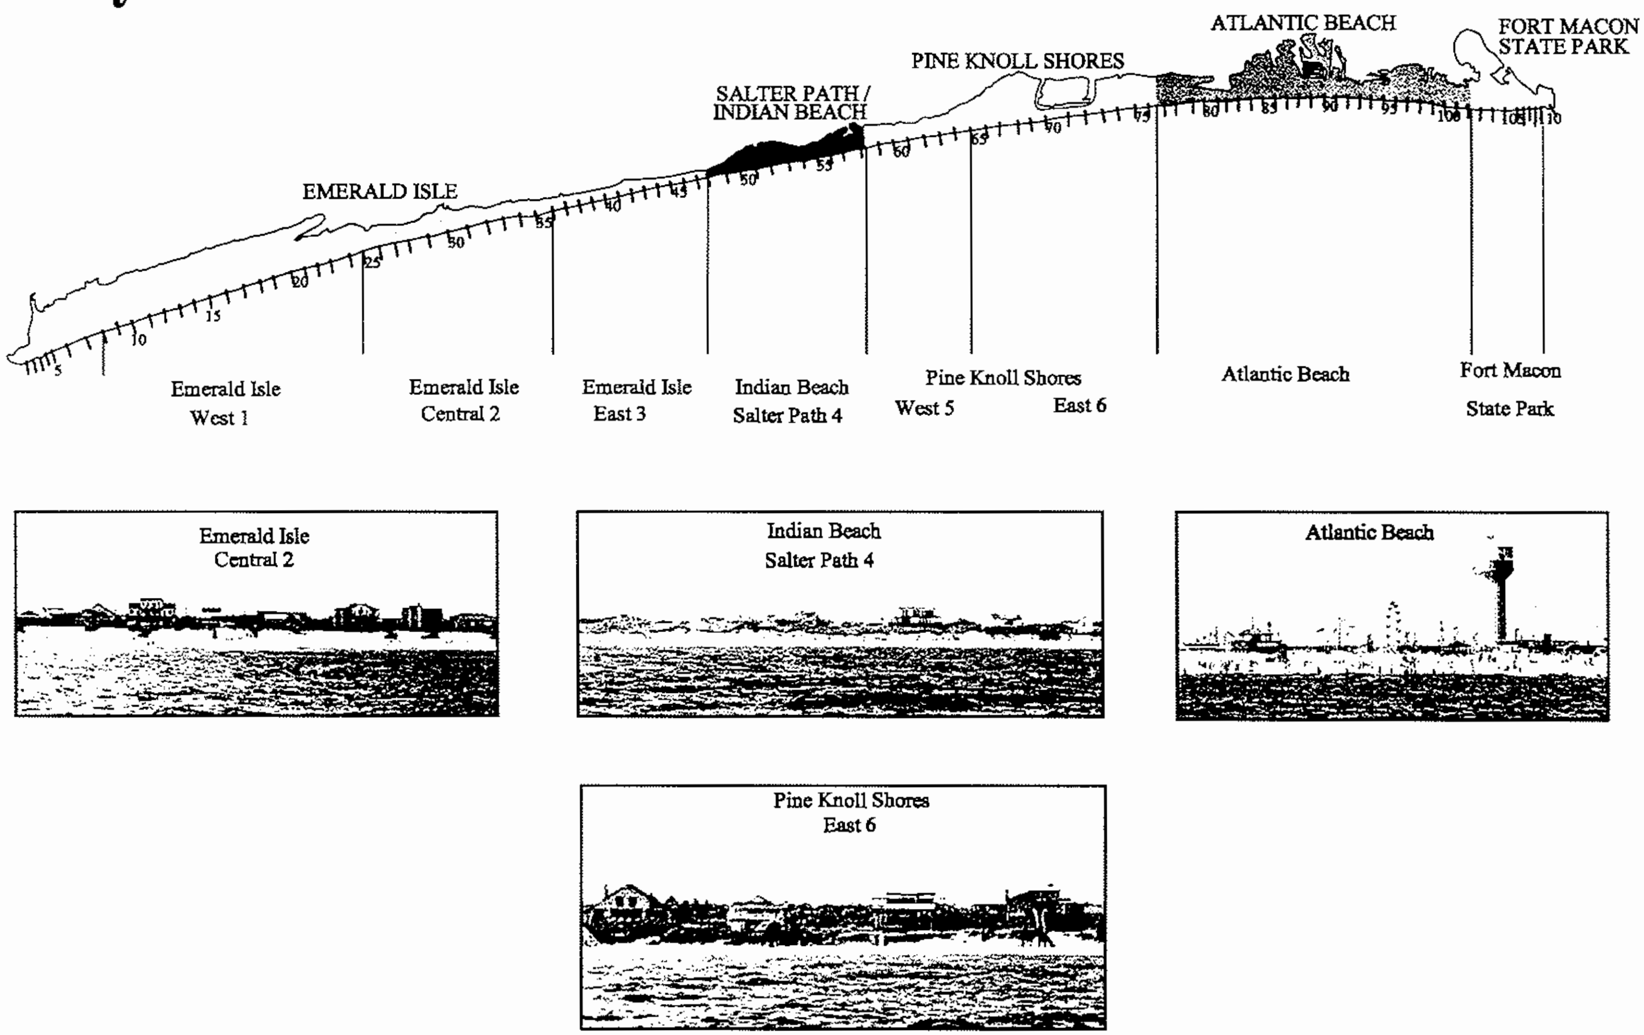

FIGURE 3.1 Location of beach and inshore profiles established and surveyed by the project team in June 1999 and June 2000. About 20 percent of the profiles were resurveyed one week after Hurricaine Floyd in September 1999.

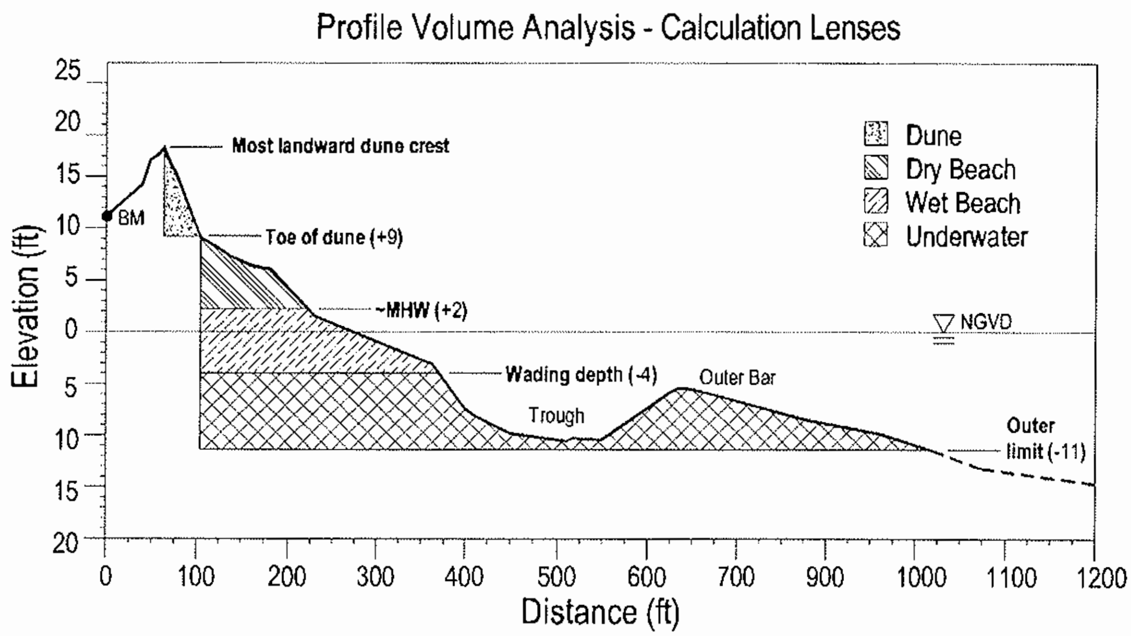
3.4.8 Volumetric Change

CSE Baird-Stroud (1999) and CSE-Stroud (2001) developed detailed volumetric analyses of Bogue Banks profiles for purposes of comparing the relative condition of the beach from one reach to another. Four reference "lenses" were evaluated as defined in Figure 3.6. These lenses represent the volume in the foredune (from crest to +9 ft NGVD), the volume on the "dry beach," and the volume in the intertidal "wet beach" and "underwater" to the outer bar. Lens datums are arbitrary but generally reflect distinct morphologic units of the beach and incorporate most of the zone of active profile change from year to year.



Foredune — Defined as the cross-section (unit volume) from the most landward foredune crest (among available surveys) to +9 ft NGVD. Note that +9 ft was determined to be a typical elevation for the base of the foredune and slightly higher than the highest dry beach.

Dry Beach — Defined as the section between +9 ft and +2 ft NGVD. The latter datum approximates local mean high water (MHW). While portions of this zone are wetted due to wave runup and setup, it generally represents the prime recreation area of the beach.

Wet Beach — Defined as the section between +2 ft and -4 ft NGVD. This area incorporates the breaker and swash zone, low-tide terrace, and inner bars out to low-tide wading depth.

Underwater — Defined as the section between -4 ft and -11 ft NGVD. The lower datum was selected based on the typical limits of the data sets. It generally encompasses the outer bar (which varies from about -5 ft to -10 ft NGVD at its crest).

FIGURE 3.6. Calculation lenses used in the analysis of Bogue Banks profiles. Unit volumes are derived by extrapolating cross-sectional areas (and area changes) over one unit length of shoreline. Reach volumes are computed by extrapolating unit volume over distances between profiles using the average-end-area method.

Figure 3.7 shows island-wide trends in unit volumes. The upper half of Figure 3.7 references the 16.8-mile reach encompassing the Towns of Pine Knoll Shores, Indian Beach, and Emerald Isle, specifically the area between beach profile lines 8 and 76 (see Fig 3.1). The lower half of Figure 3.7 incorporates results from all available profiles (1 to 111), and these results show:

- Most of the "beach" volume is underwater and along the wet beach.
- Hurricane *Floyd* caused erosion of the foredune and outer bar, and a gain along the dry beach and wet beach.
- By June 2000, unit volumes for each lens had returned to nearly identical values as June 1999 before *Floyd*.
- There is significantly less sand in the profiles from Pine Knoll Shores to Emerald Isle than occurs in other sections of Bogue Banks.

Based on available data, Hurricane *Floyd* did not produce a major net loss of sand along Bogue Banks. The dominant effect on the beach from the hurricane was a temporary cross-shore redistribution of sand. Unfortunately, the temporary effect caused loss of dune habitat and extensive damage to structures in some reaches as detailed in a later section. Poststorm survey data confirm that the majority of volume change along Bogue Banks occurs above the –11-ft contour. The hurricane, on average, did not produce a measurable buildup of the underwater profile or the inshore area beyond the outer bar. This goes against conventional wisdom (eg, Pilkey et al 1998), but supports CSE-Stroud's (2001) conclusion that closure depth (depth of measurable profile change) along Bogue Banks is substantially shallower than –30 ft NGVD at decadal scales.

On a site-specific basis, there were differences in the volumetric changes during *Floyd* and over the one-year survey period. Figure 3.8 shows averages for nine reaches, six of which represent 16.8 miles of the proposed project area (transect 8 to transect 77) — Emerald Isle west (EI-W) to Pine Knoll Shores east (PKS-E). The greatest volume loss during *Floyd* occurred along Atlantic Beach with erosion averaging ~18 cy/ft. By contrast, some reaches along the western half of Bogue Banks gained sand during *Floyd*. (Nearly all the gain occurred below mean high water.) By June 2000, most of the sand volume losses had been replaced naturally. Atlantic Beach regained over 13 cy/ft within the computation boundaries, leaving a net loss of about 5 cy/ft between June 1999 and June 2000. A similar result occurred along Pine Knoll Shores and portions of Emerald Isle. Remaining reaches experienced net gains in sand volumes (as measured out to the –11-ft NGVD contour) such that the island-wide volume change from June 1999 to June 2000 was essentially zero. This further support our conclusion that erosion rates along Bogue Banks are low compared to many beaches.

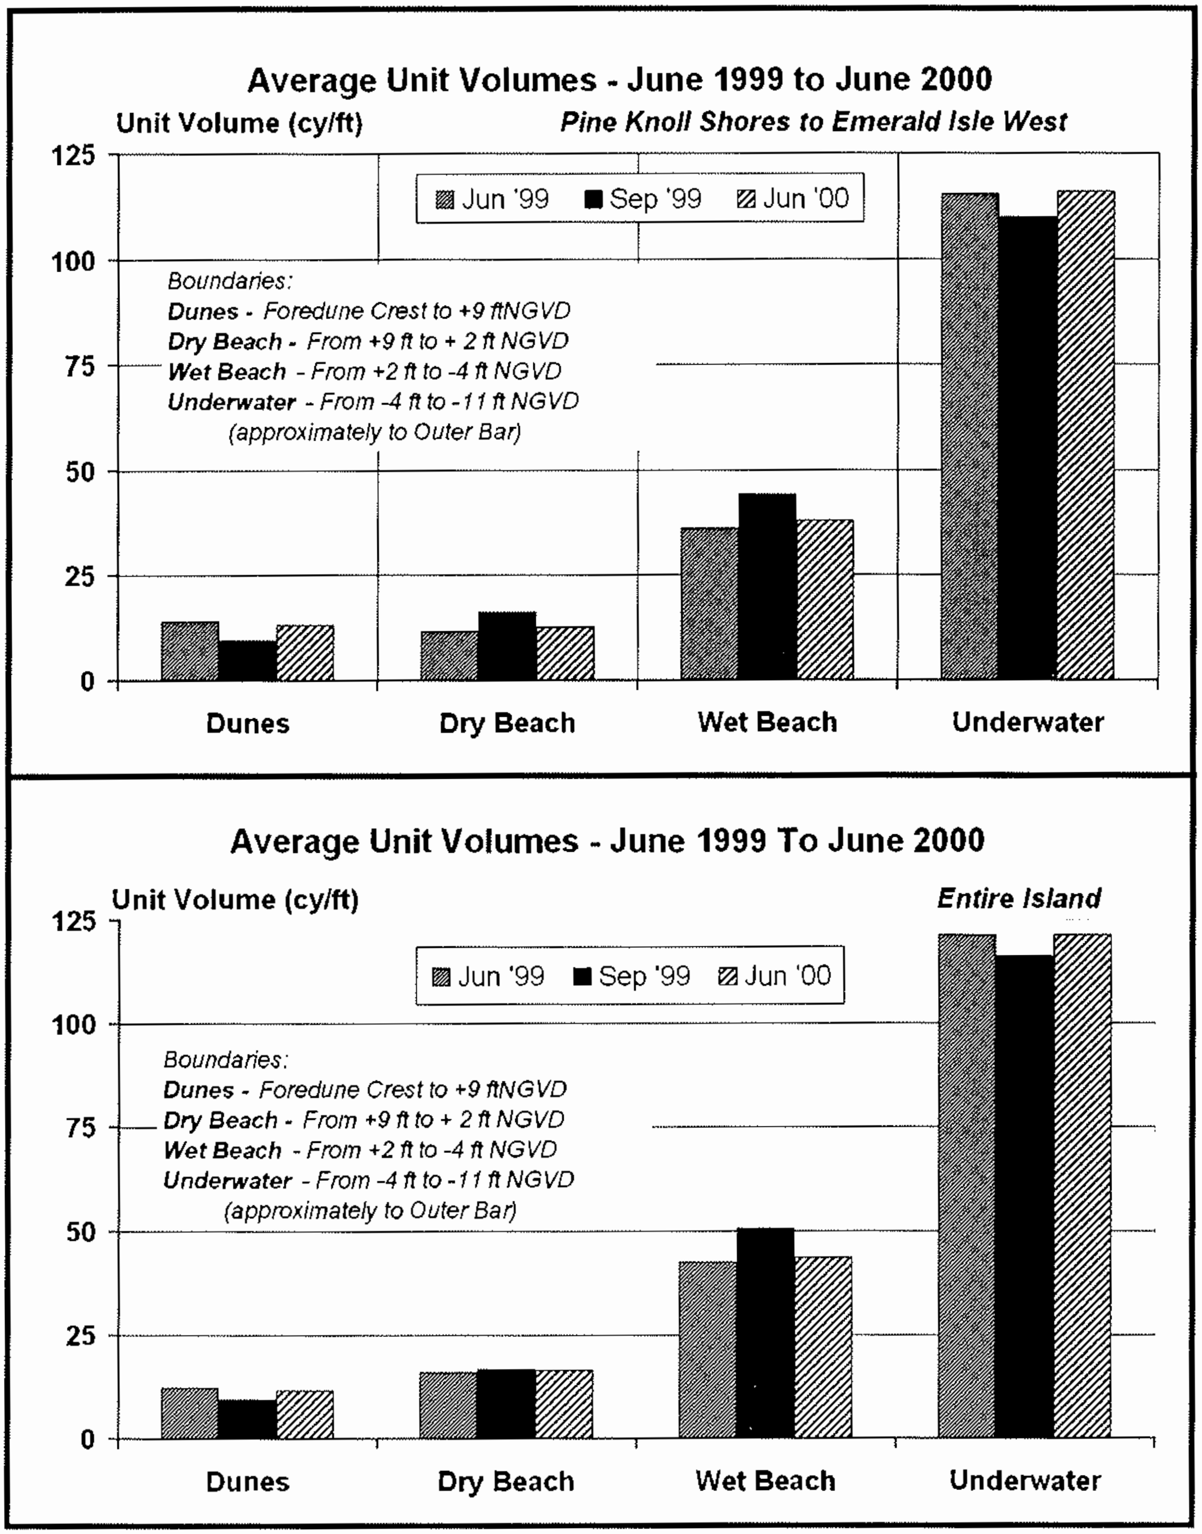


FIGURE 3.7. Island-wide trends in average unit volumes by lens for June 1999, September 1999, and June 2000. Note loss of volume in September 1999 in both the dune and the underwater lenses. Hurricane *Floyd* caused dune recession, but it also appeared to erode the outer bar and shift sand landward into the wet beach lens. There was little net change in volume island-wide as surveyed to the outer bar.

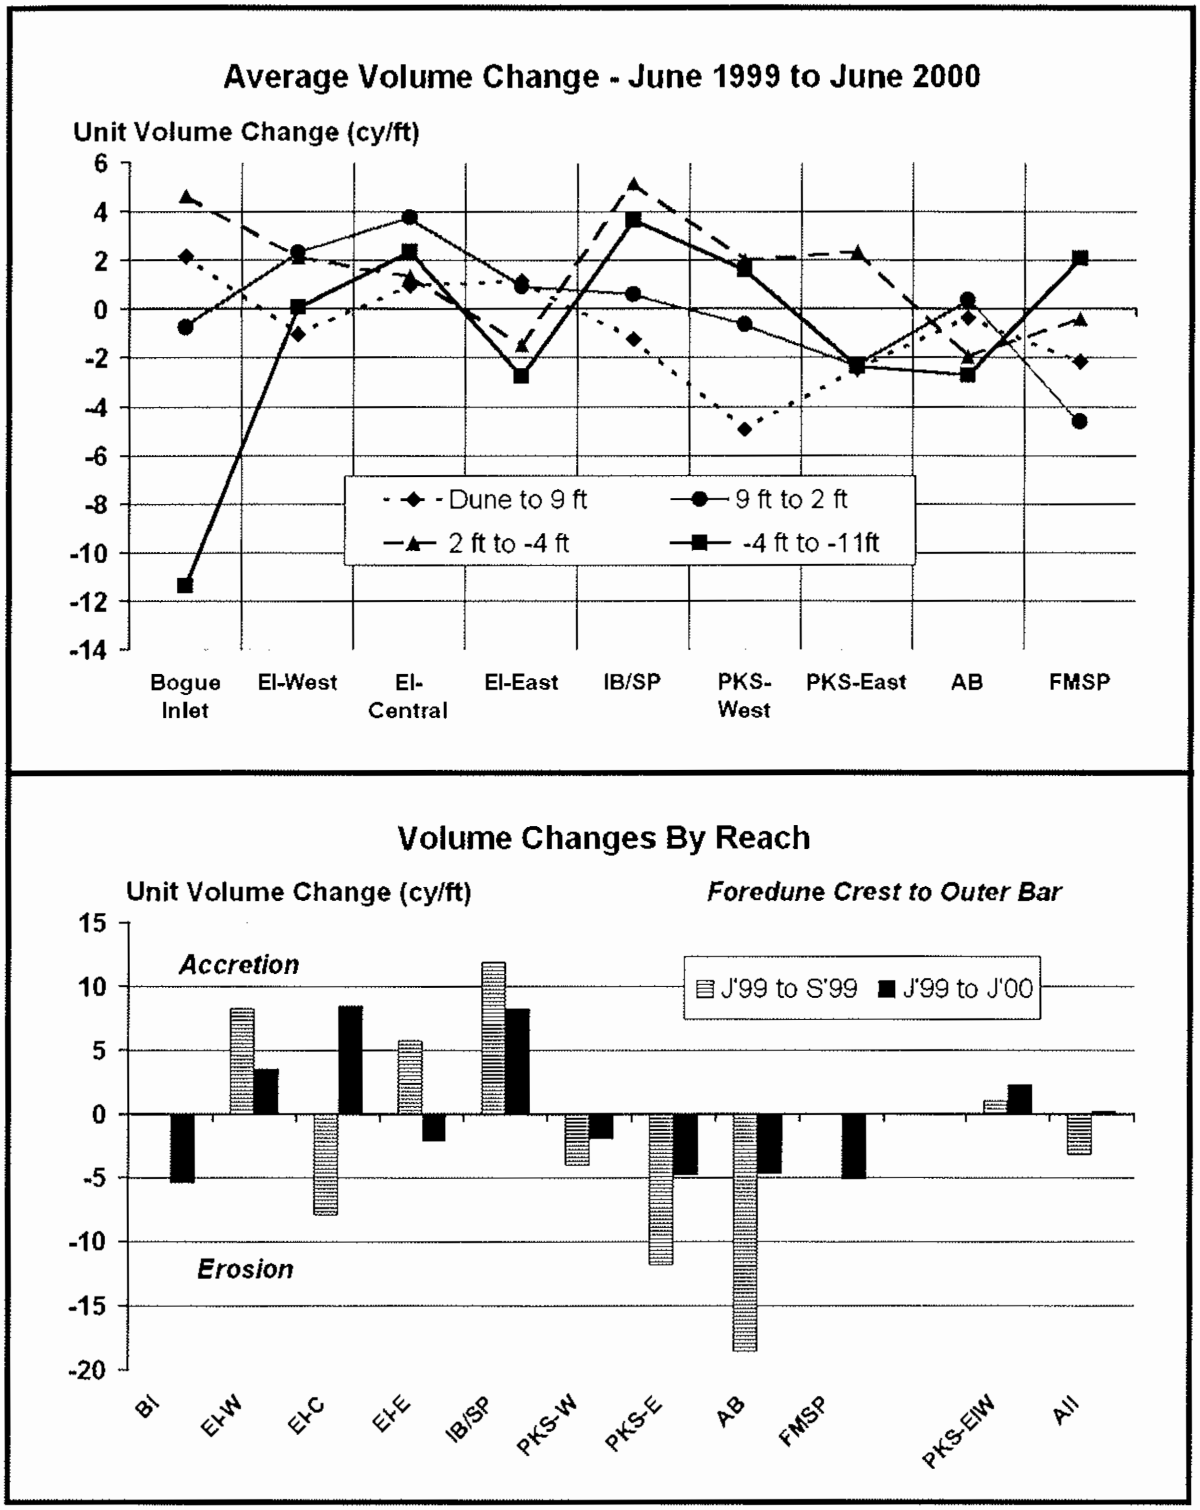

FIGURE 3.8. Average unit volume changes by lens (upper) and for all lenses combined (lower, foredune to outer bar). Greatest net losses from June 1999 to June 2000 were measured along Bogue Inlet, PKS-East, Atlantic Beach, and Fort Macon State Park. Net change for the 16.8-mile project reach (EI-West to PKS-East) was a **gain** of the order 2.35 cy/ft during the past year. The gain is believed to result from onshore movement of sediment from deeper water as well as longshore advection from Atlantic Beach.

3.4.9 Sand Volume Deficit

Profile volumes provide an objective measure of beach condition in the absence of historical data (Kana 1993). The surveys described above were used to calculate profile deficits for specific reaches along Bogue Banks. Figure 3.9 illustrates the basic concept. It is possible with profile volumes to define, on a site-specific basis, the minimum section volume necessary to accommodate a normal range of beach and inshore changes without adverse impact to backshore habitats and development. In the case of armored shorelines such as Atlantic Beach in the mid 1970s, an eroded profile means loss of dry beach area, exposure of seawalls, or chronic recession of dunes, leaving escarpments that inhibit habitat development. One utility of such analyses is that the unit volume integrates the small-scale perturbations and cross-shore variations of the profile and, therefore, can yield similar results regardless of the timing of surveys. It is a direct measure of the quantity of sand in the littoral zone (if surveys to closure are made) rather than a theoretical calculation based on the concept of equilibrium profiles (eg, Dean 1991).

CSE Baird-Stroud (1999) found that the reaches between profile 77 (Atlantic Beach/Pine Knoll Shores town line) and profile 8 (western Emerald Isle), 98 percent of which are unarmored, contained about 20-35 percent less sand than Atlantic Beach. In quantitative terms, the difference was ~30 cy/ft to 50 cy/ft. This is illustrated in Figure 3.10.

Casual observations show differences between the beach conditions of the proposed project area and Atlantic Beach. Most of Emerald Isle and all of Indian Beach and Pine Knoll Shores have negligible dry beach. Atlantic Beach, by contrast, had a 100-200 ft berm prior to Hurricane *Floyd* and nearly the same width nine months after *Floyd*. The deficit quantified by CSE Baird-Stroud (1999) became the basis for formulating the proposed nourishment project. The plan calls for nourishing the six reaches where there is a measurable deficit such that a minimum profile volume of 175 cy/ft (measured to approximately -11 ft NGVD) is achieved (see Fig 3.10). To this quantity, additional volume would be added to account for estimated yearly erosion losses over a ten-year period, differences in sediment quality between borrow sources and the native beach, and estimated volumes needed beyond the available survey limits out to closure depth. In short, the condition of Atlantic Beach was the model for restoration of other reaches along Bogue Banks because it has faired exceedingly well through five hurricanes.

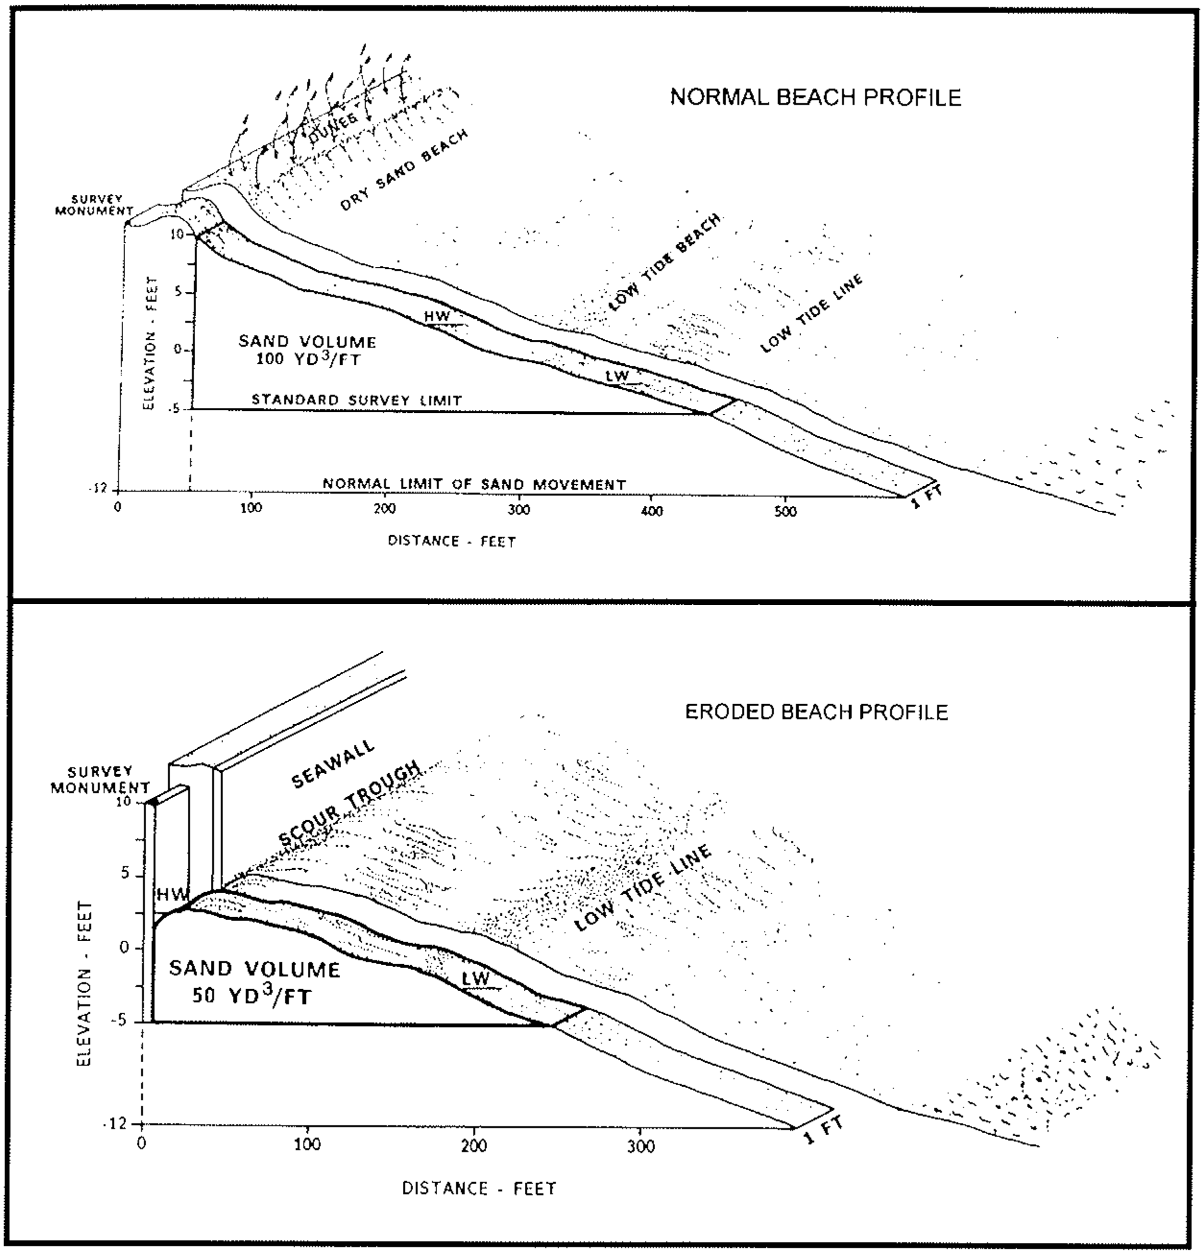

FIGURE 3.9. The concept of unit sand volume along the beach, which provides a quantitative measure of beach condition and changes before and after nourishment. The normal limit of measurable sand movement ("profile closure depth") along Bogue Banks is thought to occur at depths of about 20-30 ft (CSE-Stroud 2001; App G). The present surveys end around the outer bar in depths of ~12 ft about 800-1,000 ft from the foredune. Therefore, the data encompass the majority, but not all, of the active littoral zone. [After Kana 1990]

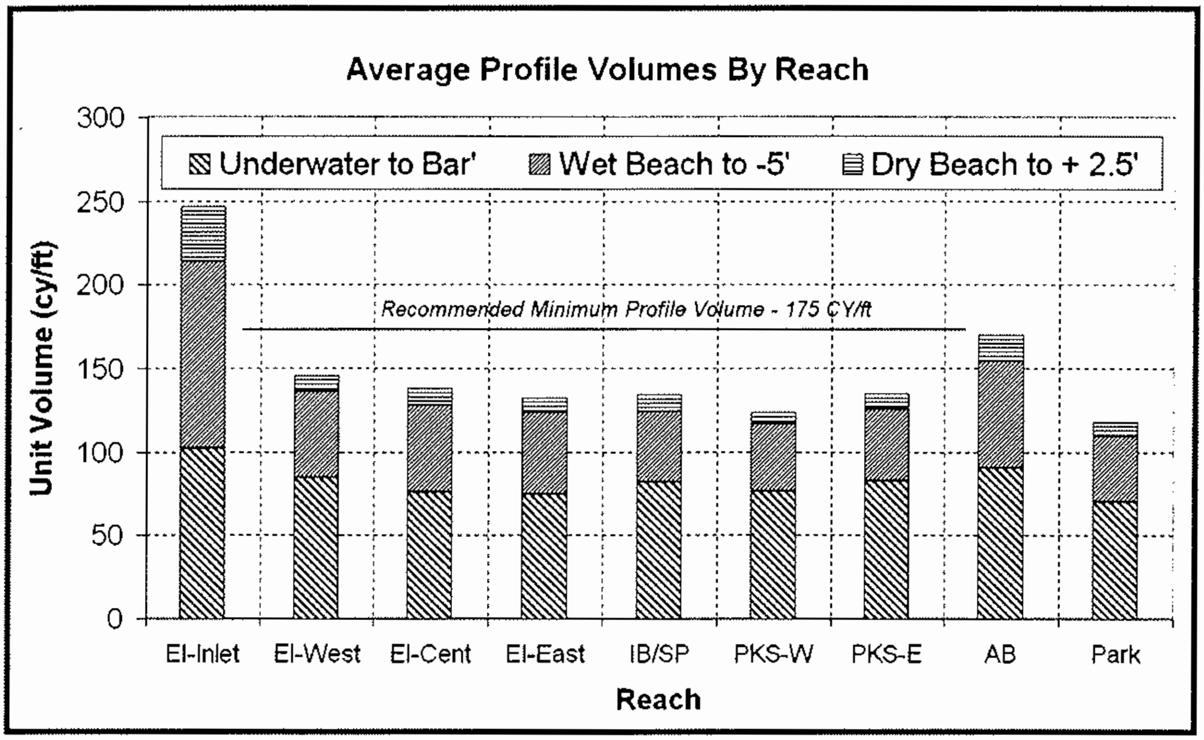

FIGURE 3.10. Average profile volumes by reach along Bogue Banks in June 1999. Atlantic Beach is healthier and contains a wider dry beach than all but one other reach. It serves as a model for the minimum profile volume needed along the island.

3.4.10 Post-*Floyd* (September 1999) Conditions

Protection of property is one of the principal objectives of the beach nourishment project. Based on an inspection by CSE of beachfront properties in the project area in September 1999 following Hurricane *Floyd*, a large number of residential structures were determined to be in immediate danger (Figs 3.11-3.14). Immediate danger was defined as suffering severe damage as a result of the loss of a protective dune or, in the case of residential single and multi-family structures, if a portion of the building was within the CAMA setback limits, the exposed units were determined to be endangered. CAMA rules for beachfront structures require that, if the structure is damaged in excess of 50 percent of its value, it cannot be repaired or replaced without meeting the required oceanfront setbacks. If there is not adequate lot depth to permit required setbacks from the street and beach, the structure and lot are assumed to be a total loss and are required to be moved to another lot.

The economic analysis used as a basis for the analysis of alternatives (Appendix F.) was based on the number of endangered structures identified in the post-*Floyd* survey. The number of endangered structures in each community is listed below:

	Single Family	Condominium	Mobile Home Lots
Emerald Isle	156	36	17
Indian Beach	10	32	15
Salter Path	15	45	7
Pine Knoll Shores	4	58	0

The post-*Floyd* survey included a visual assessment of damage within the project limits and along the nourished beach of the Town of Atlantic Beach. There were no endangered structures identified in Atlantic Beach after *Floyd*. Additionally, the level of damage to beachfront access structures (such as decks and walkways) was minimal in Atlantic Beach. By comparison, an estimated 90 percent of the beachfront structures in the Pine Knoll Shores, Indian Beach, and Emerald Isle project area suffered significant damage. As a result of the erosion associated with Hurricane *Floyd* and other smaller subsequent storms, scraping of the beach in the project area has occurred along an estimated 85 percent of the shoreline. The scraping has been repeated twice during the winter and spring months along much of the shoreline since 1999 at further expense to the ecology of the beach.

FIGURE 3.11. Emerald Isle at low tide on 21 September 1999, six days after Hurricane *Floyd* impacted the area. [UPPER LEFT] Condominiums at 26th Street. [OTHER VIEWS] Residential area between 1st Street and 21st Street.

FIGURE 3.12. Indian Beach-Salter Path area six days after Hurricane *Floyd* in September 1999. [UPPER] Campground. [LOWER] Hoffman Road.

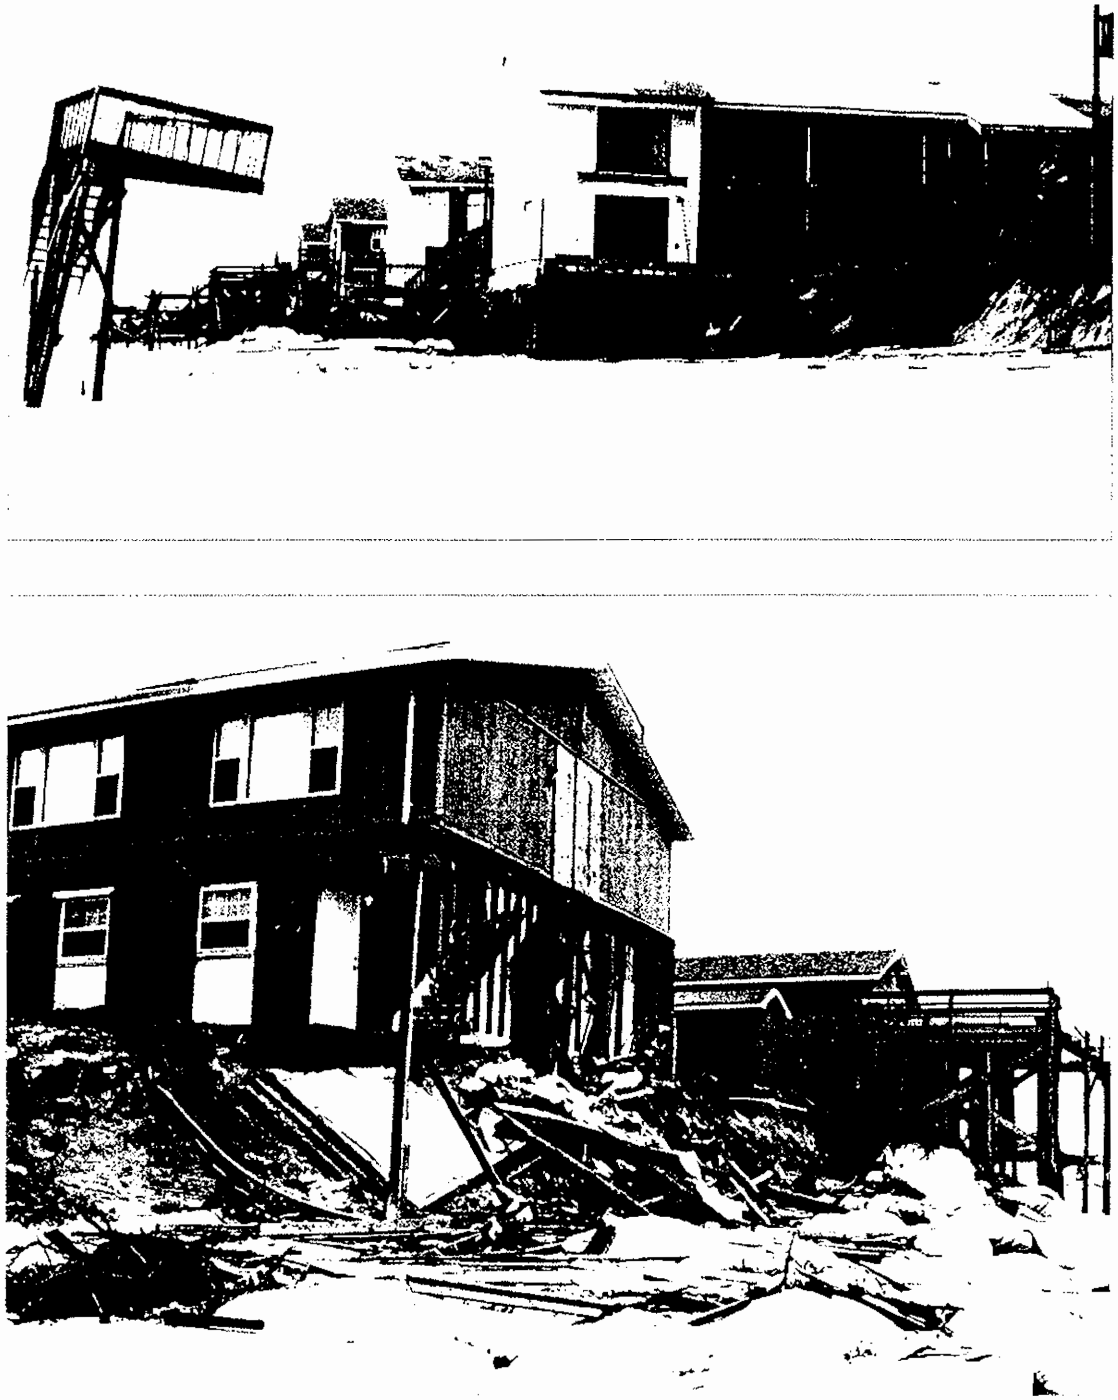

FIGURE 3.13. Pine Knoll Shores area at Pine Knoll Townes condominiums, one week after Hurricane *Floyd* at low tide. (Salter Path Road and Pine Knoll Boulevard between CSE lines 69 and 70.)

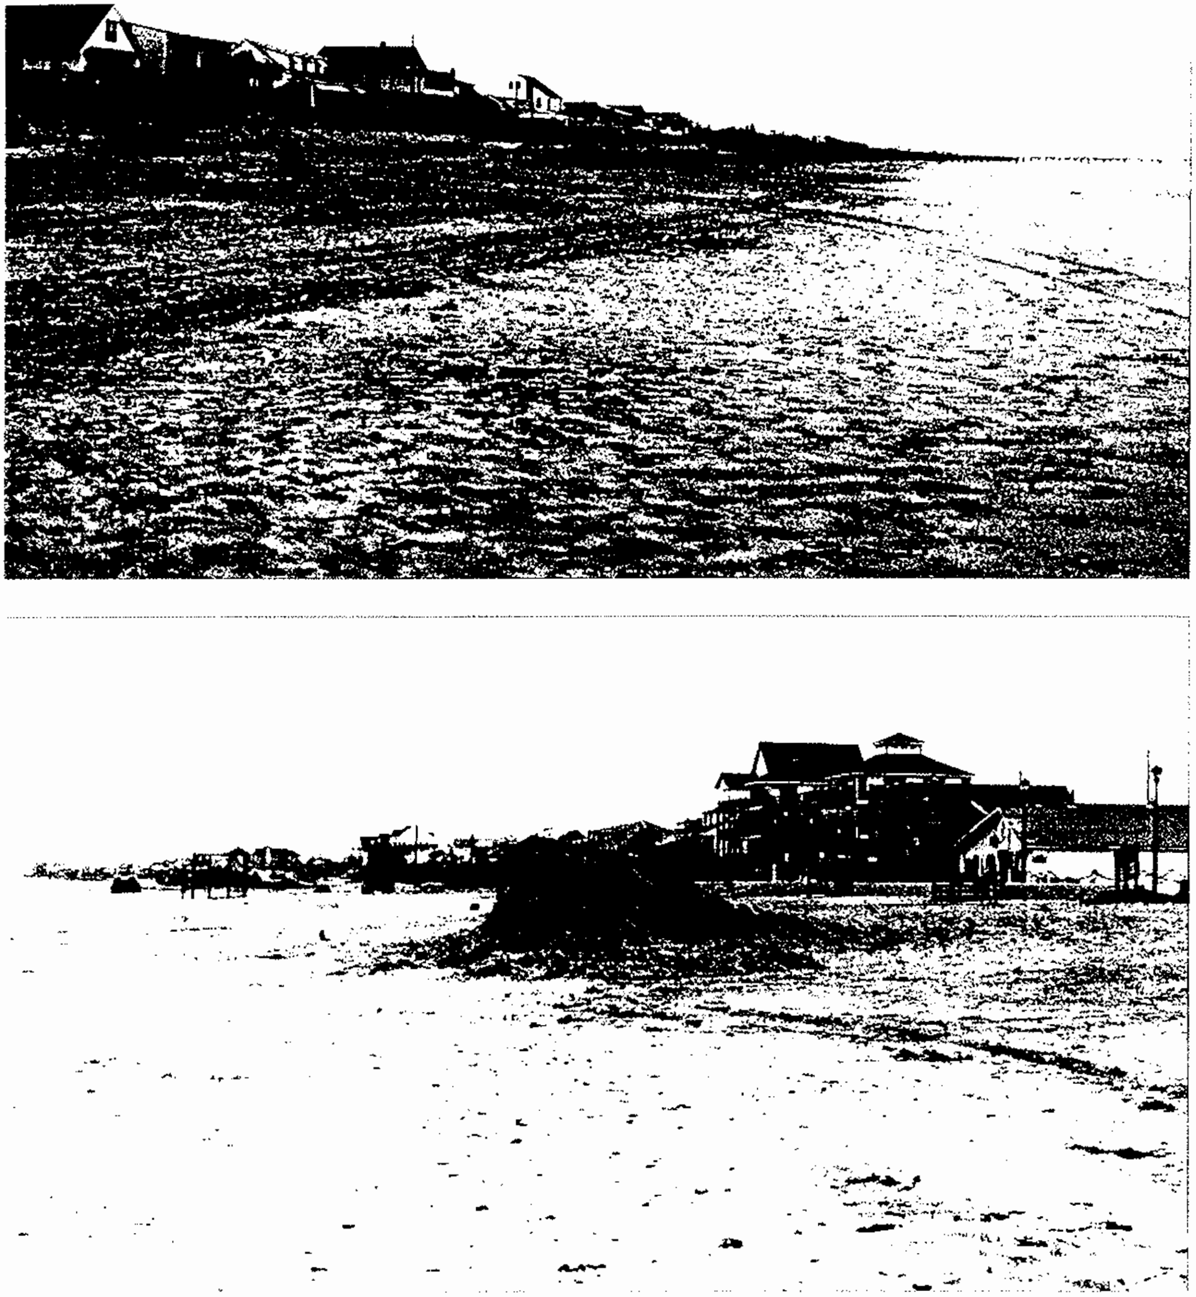

FIGURE 3.14. Atlantic Beach, one week after Hurricane *Floyd* at low tide. [UPPER] Minor escarpment in foredune around Raleigh Street beach access; houses are 75-125 ft landward of the escarpment. [LOWER] Amusement park area. Note remnant of incipient dune. Dry beach in this area is backed by a 25+ year-old seawall (low wall at right middle of photo) which was exposed >8 ft prior to the 1986 and 1994 nourishment projects. Atlantic Beach sustained little damage during *Floyd* compared to Pine Knoll Shores, Indian Beach, and Emerald Isle.

3.4.11 Present Shoreline Conditions (May 2001) Related to Development and Impacts On Threatened and Endangered Species

Based on a visual survey of the project area by CSE in November 2000 and again in May 2001, it is estimated that in excess of 85 percent of the shoreline has been bulldozed for the purpose of rebuilding dunes lost in Hurricane *Floyd* and due to continuing chronic erosion. The Town of Emerald Isle issued 139 CAMA permits for bulldozing from 1996 to present. The Town of Pine Knoll Shores issued 78 CAMA permits for bulldozing during the same period. In contrast, for the portions of Bogue Banks that have been nourished, the Town of Atlantic Beach issued only two CAMA permits for bulldozing from 1996 to present (Kelly Sheppard, Town of Atlantic Beach, pers comm, June 2001).

Recent surveys show bulldozing continuing in Emerald Isle, Indian Beach and Pine Knoll Shores on a massive scale even though there have been no serious storm events since Hurricane *Floyd*. Figure 3.15 shows the typical bulldozed beach and dune that exist along most of the project area. The beaches of Pine Knoll Shores are, for the most part, characterized by high, natural, heavily vegetated frontal dunes and absence of a dry beach berm with an escarpment at the toe of the dunes. The dunes consist of unnaturally coarse sand. There is no dry beach. These beaches are what are commonly called low-tide beaches. The summer wave climate will reshape the beaches creating a berm, but it will be limited in width, frequently overtopped, and will provide limited protection for plants to thrive near the toe of the dunes where wave swash will reach.

Division of Coastal Management rules for beach bulldozing allow removal of a maximum of one vertical foot of sand from the berm for dune building. Observations of the magnitude of sand quantities scraped and impacts on mean waterline position (as detailed in Section 2) would indicate that this rule is rarely adhered to by the property owners and scraping contractors. Figure 3.16 shows a recently bulldozed section of beach in Pine Knoll Shores where bulldozing and removal of beach sand has permitted the surf zone to move landward to less than 50 ft from the toe of the dune at low tide. Figures 3.17 and 3.18 show other representative portions of the project area where bulldozing has severely altered the natural beach and dune system.

Areas where property owners have chosen not to bulldoze the beach are characterized by steep frontal dune faces, no berm, and no high-tide beach (Fig 3.19). Further, the high elevations that characterize nearly all of Bogue Banks mean that chronic erosion leaves escarpments in the foredune, not washovers or deposits of sand landward of the shore.

In contrast to beach conditions in the project area, nourished portions of the western end of Bogue Banks (eg, Atlantic Beach near the Ocean Ridge area) are characterized by a wide dry berm and a natural frontal dune system that has required no scraping (Fig 3.20). The proposed project seeks to duplicate the favorable conditions of Atlantic Beach in the 16.8-mile reach encompassing Pine Knoll Shores, Indian Beach, and most of Emerald Isle. Without the project, scraped dunes will quickly erode again and have to be rescraped. If another hurricane impacts the area before the proposed project, many structures will be severely damaged. None of the existing conditions in the project area are favorable for beach-dune habitat preservation.

3.5 PUBLIC LANDS

The "Public Trust Doctrine" and the State Property Sovereignty Rules preserve the rights of all citizens of North Carolina for use of resources located below the mean high water line. Submerged lands, or waters of the state, commence waterward of the mean high waterline.

3.6 RECREATIONAL AND SCENIC AREAS

The beaches of Atlantic Beach, Emerald Isle, Indian Beach, Salter Path and Pine Knoll Shores are known as the Crystal Coast. This designation probably refers to the color of the ocean waters on clear calm days at the beach. The beaches of Bogue Banks provide a variety of excellent scenic and recreational opportunities for the public. Popular activities include, but are not limited to, surf fishing, swimming, surfing, walking, shell hunting, sunbathing, bird watching, and boating. Scenic vistas of the ocean are many. With erosion of the beach there has been significant losses of dry beach areas limiting many beach activities to low tide periods.

3.7 AREAS OF ARCHAEOLOGICAL OR HISTORIC SIGNIFICANCE

The maritime history of Beaufort, Morehead City and the Cape Lookout area goes back to the late 1600s and early 1700s when whalers established bases of operations on Shackleford Banks and Cape Lookout. The stability and depth of Beaufort Inlet offered a safe, deep channel for ship traffic. Not all vessels were successful navigating the inlet. In November 1718, the pirate Blackbeard lost two vessels on or near the sand bar at Beaufort Inlet.

Around 1841, John Motley Morehead, governor of North Carolina, envisioned establishing a port facility at the eastern terminus of the Atlantic and North Carolina Railroad. In 1855, the decision was made to locate the port at Sheppard's Point. By 1858, and much to the chagrin of the people of Beaufort, the Morehead City port was prospering. Ships called continually, loading cargo directly to and from rail cars.

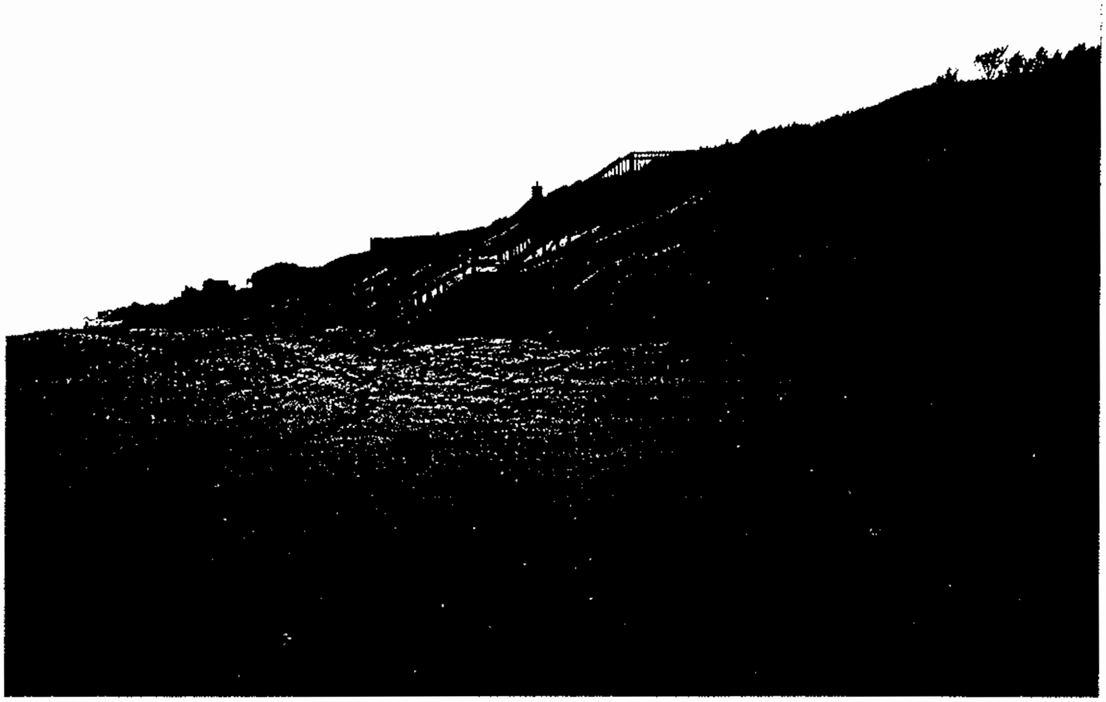

FIGURE 3.15. Typical bulldozed beach and dune conditions, Pine Knoll Shores and Indian Beach, Photo taken May 11, 2001, 5:30 p.m., near low tide. The high-tide swash line typically reaches the toe of the dune in these localities.

FIGURE 3.16. Condition of low tide beach in area of Pine Knoll Shores, recently bulldozed. Note location of swash zone relative to toe of dune. Photo taken May 15, 2001, 8:00 a.m.

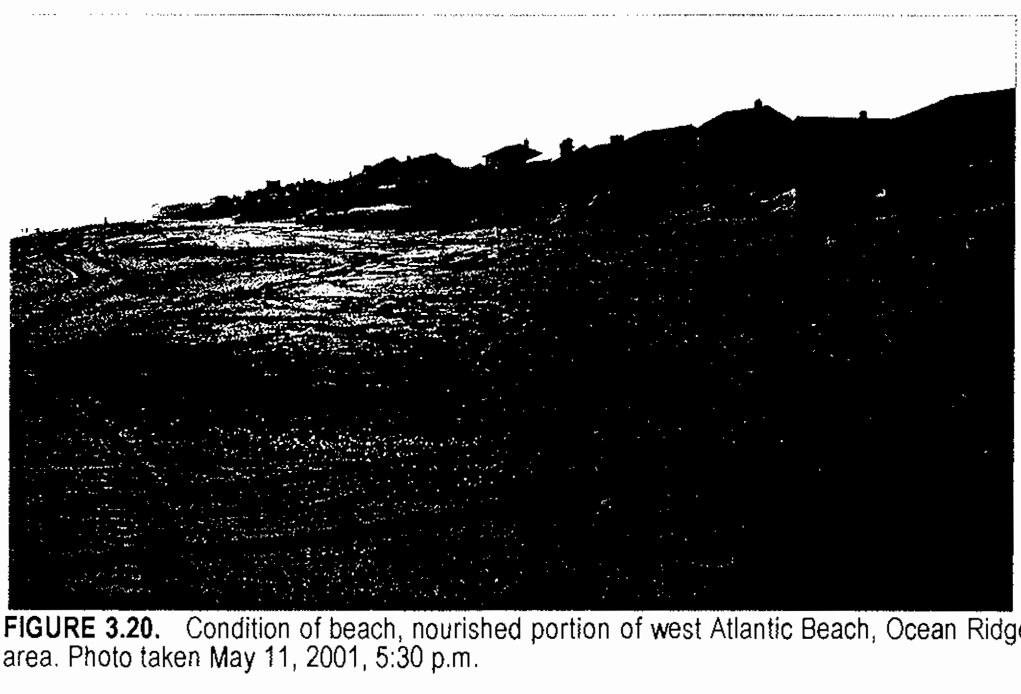

FIGURE 3.20. Condition of beach, nourished portion of west Atlantic Beach, Ocean Ridge area. Photo taken May 11, 2001, 5:30 p.m.

Development of the Morehead City port was disrupted by the Civil War. In March 1862, Union forces occupied Morehead City, the Newport River and Beaufort. Soon afterwards, Fort Macon fell under Union control. The occupation of Fort Macon provided Union forces with access to a deep-water port and a place of rendezvous to support the blockading squadron during the remainder of the war. Beaufort harbor served as a staging area for the fleets under the command of Admiral David Porter for his assault on Fort Fisher in Wilmington, the last major confederate stronghold in North Carolina. During the war, there were a number of vessel losses near Cape Lookout. Not all vessel losses were attributable to military actions. Several vessels ran aground in rough weather near Beaufort Inlet or were lost due to machinery failures.

Six years after the Civil War, the federal government instituted measures to reduce the severity of maritime losses along the coast. In 1874, seven stations were established along the North Carolina coast by the US Lifesaving Service. Stations were established along Core Banks, at Fort Macon and at Cape Lookout.

Growth of the Morehead City port was slow during the late nineteenth and early twentieth century. In the 1880s, the federal government began work to improve Beaufort Inlet in hopes of increasing maritime trade to the port communities. By 1889, jetties were constructed on Shackleford Banks and on Fort Macon to stabilize the Beaufort Inlet. Between 1905 and 1907, the channel across Beaufort Inlet was deepened to 20 ft at mean low water. Several Corps of Engineers reports between 1907 and 1914 indicated that both Morehead City and Beaufort were growing centers of maritime trade.

Many vessels transiting the North Carolina coast became victims of maritime hazards. Between July 1889 and June 1908, 82 vessels were reported lost off the North Carolina coast. To prevent vessels from wrecking off of Cape Lookout, a lightship was placed at Lookout Shoals. Mariners had complained that the lighthouse at Cape Lookout was difficult to see.

During World War I, Cape Lookout Bay served as a rendezvous area for convoys headed to Europe. Morehead City was occasionally used as a distribution point for war supplies. From 1926 to 1938, the federal government made considerable improvements to the port of Morehead City including increasing the Beaufort Inlet channel depth to 30 feet. Hostilities were evident in the Cape Lookout vicinity during World War II. German submarines sank four tankers in the Cape Lookout Area during March 1942. Since the war, Morehead City Harbor has undergone continuous improvement to its present-day condition as a deep-water port with several large vessels calling at the port each month.

The long maritime history of Beaufort Inlet and the areas near Cape Lookout indicate the possibility that shipwrecks or other valuable submerged historic resources could exist on the offshore borrow areas proposed for this project. The National Historic Preservation Act of 1966 and the Archeological and Historic Act of 1979 establish criteria for identification, documentation and assessment of submerged cultural resources. Compliance with submerged cultural resource legislation is administered by the North Carolina Division of Archives and History and the US Department of the Interior.

Tidewater-Atlantic Research, Inc (Washington NC) was contracted to conduct a remote sensing survey of the offshore borrow areas. The scope of the survey was to locate, identify and assess the significance of any underwater cultural material in the project areas. The details of the survey and report of findings are included as part of this document in Appendix B.

The North Carolina Department of Cultural Resources' State Historic Preservation Office has reviewed the proposed project and has identified six historic wreck/debris sites along the project shoreline (letter dated 29 June 2001 in the attached correspondence file). The state office has provided coordinates for the objects and instructions for notifying them in the event that debris is observed. The state noted that they have ". . . no objection to deposition of additional sand on the archaeological sites as it will serve to better protect them." The contractor for the project will be instructed to keep heavy equipment away from the designated areas.

3.8 AIR QUALITY

The air quality section of North Carolina Department of Environment and Natural Resources has jurisdiction over air quality in Carteret County. According to the Wilmington District Office, ambient air quality in Carteret County is in compliance with the National Ambient Air Quality Standards.

3.9 WATER RESOURCES

Water quality around Bogue Banks is generally high due to large tidal flows and resultant flushing associated with Bogue Inlet and Beaufort Inlet. Waters of Bogue Sound west of a line from the mouth of Gales Creek to Rock Point in Indian Beach are classified as outstanding resource waters (ORW), which are waters of the state that are unique and of a special state or national recreational or ecological importance that require special protection to maintain existing uses. Waters east of Rock point in Bogue Sound are classified SA. SA waters are suitable for shellfishing for human consumption. Ocean waters of Onslow Bay off of Bogue Banks are of high quality. This quality is due to the fact that no rivers draining large urbanized watersheds discharge directly into Onslow Bay. The White

Oak River in the western end of the county and the Newport River in the east have relatively small agricultural, forested, and lightly developed watersheds.

3.10 GROUNDWATER RESOURCES

Groundwater is plentiful throughout Bogue Banks. It is near the surface in many places, especially in the early spring and winter. The underlying limestone deposits of the Castle Hayne formation are the source for water supplies on Bogue Banks. These formations are below the surficial aquifers in the island consisting of a freshwater lens which varies in depth depending on rainfall amounts and has water that is often salty or has high concentrations of dissolved iron and hydrogen sulfide.

3.11 INTRODUCTION OF TOXIC SUBSTANCES

No chemical analysis of the borrow area materials has been done to date. It is unlikely that the borrow area sediments have accumulated any toxic or hazardous substances regulated by CERCLA or RCRA. There have been no known spillage, storage, treatment or disposal of regulated toxic materials within the borrow areas. There are no known discharges to Onslow Bay that could be a source of contaminants. For this reason, it is doubtful that chemical analysis of the borrow area material would contain heavy metals exceeding the EPA standards. The borrow area sediments consist of medium sands with shell fragments and low mud percentage (detailed in Section 3.16). These types of inert mineral materials do not typically trap contaminants.

3.12 NOISE LEVELS

Noise levels in the project areas are relatively low. No commercial or industrial activities exist in the project areas that create increased ambient noise levels. However, Bogue Air Base (USMC Cherry Point) is located on the mainland in Bogue Community. This base is utilized by Harrier jets that periodically conduct military training exercises. Generally, noise levels in the project areas are those associated with public use. The residential nature of the ocean shoreline areas generally equates to low ambient noise levels.

3.13 WATER SUPPLY AND WASTEWATER SYSTEMS

3.13.1 Water Supply

Potable water supply on Bogue Banks is provided by municipal water systems and by privately owned public utility companies. Bogue Banks Water Corporation supplies water to the Town of Emerald Isle. Carolina Water Service provides water to Indian Beach and Pine Knoll Shores. The Town of Atlantic Beach operates and maintains the water supply and distribution system for the town. The water source for all systems is deep wells to aquifers of the Castle Hayne limestone formations which run beneath Bogue Banks. The water is hard but is otherwise of excellent quality.

3.13.2 Wastewater Systems

Wastewater treatment and disposal on Bogue Banks is regulated by the Carteret County Environmental Health Department for systems less than 2,000 gallons per day, and by the NC Department of Environment and Natural Resources, Division of Water Quality for systems larger than 2000 gallons per day. Treatment and disposal of wastewater on Bogue Banks is accomplished in many conventional and innovative ways. Single family residential systems are nearly all conventional septic tanks with subsurface nitrification fields. In some areas, where soils are not suitable for conventional septic systems, septic tanks with on-site low pressure pumped (LPP) subsurface disposal is employed. Multi-family residential developments and hotels utilize collection systems with centralized treatment and disposal facilities. Treatment is generally by package plants employing extended aeration and on-site subsurface LPP disposal. There are no known direct effluent discharges to Bogue Sound or Onslow Bay from wastewater treatment facilities on Bogue Banks.

3.14 MARINE RESOURCES

The first two regions below are commonly divided by the breaker zone. That is, offshore refers to the area between the breakers and the edge of the continental shelf, and nearshore is the region between breakers and the mean low water line that is the lower boundary of the intertidal zone (CERC 1984). For purposes of examining environmental impacts, it is more sensible and more common to examine "nearshore" resources out to the depth of closure, rather than the moving boundary of a breakpoint. That is, the boundary between nearshore and offshore will be (for the purposes of this EA) the seaward limit of sediment motion (by waves), termed the "depth of closure" for beach surveys. Exactly what that depth is for this site is examined in detail in Appendix G2 and is summarized in the "Depth of Closure" part of Section 3.4. Borrow Areas A, B1, and B2 are outside closure depth.

3.14.1 Offshore Resources

3.14.1.1 ***Sediment*** — Offshore areas in North Carolina have been described as more stable than the nearshore zone, because of the lack of sediment motion by waves. USEPA (1983) describes the offshore region as fine sand with low-to-moderate relief, scattered among hard bottom. Studies for the present project characterize the offshore sediments by means of grab samples, cores, long vibracores, sidescan sonar survey, and a magnetometer survey. In addition to identification of potential cultural resources in the borrow areas, the sidescan sonar survey was used to identify any large natural features (rocks). None were found in the borrow areas. The offshore sediment conditions are described in Section 3.16 below and in Appendix E.

3.14.1.2 ***Biology*** — Biological resources in the offshore region of the Carolinas have been categorized as having low biomass, high diversity, and large seasonal variability (USEPA 1983). The latter characteristic of seasonal variability has a significant impact on monitoring plans and is the reason for our plan of sampling on several dates, detailed below.

3.14.1.3 ***Vertebrates*** — Assessment of the significance of the offshore mining of sands for the renourishment involves evaluation of potential impacts on demersal fishes and crustaceans at the borrow site. The fish and crustacean community changes seasonally, so sampling is needed to document presence and relative abundance of demersal fish and crustaceans and to describe their utilization of benthic invertebrate prey. Trawl sampling was conducted in late fall 1999, coincident with the sampling of the benthos. The results of sampling the fish and mobile crustacean community at and around the proposed offshore borrow sites are included here in a report as Appendix C (revised report by UNC Institute of Marine Science). Two additional trawl samplings were completed later in winter 2000 to document over-winter use of the borrow sites by fishes. [Trawl results are included in Appendix C.] Analysis includes not only the information on fish and crustacean abundances, but also a description of their diet from gut contents in the late fall 1999 and winter 2000 collections.

Table 4 in Appendix C presents the results of trawling for fishes and crustaceans. The sampling detected relatively large numbers of demersal fish occupying the sea-floor habitat during this period. Offshore areas were dominated by spot, which accounted for more than 50 percent of total catch and was sufficiently abundant there to create a pattern of slightly higher fish densities offshore than inshore. In addition to spot, pinfish, pigfish, and croaker were the most common species offshore. Inshore fishes were dominated by croaker, silver perch, silversides, and sea mullet.

3.14.1.4 ***Invertebrates*** — The benthic invertebrate community at the offshore borrow sites changes across the seasons. The applicants have initiated sampling in fall and spring to assess impacts and recovery. An initial set of samples was collected in the fall of 1999 to provide fall baseline data to characterize the benthic invertebrate community at the prospective offshore borrow sites and at nearby control sites that will not be excavated prior to any disturbance from the renourishment project. Also included is an analysis of composition of surface sediment samples in each of the borrow sites and control sites, so as to characterize the sedimentary habitat in which the invertebrates live. The fall 1999 invertebrate data set and summary statistics are given in Appendix C.

The applicants retained the firm of Coastal Science Associates, Inc (CSA) (Dr. Bart J. Baca) to perform a pre-nourishment biological sampling following standard protocols for projects of this type. CSA conducted detailed samplings of the beach and offshore areas in June 2001 according to the scope of work given in Appendix A-4. Preliminary results include a power analysis to demonstrate the adequacy of the sampling scheme to detect changes. The applicants plan to conduct another prenourishment biological monitoring by CSA in early November 2001. Postnourishment sampling will then be performed in June and November for 2002, 2003, and 2004 (following each phase of the project). More details on the biological monitoring plan are given in Appendix A-4.

Results from the fall 1999 sampling are summarized in Table 2 of Appendix C. Results suggest slightly higher macrofaunal abundances in the borrow areas than in their respective control areas. The polychaetes accounted for more than 50 percent of the total macrofauna in these late-fall 1999 samples. Other common phyla in order of abundance were molluscs, nemerteans, crustaceans, and echinoderms. Table 3 of Appendix C shows the analysis of the 40 belt transects for larger benthic invertebrates. The inshore borrow areas revealed higher numbers of these larger invertebrates than the offshore sites. No consistent difference appeared between borrow and control areas in these data. Gastropods were the most common taxon represented in these samples.

3.14.2 Nearshore Resources

3.14.2.1 ***Sediment*** — Sediment sampling of the nearshore (inland of the borrow sites, but subtidal) occurred at several locations along the project area. The appropriate sample numbers to reference in Appendix E from west to east are C21a1, C20a1, C16a1, C12a1, C9a3, and C7a2. Sample C4a1 was taken in Atlantic Beach outside the project area. Sieve analyses, mud content, and carbonate content are detailed in Appendix E.

3.14.2.2 ***Biology*** — Alterations to seabed sediments in the surf zone will be essentially the same as on the dry beach, except that there will be sorting into a finer size. Quantification of submarine organisms inshore of the borrow areas will thus rely on the dry-beach and intertidal sampling program outlined below. A baseline study of benthos in nearshore waters of South Carolina by Van Dolah and Knot (1984) found that infaunal assemblages at nearshore subtidal areas were more complex than those at intertidal areas. These data are expected to be comparable to those of the Bogue Banks project area. Based on their sampling, 243 species representing 24 major taxa were found. Dominant species were polychaetes and amphipods with oligochaetes, pelecypods, and decapods highly represented. Benthos in the area were identified as those that serve as food for commercially important species and were essential in marine food chains. Commercially important species include adult spots which are benthic feeders, primarily eating polychaetes and benthic copepods, and Atlantic croaker that are also bottom feeders preying on polychaetes and bivalves. Pink and white penaeid shrimp also prefer benthos (USFWS 1992a). The nearshore benthic communities offshore of North Carolina have been characterized by benthic infaunal assemblages with low abundance and high diversity (USEPA 1983).

3.14.3 Intertidal Resources

3.14.3.1 ***Sediment*** — Six native-beach samples were taken on the low-tide terrace at six different transects along the island. Sieve analyses, mud content, and carbonate content are detailed in Appendix E. A total of 20 samples (2 on the dune, 6 on the berm, 6 on the beach face, and the 6 low-tide terrace) was used to determine a composite native-beach size distribution. These were later supplemented with an additional 64 samples (32 pairs) described in Section 3.16 and in Appendix E.

3.14.3.2 ***Vertebrates*** — Twice-yearly sampling by seine of fish in the surf zone will be conducted as part of the biological monitoring for the project (see Appendix A-4). Fish densities are intermittent and generally fluctuate greatly within the surf zone because of the tendency for shoaling by various species. Approximately

15 fish species have been observed in the surf zone in the project area (Peterson et al. 2000), with Florida pompano (*Trachinotus carolinus*), Gulf kingfish *(Menticirrhus littoralis*), and two species of silversides (*Menidia menidia* and *Membras martinica*) accounting for around 99% of the total fish population sampled in summer 1998. Other species observed include bay anchovy, pinfish, bluefish, mullet, flounder and filefish.

3.14.3.3 ***Invertebrates*** — Organisms in the high-energy sandy intertidal environment include mole crabs, coquina clams, amphipods, isopods, and polychaetes. Although none of these species are commercially important, they constitute considerable biomass and serve as important food source for surf-feeding fish and shore birds. A June 2001 sampling has been completed to serve as the first of two "before-renourishment" monitoring data for the intertidal invertebrates of Bogue Banks beaches. The invertebrate community of the intertidal beaches is strongly seasonal; therefore, two representative seasons have been selected to monitor impacts of the project. The applicants plan to perform sampling in June and November before and after each phase of construction. An initial preproject sampling was conducted in June 2001 (see Appendix A-4).

UNC Institute of Marine Science collected data on abundances of intertidal beach invertebrates from all along Bogue Banks from 1997-1999 from studies conducted by L. Manning and others (unpubl: see Table 9 of Appendix C for example). The applicants initiated prenourishment sampling in June 2001 and have scheduled a second prenourishment sampling in early November 2001. Postnourishment sampling will be performed twice per year after completion of each phase of the project (June and November) for comparative purposes according to the biological monitoring plan outlined in Appendix A-4.

3.14.4 Beach and Terrestrial Resources

3.14.4.1 ***Sediment*** — The width of the berm at the base of the dune system varies considerably with location along the island and with season. Along most of the project area, the winter berm is nonexistent, because of the continuing erosion. Dune habitat is now also decreasing due to the erosion of the base or toe of the dunes by waves that travel unimpeded over the eroded wet beach to directly attack the dunes. As a result of the nourishment project, the beach is the one resource area that is expected to have beneficial impacts on the species present, primarily due to increased habitat area. Native-beach samples were taken on the dune, berm, beach face, and low-tide terrace at 22 different transects along the island, along with two dune samples. Sieve analyses, mud content, and carbonate content are detailed in Appendix E. A total of 84 samples was used to determine a composite native-beach size distribution.

3.14.4.2 ***Biology*** — The dunes along the beach are covered with American beach grass and sea oats. The dominant vegetation along the ocean side of the dune system also includes grassed areas, shrubs, and ornamental trees. Wildlife found along the ocean side of the island is limited as a result of development. Animals present in the project area are primarily those that can customarily tolerate man's presence, such as sea gulls, pigeons, starlings, house sparrows, and small rodents. The beach and dune system serves as an important nesting and food-source area for certain shorebirds (USFWS 1992a). Baseline sampling of the nourishment sites and control sites was initiated by the applicants in June 2001.

3.15 THREATENED AND ENDANGERED SPECIES

Species to be considered in this environmental assessment were provided by USFWS and the NMFS and are listed in the following table, followed by a description of these species. (Section 4 contains a description of potential impacts to these species as a result of the proposed beach nourishment project.)

Common Name	Scientific Name	Status	Habitat present?	Known observation*
Mammals				
Eastern cougar	*Felis concolor couguar*	E	no	no
Finback whale	*Balaenoptera physalus*	E	no	no
Humpback whale	*Megaptera novaeangliae*	E	yes	yes**
Right whale	*Eubaleana glacialis*	E	yes	yes**
Sei whale	*Baleanoptera borealis*	E	no	no
Sperm whale	*Physeter catodon*	E	no	no
West Indian manatee	*Trichechus manatus*	E	yes	no
Birds				
Piping plover	*Charadrius melodus*	T	yes	no
Red-cockaded woodpecker	*Picoides borealis*	E	no	no
Roseate tern	*Sterna douglallii*	E	no	no
Wilson's plover	*Charadrius wilsonia*	SR	yes	no
Reptiles				
American alligator	*Alligator mississippiensis*	T(S/A)	no	no
Green sea turtle	*Chelonia mydas*	T	yes	yes**
Hawksbill sea turtle	*Eretmochelys imbricata*	E	yes	yes**
Kemp's ridley sea turtle	*Lepidochelys kempi*	E	yes	yes**
Leatherback sea turtle	*Dermochelys coriacea*	E	yes	yes**
Loggerhead sea turtle	*Caretta caretta*	T	yes	yes
Fish				
Shortnose sturgeon	*Acipenser brevirostrum*	E	no	no
Plants				
Rough-leaf loosestrife	*Lysimachia asperulaefolia*	E	no	no
Seabeach amaranth	*Amaranthus pumilus*	T	yes	yes
Moundlily yucca	*Yucca gloriosa*	SR	yes	yes

KEY

Status	Definition
E	A taxon "in danger of extinction throughout all or a significant portion of its range."
T	A taxon "likely to become endangered within the foreseeable future throughout all or a significant portion of its range."
T(S/A)	Threatened due to similarity of appearance - a species that is threatened due to similarity of appearance with other rare species and is listed for its protection. These species are not biologically endangered or threatened and are not subject to Section 7 consultation.
SR	State designation. Species designated as being very rare, generally with 1-20 populations in the state. These species are not subject to Section 7 consultation and are not considered in the biological assessment.

* Observation according to NC Natural Heritage Program data.

** Species is known to migrate along the coast of NC (Wynne 1999).

The presence of these species in the project area depends on the availability and abundance of appropriate habitat. Since the Bogue Banks project area does not contain any freshwater or forested areas, the eastern cougar, red-cockaded woodpecker, American alligator, shortnose sturgeon, and roughleaf loosestrife are not likely to be found at this site. Listed species that could potentially be located at Bogue Banks are the whale species, West Indian manatee, piping plover, sea turtle species, and seabeach amaranth.

On 5 July 20001, a final biological assessment was submitted to the USFWS and the NMFS, pursuant to Section 7 of the Endangered Species Act of 1973. This assessment determined that the proposed action may affect the hawksbill sea turtle, leatherback sea turtle, Kemp's ridley sea turtle, green sea turtle, loggerhead sea turtle, and the seabeach amaranth. Other federally listed endangered or threatened species would not be affected. Endangered species coordination with the Protected Resources Division was completed 26 July 2001 with a letter from JE Powers (NMFS, St Petersburg) to Col JW DeLoney (USACE, Wilmington) and by a letter from USFWS dated 20 September 2001.

3.15.1 Mammals

3.15.1.1 ***Right Whale, Finback Whale, Humpback Whale, Sei Whale, and Sperm Whale*** – Humpback whales are often found in protected waters over shallow banks and shelf waters for breeding and feeding. They migrate toward the poles in summer and toward the tropics in winter and visit the North Carolina coast during seasonal migrations, especially between December and April (Conant 1993). They eat schooling fish such as herring and can consume up to 1.5 tons per day of krill. Right whales swim very close to the shoreline and are often noted only a few hundred meters offshore (Schmidly 1981). They feed primarily on copepods and euphausids. While this whale usually winters in the waters between Georgia and Florida, it can on occasion be found in the waters off North Carolina. Sighting data provided by the Right Whale Program of the New England Aquarium indicates that 93 percent of all North Carolina sightings between 1976 and 1992 occurred between mid-October and mid-April (Chris Slay 1993). The number of right whales documented in the vicinity of Morehead City during a single season ranges from 2 to 25 (USACOE 1989).

3.15.1.2 ***West Indian Manatee*** – The manatee is an occasional summer resident of the North Carolina coast. The species can be found in shallow (5 feet to usually less than 20 feet), slow-moving rivers, estuaries, saltwater bays, canals, and coastal areas (USFWS 1991). The West Indian manatee is herbivorous and eats aquatic plants such as hydrilla, eelgrass, and water lettuce (USFWS 1999). During winter months, the United States' manatee population confines itself to the coastal waters of the southern half of peninsular Florida and to springs and warm water outfalls as far north as southeast Georgia. They are sighted frequently in southeastern North Carolina with most records occurring in July, August, and September, as they migrate up and down the coast (Clark 1993). However, scattered records of this species in the region span all seasons. Based on this data, the manatee is considered a year-round resident with a maximum population in the late summer months. Manatee population trends are poorly understood, but deaths have increased steadily. A large percent of mortality is due to collisions with water crafts, especially of calves. Another closely related factor in their decline has been the loss of suitable habitat through incompatible coastal development, particularly destruction of sea grass beds by boating facilities.

3.15.2 Birds

3.15.2.1 *Piping Plover* – The Atlantic Coast piping plover population breeds on coastal beaches from Newfoundland to North Carolina (and occasionally in South Carolina) and winters along the Atlantic Coast from North Carolina south, along the Gulf Coast, and in the Caribbean (USFWS 1996). Since being listed as threatened in 1986, the population has increased from approximately 800 pairs to almost 1350 pairs in 1995, although most of this increase may be attributable to an increase in surveying intensity. Piping plovers nest above the high tide line on coastal beaches, sand flats at the ends of sand spits and barrier islands, gently sloping foredunes, blowout areas behind primary dunes, sparsely vegetated dunes, and washover areas cut into or between dunes (USFWS 1996). Feeding areas include intertidal portions of ocean beaches, washover areas, mud flats, sand flats, wrack lines, and shorelines of coastal ponds, lagoons, or salt marshes. Loss and degradation of habitat due to development and shoreline stabilization have been major contributors to the species' decline.

Most piping plovers at Bogue Banks have been observed at the west end of Emerald Isle as predominantly a migratory and winter resident (David Allen, pers. comm.). During a 1991 USFWS International Piping Plover Census (winter), four piping plovers were observed and during a 1996 winter census, one individual was observed. In addition, both Bogue and Beaufort inlets contain intertidal flats exposed at low tide that are prime feeding and roosting habitats for a variety of shorebirds and colonial waterbirds including pelicans, cormorants, terns, and black skimmers. These areas may be used by piping plovers as well.

3.15.2.2 *Roseate Tern* – Roseate terns breed primarily on small offshore islands, rocks, cays, and islets. Rarely do they breed on large islands. They have been reported nesting near vegetation or jagged rock, on open sandy beaches, close to the waterline on narrow ledges of emerging rocks, or among coral rubble (USFWS 1999). This species is primarily observed south of Cape Hatteras, particularly at Cape Point within Cape Hatteras National Seashore, during the months of July and August.

3.15.3 Reptiles

3.15.3.1 *Hawksbill Sea Turtle* – Hawksbill sea turtles are found mainly in tropical waters of the Atlantic, Pacific and Indian Oceans. Nesting in the United States for this species occurs in spring and is generally restricted to Florida. Although it is not considered common along the North Carolina coast, the hawksbill may be found in North Carolina waters all year and can be present in inshore waters April through December (Epperly et al 1995). The hawksbill is found along submerged rocky areas, reefs, shallow coastal areas, lagoons of oceanic islands and narrow creeks (USFWS 1991). It is not often seen in water over 65 ft deep. Its diet includes algae, fish, mangrove, barnacles, clams, sponges, snails, and sea urchins.

3.15.3.2 ***Leatherback Sea Turtle*** – Leatherback sea turtles are found mainly in tropical waters of the Atlantic, Pacific and Indian Oceans. Nesting in the United States for this species occurs in spring and is generally restricted to Florida. Although it is not considered common along the North Carolina coast, the leatherback may be found in North Carolina waters all year and can be present in inshore waters April through December (Epperly et al 1995). The leatherback is an open-ocean species that sometimes moves into shallow bays, estuaries, and even river mouths. The preferred diet is jellyfish and may also include sea urchins, squid, shrimp, fish, blue-green algae, and floating seaweed. It is also found along the Atlantic coastline from Massachusetts southward to Brazil.

3.15.3.3 ***Kemp's Ridley Sea Turtle*** – Kemp's ridley sea turtles inhabit shallow coastal and estuarine waters, often in association with subtropical shorelines of red mangrove. The entire population nests on ~15 miles of beach in Mexico between the months of April and June (USFWS 1991). Outside of nesting, the major habitat for adult Kemp's ridleys is the near-shore and inshore waters of the northern Gulf of Mexico, especially Louisiana waters. However, immatures have been observed along the Atlantic coast as far north as Massachusetts. Although the Kemp's ridley has been documented to nest in North Carolina only once, juveniles of the species are known to migrate in estuarine and oceanic waters off of the North Carolina coast (Schwartz 1977; Epperly et al 1995). Overharvesting of both eggs and adults for food and the skin has been a major factor in their decline. Currently the major threat is drowning when inadvertently caught in shrimp nets. The total population is currently estimated to be 1500 to 3000 individuals.

3.15.3.4 ***Green Sea Turtle*** – With an estimated population of no more than 600,000 adults worldwide, the green turtle exists in both tropical and temperate seas and oceans (USFWS 1992). The North American distribution ranges from Massachusetts to Mexico, and from British Columbia to Baja California. Green sea turtles generally favor protected waters inside reefs, bays, estuaries, and inlets. Primary habitat appears to be lagoons and shoals supporting an abundance of marine grass and algae. These turtles are predominantly herbivorous, feeding upon marine algae and shallow beds of marine grasses. However, additional food sources may include mollusks, sponges, crustaceans, and jellyfish. The major reasons for the decline in green turtle numbers include over-exploitation of eggs and meat for food, commercial fishing and dredging operations, and nesting habitat destruction associated with outer beach development (USFWS 1992). Green sea turtle nesting habitat consists of open beaches with a sloping platform and minimal human disturbance. Eastern United States nesting is primarily limited to Florida's east coast (300 to 1000 nests reported annually). Although occasional nesting has been documented as far north as North Carolina and false crawls have been documented at Emerald Isle Beach, no nests have been observed within the project site. However, juvenile green sea turtles are known to migrate in estuarine and oceanic waters off of the North Carolina coast (Schwartz 1977; Epperly et al 1995).

3.15.3.5 ***Loggerhead Sea Turtle*** – The loggerhead turtle utilizes the Bogue Banks upper beach fronts for its seasonal (March-October) nesting events. Off the Carolina coast these turtles commonly occur at the edge of the continental shelf when they forage around coral reefs, artificial reefs, and boat wrecks. They feed on benthic invertebrates including mollusks, crustaceans, and sponges (Morrimen 1982). They have also been found to eat fish, clams, oysters, sponges, jellyfish, shrimp, and crabs when near shore. Research has shown that the turtle populations have greatly declined in the last 20 years due to loss of nesting habitat along the beachfront and by incidental drowning in shrimp trawl nets. Dredging activities in the warmer months of the year could impact the sub-adults but this has not been well documented. It appears that the combination of poorly placed nests coupled with unrestrained human use of the beach by auto and foot traffic has impacted this species greatly. Eroding steep beach escarpments, lights, sand fences, and other physical barriers (debris) often cause the mature females to select poor nesting sites at the dune toes which causes higher nestling mortality rates. Loggerhead turtles are known to regularly nest from Bogue Inlet to Beaufort Inlet, including the entire stretch of the project site. Between 1995 and 1999, an average of 28 nests per year were recorded within the project area (Ruth Boettcher, pers. comm.). In addition, juveniles are known to migrate in estuarine and oceanic waters off of the North Carolina coast (Schwartz 1977; Epperly et al 1995).

3.15.4 Fish – ***Shortnose Sturgeon*** – This species ranges along the Atlantic seaboard from southern Canada to northeastern Florida (USFWS 1999). The shortnose sturgeon feeds on invertebrates and stems and leaves of macrophytes. From historical accounts, it appears that this species was once fairly abundant throughout North Carolina waters, however, many of these early records are unreliable due to confusion between this species and the Atlantic sturgeon (*Acipenser oxyrhynchus*). Because of the lack of suitable freshwater spawning areas in the project area and the requirement of low salinity waters by juveniles, any shortnose sturgeons present would most likely be non-spawning adults.

3.15.5 Plants – ***Seabeach Amaranth*** – Seabeach amaranth is an annual herb that occurs on beaches, lower foredunes, and overwash flats (Fussell 1996). Weakley (1986) found that in North Carolina the plant is most common on overwash flats on accreting ends of barrier islands. This species occupies elevations ranging from 0.2 to 1.5 m above mean high tide (Weakley and Bucher 1992). Historically, seabeach amaranth was found from Massachusetts to South Carolina. But according to recent surveys (USACE 1992-1995), its distribution is now restricted to North and South Carolina with several populations on Long Island, New York. The decline of this species is caused mainly by development of its habitat, such as inlet areas and barrier islands, and increased ORV and human traffic which tramples individuals (Fussell 1996).

Between 1992 and 1995, annual surveys of amaranth were conducted all along the North Carolina coast including Bogue Banks (NCNHP 1995). The results are as follows:

	# Plants Observed at Bogue Banks	# Plants Observed within Project Area
1992	2,556	159
1993	3,762	232
1994	1,181	182
1995	14,776	391

No survey was conducted in 1996 because of early summer hurricanes that washed away or buried most of the plants. In 1997, certain sections of Bogue Banks were surveyed, but were found to support very low numbers of amaranth. In August of 2000, staff of Land Management Group, Inc., performed an amaranth survey along the beaches of Bogue Banks from Bogue Inlet to Beaufort Inlet. Approximately 40 individuals were found. Most plants were located along Atlantic Beach, in areas that have received nourishment in the last ten years. The individuals were located on the foredune at and above the dune toe. On the remaining beach, including Pine Knoll Shores, Salter Path, Indian Beach, and Emerald Isle, six plants were observed (Fig 3.21). These individuals were located several feet above the dune toe in an area were extensive beach scraping has occurred.

3.15.6 Other Species

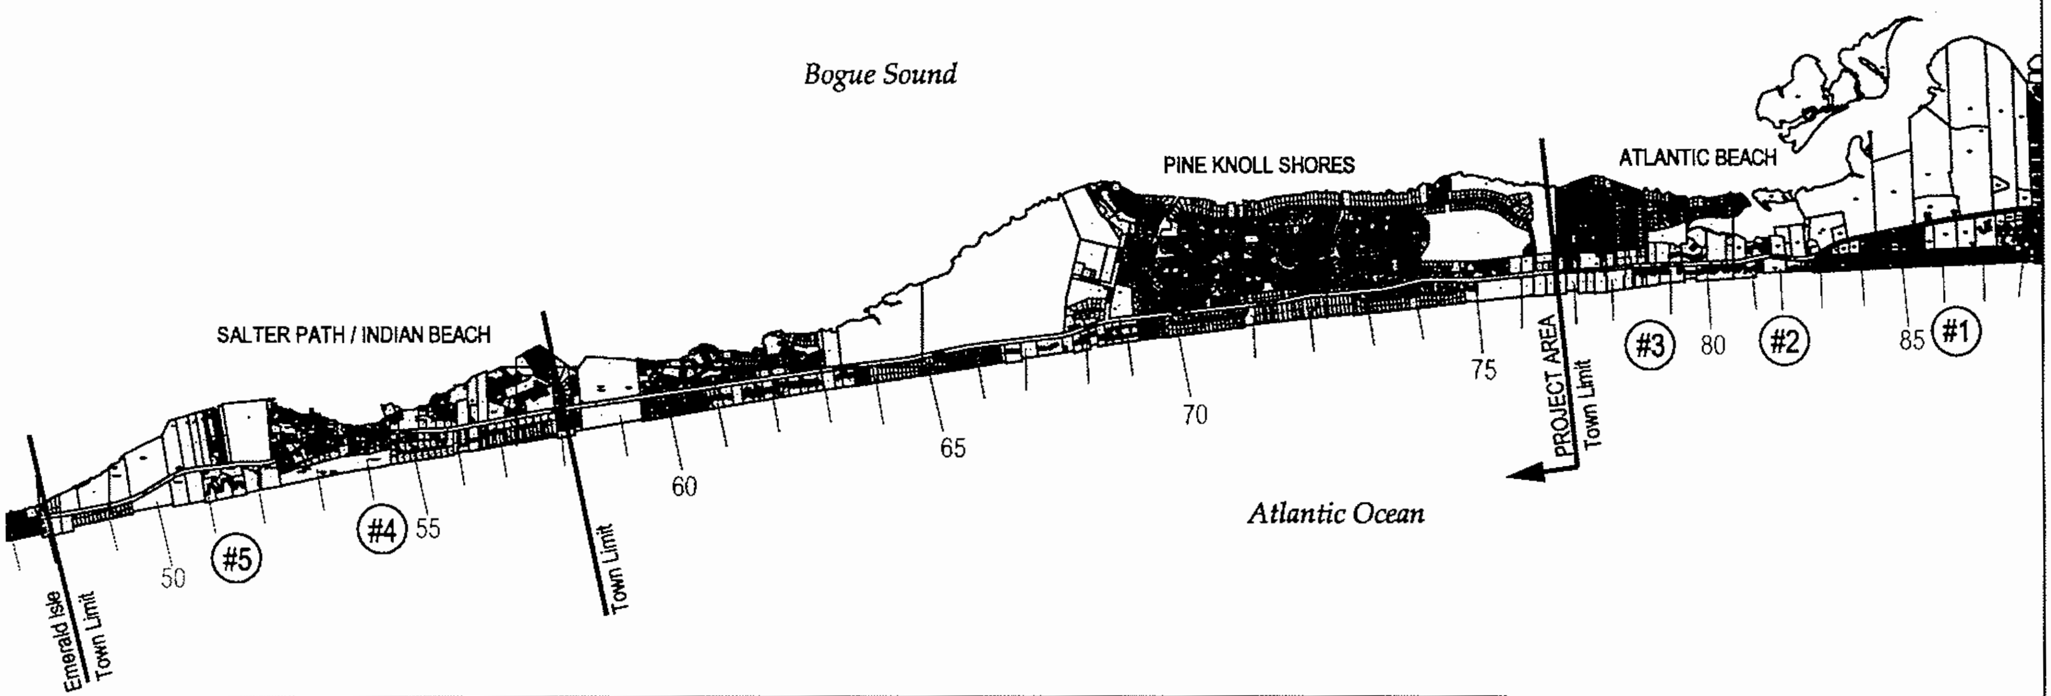
In addition to the federally listed species, two other species with a state status of significantly rare (SR) have been observed in the proposed project area and are discussed here. The Wilson's plover is a state "watch list" species (categories W1 and W5), indicating that it is known to be declining and that there are threats to its habitat. It has been observed on the eastern side of Bogue Inlet (NCNHP data). This coastal bird species breeds along the coast from Maryland southward and winters from the Gulf Coast and Florida southward (Fussell 1996). In North Carolina, this species breeds primarily from Portsmouth Island southward. Wilson's plovers breed mostly on barrier islands and on dredged material islands within estuaries. This species is often found breeding at sites having similar habitat to those preferred by piping plovers; however Wilson's plovers utilize a broader range of habitat, including habitat with greater vegetative cover. The moundlily yucca plant has also been observed within the proposed project site. It was observed at Indian Beach in 1992 by NC Natural Heritage personnel and is generally found in moist depressions in sand dunes (Radford et al 1964).

3.16 GEOLOGICAL SETTING AND PROPOSED BORROW AREAS

As part of the planning for the proposed project, CSE-Stroud (2001) completed a detailed investigation of potential borrow areas. Via a combination of literature review and over 200 borings, three offshore borrow areas were identified for use in the proposed project. This section summarizes results of the literature review and field sampling of offshore sediments.

3.16.1 Geologic Setting

Numerous scientific studies address the geology, geomorphic history, and sediments of the North Carolina coast (Table 3.1). In contrast, relatively few reports present field data on these topics for the area of Bogue Banks and immediate offshore zone (Table 3.2). The salient points of these studies with respect to nourishment planning and identification of viable borrow areas include:



SEABEACH AMARANTH LOCATIONS

TABLE 3.1. Selected references providing background information on the geology, geomorphic history, and sediments of the North Carolina coast (not specific to Bogue Banks).

NOTE: While by no means a complete list, these references provide an excellent overview of geologic processes, landforms, and sediments along the North Carolina coast. Their authors tend to be the researchers who frequently appear in the literature. Many remain active in the profession and continue to offer new insights regarding shoreline evolution. The list focuses on publications having relatively wide distribution. We particularly recommend *Geology of Holocene Barrier Island Systems* (R.A. Davis, editor, Springer-Verlag 1994) for its collection of synthesis papers under one cover.

- Bogue Banks is a Holocene barrier island within the less exposed western "limits" of the Cape Lookout cuspate foreland with strikingly different topography and profile compared to the northeastern-limit barriers, Core Banks and Portsmouth Island (Heron et al 1984).

- During Quaternary times, the shoreline off Bogue Banks was transgressive under the influence of deglaciation and rapid sea-level rise across the gently sloping continental shelf of the Carolinas.

- Whether or not Bogue Banks existed as a single or series of subaerial barriers prior to 4000 years ago, only a thin sediment cover remains offshore--most of the inner continental shelf consists of outcropping Tertiary hard bottom (Fig 3.22) (Hine and Snyder 1985).

- As sea-level rise slowed and approached its present elevation about 4000 ago, Bogue Banks began to accumulate sediment from reworked paleo-inlet deltas and littoral sources (Hine and Snyder 1985).

- Bogue Banks became a "regressive barrier" accreting seaward and vertically via build-up of the shoreface for several thousand years up to this century.

- Accumulation of littoral sediments in the area of present-day Bogue Banks, infilled paleochannels (inlets), the most recent of which were (Fisher 1967):
  - Prehistoric relict inlet near the causeway to Atlantic Beach.
  - Two relict inlets (noted on Fig 3.22 as #1 and #2) in eastern Emerald Isle, approximately 0.1 and 2.0 miles west of Indian Beach, respectively.
  - Relict Cheeseman Inlet (closed sometime between 1860 and 1886) along west Atlantic Beach about one mile east of Pine Knoll Shores.

- With the exception of a short-term breach in the low area of eastern Emerald Isle during Hurricane *Donna* (1960), Bogue Banks has existed as a contiguous ~25-mile-long barrier island for almost 150 years.

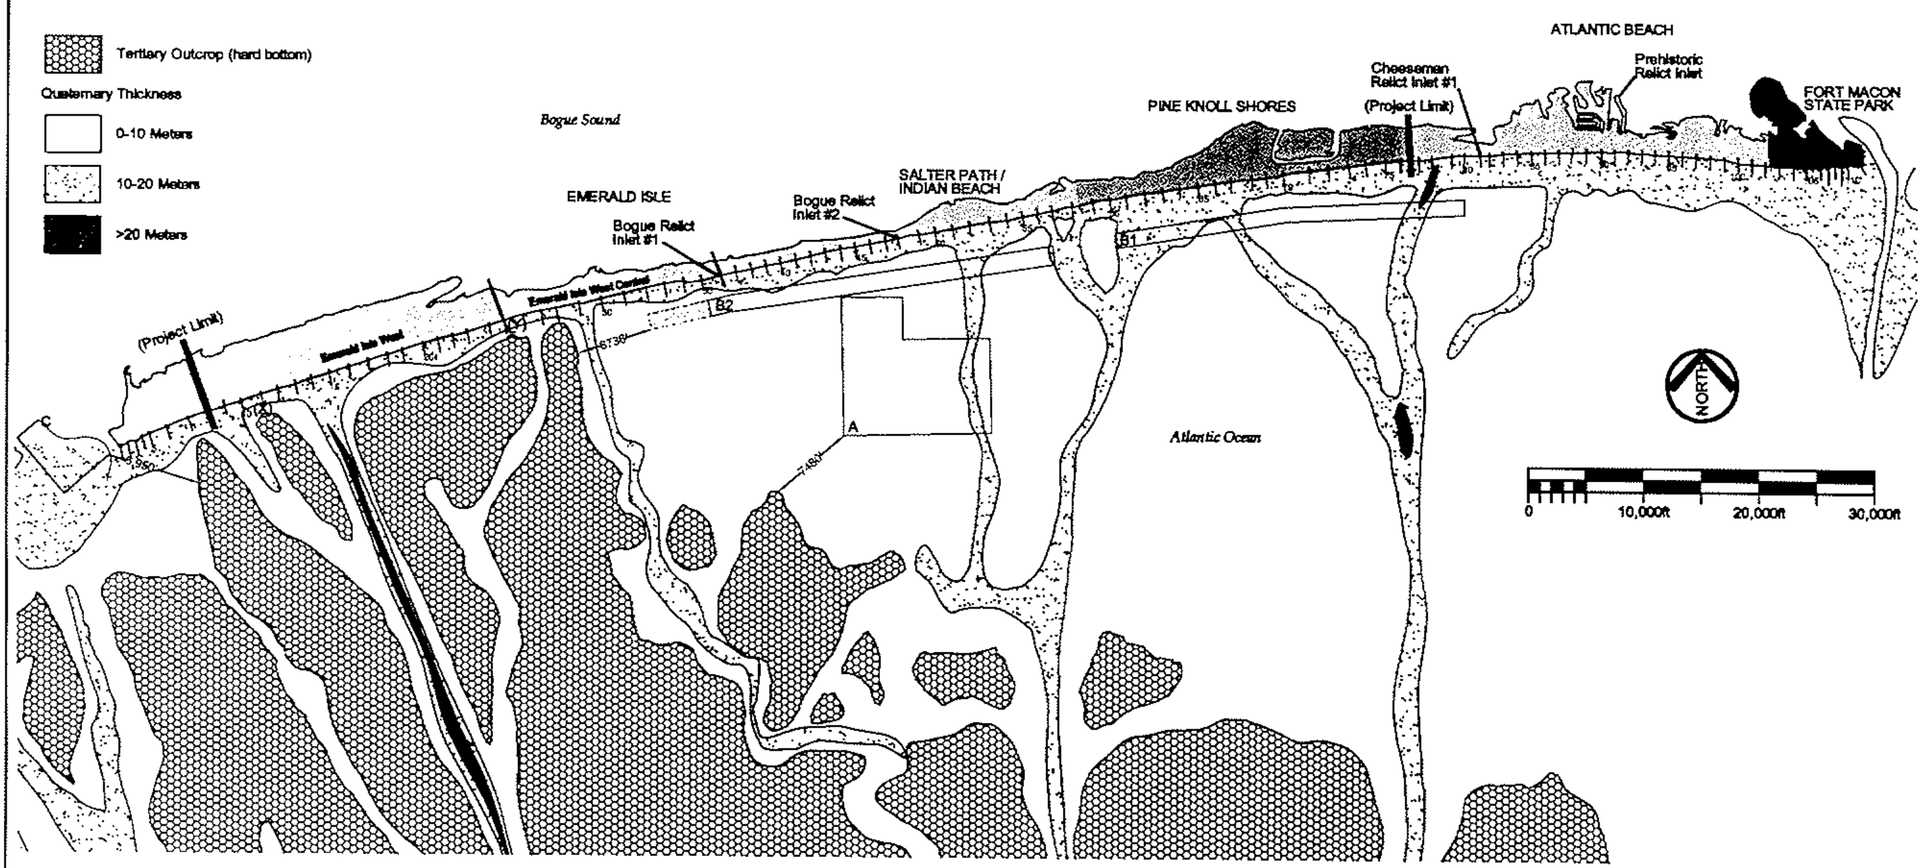
- Bogue Inlet to the west and Beaufort Inlet to the east constitute the primary boundaries of the Bogue Banks littoral cell.

- Bogue Banks's bounding inlets contain huge reservoirs of littoral sand in the form of ebb- and flood-tidal deltas.

- Bogue Banks' positional stability allowed accretion of high dune ridges--in some areas, exceeding 40 feet (ft) above sea level and along most of the shoreline reaching 20 ft. Relief and absolute elevations across Bogue Banks are much greater than Core Banks and Portsmouth Island.

- High relief along Bogue Banks inhibits formation of washovers. Low longshore transport rates lessen the rate of sand loss to the inlets compared to east-facing barrier islands in other parts of Carteret County. Average erosion rates have been low (0-5 ft/yr) since 1939 according to all available published reports.

- Subaerial sediments range from medium to coarse sand and crushed shells along the upper beach to fine sand in the dunes to mixtures of sand, coarse shells, and mud in back-barrier areas. The foreshore sediments coarsen toward the step (inshore breakpoint), then fine to the inner trough and bar. Seaward of a shore-parallel bar situated about 400 ft offshore, sediments fine along the lower shoreface (USACE 1992).



Interpretation of Tertiary (hard bottom) outcrops and estimated Quaternary layer thickness (of unconsolidated sediments) based on Hine and Snyder (1985, Figure 6). Infilled paleochannels comprise the thickest deposits but have limited areal extent and highly variable sediment texture including high percentages of fines. Potential borrow areas A, B1, B2, & C identified in the present study are superimposed. Ground truth surveys conducted by CSE (2000) indicate there is no exposed hard bottom inside the -35 ft contour along western Emerald Isle. The closest hard bottom to the project area is estimated to be at least 3000 ft offshore in the vicinity of transect 20-28.

Closest distance to Tertiary outcrop

Borrow area A..................7500ft
Borrow area B2................6700ft
Borrow area C..................6,950ft

Project Reach

Emerald Isle West (Y)........1600ft (from outer bar)
Emerald Isle Central (X).....1600ft (from outer bar)

3.16.2 Survey Design

Despite a limited supply of beach-quality sand offshore of Bogue Banks as inferred from the literature (see Table 3.2), more detailed confirmation was required before ruling out alternative borrow areas. The applicants initiated a reconnaissance-level survey during initial planning of the Bogue Banks restoration project based on the following desirable criteria:

- Viable sand deposits closer to the project areas than Beaufort or Bogue Inlets could potentially yield very large cost savings for the project.
- Sediments that are somewhat coarser (on average) than the native beach and coarser than the material typically available from channel maintenance would improve the durability of the nourishment projects.
- Deposits with lower mud/fine-sand content than previously used in Corps disposal projects would reduce the rate of fill losses and minimize turbidity in nearshore waters.
- If broad, shallow areas (at least 1-2 ft thick) could be confirmed, hopper dredges or alternate equipment could be used for excavations, and the rate of environmental recovery might be more rapid based on experience elsewhere (Jutte et al 1999a,b).

The sediment survey encompassed the following field sampling over three phases between June 1999 and November 2001:

- *Beach sampling and textural analysis* (June 1999) to quantify native material — 20 samples divided among dune (2), berm (6), beach face (6), and low-tide terrace (6) at CSE-Stroud transect 10 (west Emerald Isle), transect 30 (central Emerald Isle), transect 50 (Indian Beach), transect 70 (Pine Knoll Shores east), transect 90 (Atlantic Beach), transect 110 (Coast Guard Station); spacing of transects was approximately 20,000 ft. These were supplemented by 64 additional beach samples (32 analyzed pairs) between transects 48 and 78 in May 2001 following a request for more data from the USFWS (interagency meeting of 11 May 2001–detailed results submitted 24 May 2001 with letter to Garland Pardue, USFWS, Raleigh, NC).
- *Phase I borrow source sampling* (June 1999) — *offshore reconnaissance* — 53 short cores by divers in a regional grid pattern encompassing a 16-mile length of coast from central Atlantic Beach to central Emerald Isle and extending between ~0.25 and 3 miles offshore. Generally consisted of shore-perpendicular transects of 3-5 boring locations at approximate two-mile intervals in the longshore direction. Additional, more closely spaced cores were collected 0.5-1 mile from the most promising sites. Cores average about 2 ft long. Other potential sources were sampled but rejected for various reasons as detailed in the EIS for the project. Three offshore borrow areas (A, B1, and B2) were tentatively identified for further sampling (CSE Baird-Stroud 1999).

- *Phase II confirmation sampling* (November 1999)
  - *Borrow area A (western half)* — 46 borings (averaging ~2.3 ft) at ~1200-1500 ft spacing; eight vibracores (3-9 ft) at ~3000 ft spacing.
  - *Borrow area B1* — four diver borings (~2.8 ft); three vibracores (7.5-11 ft).
  - *Borrow area B2* — seven diver borings (~2.9 ft); three vibracores (~9-10 ft).
  - Phase II sampling formed the basis of proposed borrow areas A, B1, and B2 as shown on the permit application for the project (P/N ID #200000362).

- *Phase III borrow area refinement sampling* (November 2000-March 2001)
  - *Borrow area A)* — 13 additional borings (averaging ~2 ft)
  - *Borrow area B1* — 32 additional borings (averaging ~3.4 ft)
  - *Borrow area B2* — 25 additional borings (averaging ~3.0 ft)

  Phase III sampling serves as the basis for further refining the borrow areas proposed for the project as detailed herein. (Note: The refined areas are fully within the boundaries specified in the permit application for the project.)

CSE Baird performed all Phase I sampling and the diver sampling for Phase II. Athena Technologies, Inc. (Columbia, SC) performed the vibracore sampling under subcontract to CSE Baird.

The only known borings prior to the 1999 survey in the primary offshore region (central Bogue Banks) were those collected in the early 1980s by university researchers (Dr. SR Riggs and Dr. AC Hine, principal investigators, as reported in Hine and Snyder 1985) (Fig 3.23). That regional survey of Onslow Bay included approximately 20 vibracores on the inner shelf inside the 20-meter depth contour off Bogue Banks. The Hine and Snyder (1985) borings generally describe a shore-parallel line about 3-3.5 miles offshore. Several borings were made closer to shore in presumed paleochannels off the western end of Atlantic Beach and western Emerald Isle (Fig 3.23). Hine and Snyder noted for the area thin layers of Holocene sands and crushed shell overlying more heterogeneous Pleistocene sediments. Paleochannels (Fig 3.23) reportedly contained admixtures of mud, sand, shells, and phosphatic material.

The applicants' studies focused on the uppermost ~2-3 ft layer for three reasons:

1) Preliminary evidence suggested that the "Holocene" section was more likely to contain beach-quality sediments.

2) Hopper dredges reportedly work most efficiently in borrow areas where the depth of cut is of the order 1-2 ft (E. Elefson, August 1999, Weeks Marine, pers. comm.).

3) Given a fixed budget for offshore surveys, many more shallow borings could be obtained by divers working out of small craft compared to the number of vibracores possible using much larger equipment.

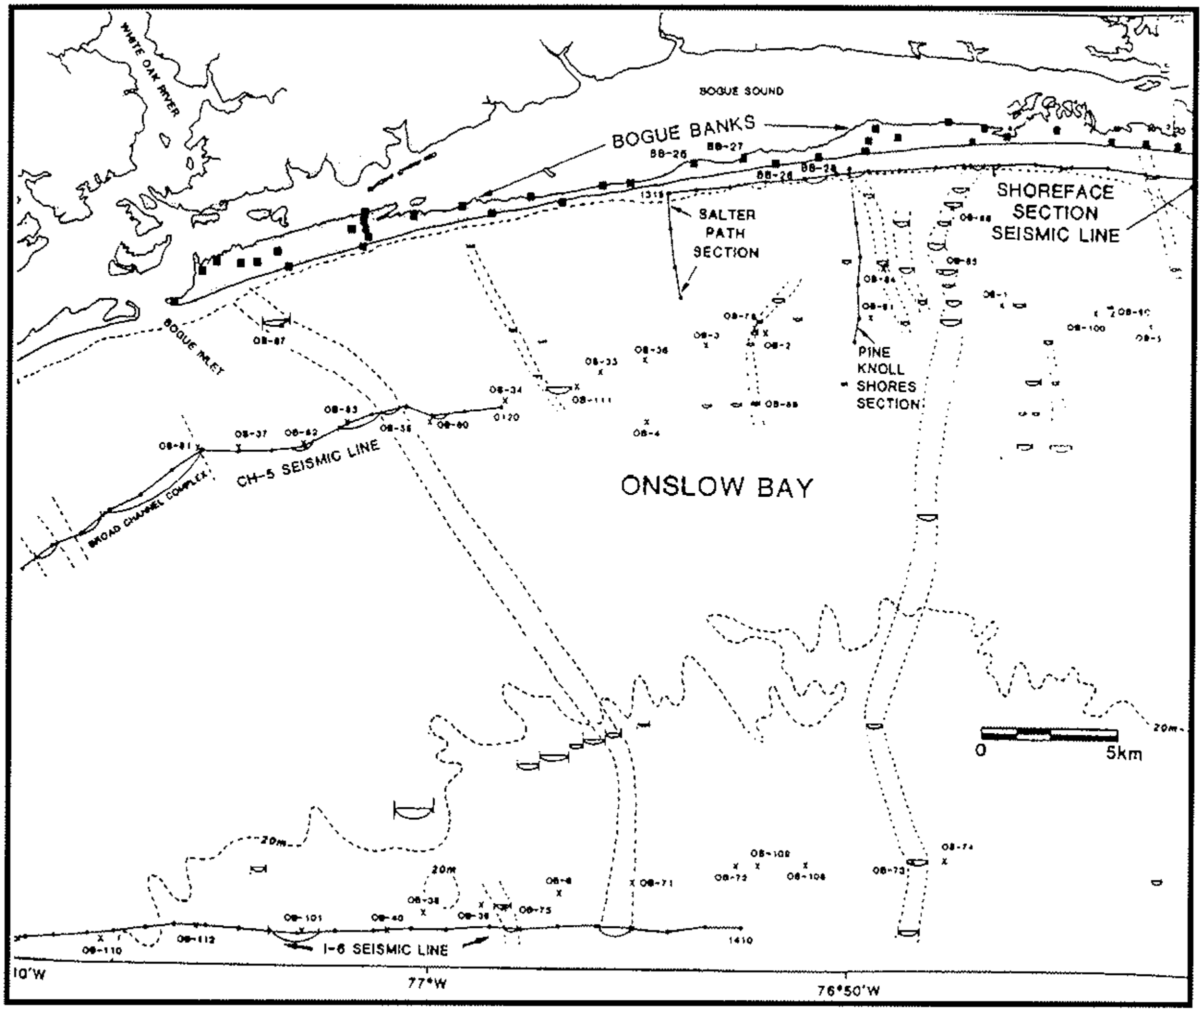

FIGURE 3.23. Vibracore locations and inferred positions of buried paleochannels (dashed lines perpendicular to the shoreline) offshore of Bogue Banks. Outer depth contour is 20 meters (~65 ft). [From Hine and Snyder 1985, Fig 2]

The study design provided for a three-phased search whereby preliminary borrow areas would be defined using a coarse regional grid of samples, then refined in Phase II and Phase III by a more detailed search. Phase II also provided for a representative sampling of thicker sections using a large vibracore rig sufficient to recover ~10-ft samples.

In total, the 1999-2001 surveys accomplished the following:

- Characterized the upper 2-3 ft of sediments in an approximate 50 square mile area off Bogue Banks.
- Identified potential offshore borrow areas representing approximately 10 square miles.

- Confirmed sediment in potential borrow areas in sufficient detail to develop isopach maps of textural properties.

- Obtained ~90 percent of the borings in the most promising four square miles, yielding an average ~40 borings per square mile in the proposed borrow areas. This density of borings is unprecedented for projects of this type.

3.16.3 Laboratory Analysis

Sediment samples were collected and stored as follows.

Diver cores — two-inch aluminum barrels driven by hammer to refusal, cut, and temporarily capped in situ; then decanted, cut to sediment level, and recapped in the field noting penetration depth and recovery thickness; stored vertically for transport to the lab.

Vibracores — 2½-inch steel barrels driven remotely via large-scale vibrator to the depth of refusal; removed, cut, capped, and measured for penetration depth and recovery thickness.

Grab samples (beach) — hand samples from the upper three inches placed in sample bags.

Samples were logged, split, and analyzed as follows.

1) **Diver and vibracore cores** — split by saw, logged, and one-half sampled as a single or multiple composite; the remaining core half was sealed in plastic in its half barrel and archived.

   Phase I samples — visual estimates of mud percentages; then washed, dried, and dry-sieved using 0.25 phi (ϕ) intervals from -1ϕ to 4ϕ – that is, granule (2 mm) to very fine sand (0.0625 mm); fractions retained >2 mm and <0.0625 mm were noted.

   Phase II and Phase III samples — same handling and grain-size analysis procedures as Phase I samples except nearly all tested for percent mud and percent carbonate via subsampling.

   - *Percent mud* was determined by drying an undisturbed sample (composite from the length of the core), weighing it, rewetting and disagregating the sample, decanting the mud fraction until the water ran clear, redrying the sample, then reweighing it. Percent mud is computed from the difference in dry weight of the unwashed and washed samples.

   - *Percent calcium carbonate* was determined from a 20-gram subsample that had been washed and dried, then treated with repeated quantities of 10 percent dilute HCL for several hours until all reactions stopped. Samples were redried and reweighed for comparison with the untreated sample weight, and the percentage of carbonate material is computed.

2) **Native beach samples** — representative splits were obtained, washed, dried, and dry-sieved at 0.25ϕ intervals. No mud analyses were performed because the grab samples were void of mud. Percent calcium carbonate was determined via the same procedure for Phase II cores and groupings of native beach samples (ie, physical composites of multiple berm, beach face, etc, samples).

Raw data were entered into spreadsheets and analyzed via custom software (CSE's BPAS system) which automates computation of standard statistical parameters [including moment measures and the graphic parameters of Inman (1952) and Folk and Ward (1957)]. Grain-size distributions (GSDs) were graphed as frequency and cumulative frequency distributions using phi (ϕ) and millimeter (mm) axes for cross-reference. To facilitate evaluation and comparison with other engineering sieve sizes, Figure 3.24 shows the general relationships of grain size (mm), phi value, sediment classification, and ASTM sieve mesh sizes.

Sediment quality and compatibility for beach nourishment were based on the technique of James (1975) (CERC 1984), whereby a population of potential borrow area samples is compared statistically with the native beach size distribution.

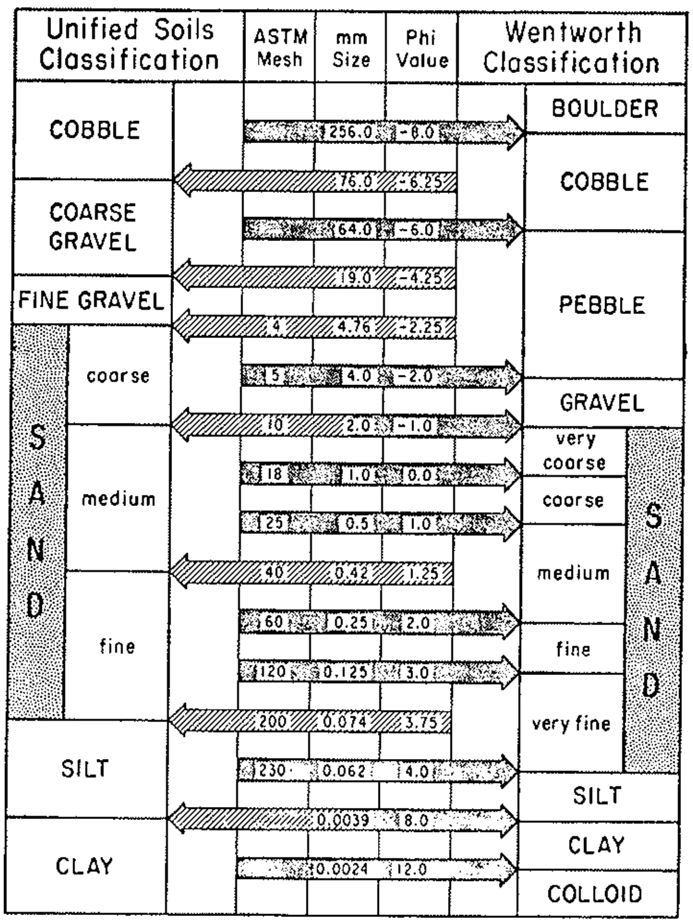

FIGURE 3.24. Grain-size scales (soil classification).

James (1975) presents methodology for computing the overfill ratio (R_A), which represents how similar a particular size distribution of sediments is compared to the native population of sediments. R_A's of nearly 1.0 suggest the sample will perform more or less equal to the native population. Higher R_A's represent the ratio of non-native "borrow" material required to perform as 1.0 unit of native material. Thus, an R_A equal to 2.0 suggests it will take twice as much material to equal 1.0 unit of native sediment.

The concept of overfill ratios is not a perfect predictor of nourishment performance, but it remains perhaps the most useful and proven technique for comparing nourishment sediments (NAS 1995). The primary factors considered are mean grain size and sorting (standard deviation measure of the size distribution). Experience has shown that borrow sources at least as coarse as the native beach (Dean 1991, CERC 1984) or having significant coarse fractions (Kana and Mohan 1998) perform equal to or better than native sediments (as measured by durability of the dry beach). Borrow sediments that are finer than native or that contain high percentages of fine material perform worse (NAS 1995). This response is related to profile adjustment (function of wave energy and wave steepness) as well as the background erosion rate. Obviously, the concept of R_A as a predictor of performance assumes that the scale of the nourishment is relatively large and covers a reasonable length of shoreline. Short projects do not perform as well for another reason– because end losses cause spreading away from the nourishment "bulge" (NAS 1995).

For purposes of the present study, we determined R_A's following standard practice, using the James (1975) nomogram in CERC (1984). Sediment quality and borrow area suitability was based on the R_A's, mean grain size and sorting parameters, percent mud, percent carbonate, percent coarser than 2 mm (ie, granule, or larger), and proximity to the project area. Isopach maps of various sediment size and quality parameters are given in Appendix A.

3.16.4 Sediment Results

This section provides a summary of results and refers to data sets contained in the EIS (CSE-Stroud 2001) and various supplements (eg, 24 May 2001 letter and data set to Garland Pardue, USFWS; 19 June 2001 letter to Col. J. DeLony, USACE). These previously submitted data sets include core locations, beach sample locations, and offshore core sediment characteristics (grain-size distribution curves and statistics).

3.16.4.1 ***Beach Composites*** – Native-beach size distributions were established using statistical composites of physical composite results of individual samples. Table 3.3 contains the individual sample results (primary statistics) from 21 dune/beach/low-tide terrace samples distributed in six transects along Bogue Banks collected in 1999 and 64 (32 pairs) supplementary samples collected in May 2001. Of the three dune samples from 1999, only two were considered representative of natural dunes, which tend to have finer sediment than beach-face samples. At stations CSE-Stroud 30, CSE-Stroud 50, and CSE-Stroud 70, repeated dune scraping has introduced anomalously coarse sands from the berm. Therefore, these stations were not sampled at the dune. At station 110 (Coast Guard station), nourishment via Corps spoil projects has introduced a coarse sediment which similarly does not reflect native dune sands; therefore, it was eliminated from the 1999 composites (top half of Table 3.3). The supplementary samples in 2001 yielded nearly identical composite statistics based on 28 or 32 samples depending on how many dune samples are included in the analysis (bottom of Table 3.3).

SUMMARY

1) As Reported In SEPA Final EIS dated 4 April 2001

Native Composite (20 Samples @ Dune Face, Berm, Beach Face, Low tide terrace)

Mean = 1.725 phi (Mn) ***Std dev = 0.773 phi (SDn)*** ***Skewness = -0.648***

Mean = 0.302 mm ***Std dev = 0.585 mm*** ***Skewness = -0.648***

Native Composite (12 samples at berm, beach face)

Mean = 1.466 phi (Mn) ***Std dev = 0.830 phi (SDn)*** ***Skewness = 0.542***

Mean = 0.362 mm ***Std dev = 0.563 mm*** ***Skewness = 0.542***

2) Based On May 2001 Supplementary Beach Sampling For Beach Transects 48 - 78

Native Composite (28 Samples @ Dune Face, Berm, Beach Face, Low tide terrace)

Mean = 1.747 phi (Mn) ***Std dev = 0.696 phi (SDn)*** ***Skewness = -0.714***

Mean = 0.298 mm ***Std dev = 0.617 mm*** ***Skewness = -0.714***

3) Average of June 1999 and May 2001 Results

Native Composite (48 Samples @ Dune Face, Berm, Beach Face, Low tide terrace)

Mean = 1.736 phi (Mn) ***Std dev = 0.735 phi (SDn)*** ***Skewness = -0.681***

Mean = 0.300 mm ***Std dev = 0.601 mm*** ***Skewness = -0.681***

Review of the results confirmed coarsest sediments tend to reside on the berm and beach face (medium sand, moderately sorted, coarse-skewed) with finer sediments occurring along undisturbed dunes and low-tide terrace (typically fine sand, well sorted). Composite "12" (from the initial 1999 samples) yielded a mean grain size of 0.362 mm (1999 samples) along the beach face and berm, whereas composite "20" yielded a mean size of 0.302 mm. Considering that the proposed nourishment is designed to widen the recreational beach including part of the underwater profile, we elected to use the composite "20" as a "native" beach (1999 samples). This weights the composite toward the coarse sizes common along the beach face, berm. and low-tide terrace where the majority of the nourishment sand will be placed.

Also, it was elected not to include samples over the outer bar or further offshore (even if these areas are part of the littoral zone), because they tend to be much finer than the beach face and would weight the "result" toward less stable sediment sizes. Similarly, it was elected to only include two dune samples in composite "20" because a relatively small percentage of nourishment sediments will be subject to aeolian processes or contribute to dune building after construction. These results were updated with additional samples in 2001, and it was found that virtually the same mean grain size and sorting resulted for the 28- or 32-sample composites (bottom of Table 3.3). Combining the 1999 samples and 2001 samples yielded a composite of 48 beach samples as follows: mean = 0.300 mm, standard deviation = 0.601 mm. These latter values were adopted as the revised native beach composite.

The "native" composite selected for a baseline in the 1999 study is considerably coarser than the native sediment distribution used by the USACE (1976) in planning for potential disposal projects along Atlantic Beach. The Corps sampled at 2-ft intervals from the berm to -30 ft mean low water (MLW) along four transects at the eastern end of Bogue Banks. Their statistical composites yielded a mean grain size of 0.17 mm (2.52ϕ) and standard deviation of 0.77ϕ. The Corps results confirm the fining of sediments offshore but tend to weight the result toward less stable material. The native composite that was chosen is more conservative for beach nourishment planning because it eliminates from consideration certain fine deposits that characterize the area seaward of the bar. Use of a coarser "native" size distribution lowers the amount of potentially beach-compatible material in our search areas. At the same time, it better distinguishes beach-compatible sediment from marginally acceptable sediment.

3.16.4.2 ***Phases I-III Offshore Core Samples*** – The Phase I through Phase III sediment test results are presented in Table 3.4 and in Figures 3.25-3.26 (overfill ratios only). Detailed isopach maps of mean grain size, percent mud, percent calcium carbonate material, and percent coarser than 2 millimeters (mm) are given in Appendix E.

3.16.4.3 ***Proposed Borrow Areas*** – Offshore borings were used to delineate three potential borrow areas: A, B1, and B2 offshore of Pine Knoll Shores, Indian Beach, and Emerald Isle as described in the permit application (ID 200000362). As a result of additional sampling in January-March 2001, the potential borrow areas were further refined as shown by shading on Figures 3.25-3.26 based on the following general criteria:

- R_A's should be as low as possible, approaching 1.0.
- Mud percent should be as low as possible and generally less than 5 percent.
- Calcium carbonate percentage should be at least 20 percent to match the native beach.
- Borrow sediments should be coarse-skewed, with a significant portion of granular-sized sediments to improve stability and match the coarse sediments in the lower beach face/step along Bogue Banks.

Based on this review, the preferred borrow sediment is a combination of sediments from portions of borrow areas A, B1, and B2 as shown by shading and as given by specific coordinates in Figures 3.25 and 3.26.

The revised borrow areas total 2,810 acres and are represented by 133 borings. Table 3.5 summarizes key sediment parameters (averages of individual sample results). The mean grain size in borrow area:

- A ranges from 0.51 mm to 0.54 mm (coarse sand).
- B1 averages 0.28 mm (medium sand).
- B2 averages 0.313 mm (medium sand).

Note that the native beach averages 0.30 mm. Percent mud in each borrow area ranges 3.1 to 4.0 (federal standard is 10 percent). The percentage of shell material (calcium carbonate) ranges 27-45 percent. Approximately 7-20 percent of each deposit considered for use as borrow sediment consists of granular-shelly material with grain diameters of >2 mm.

TABLE 3.4. Potential borrow area sediment quality and compatibility factors (RA). Revised May 2001

Native Beach		~15-20	~5		* @ 2 ft cut ** @ 3 ft cut

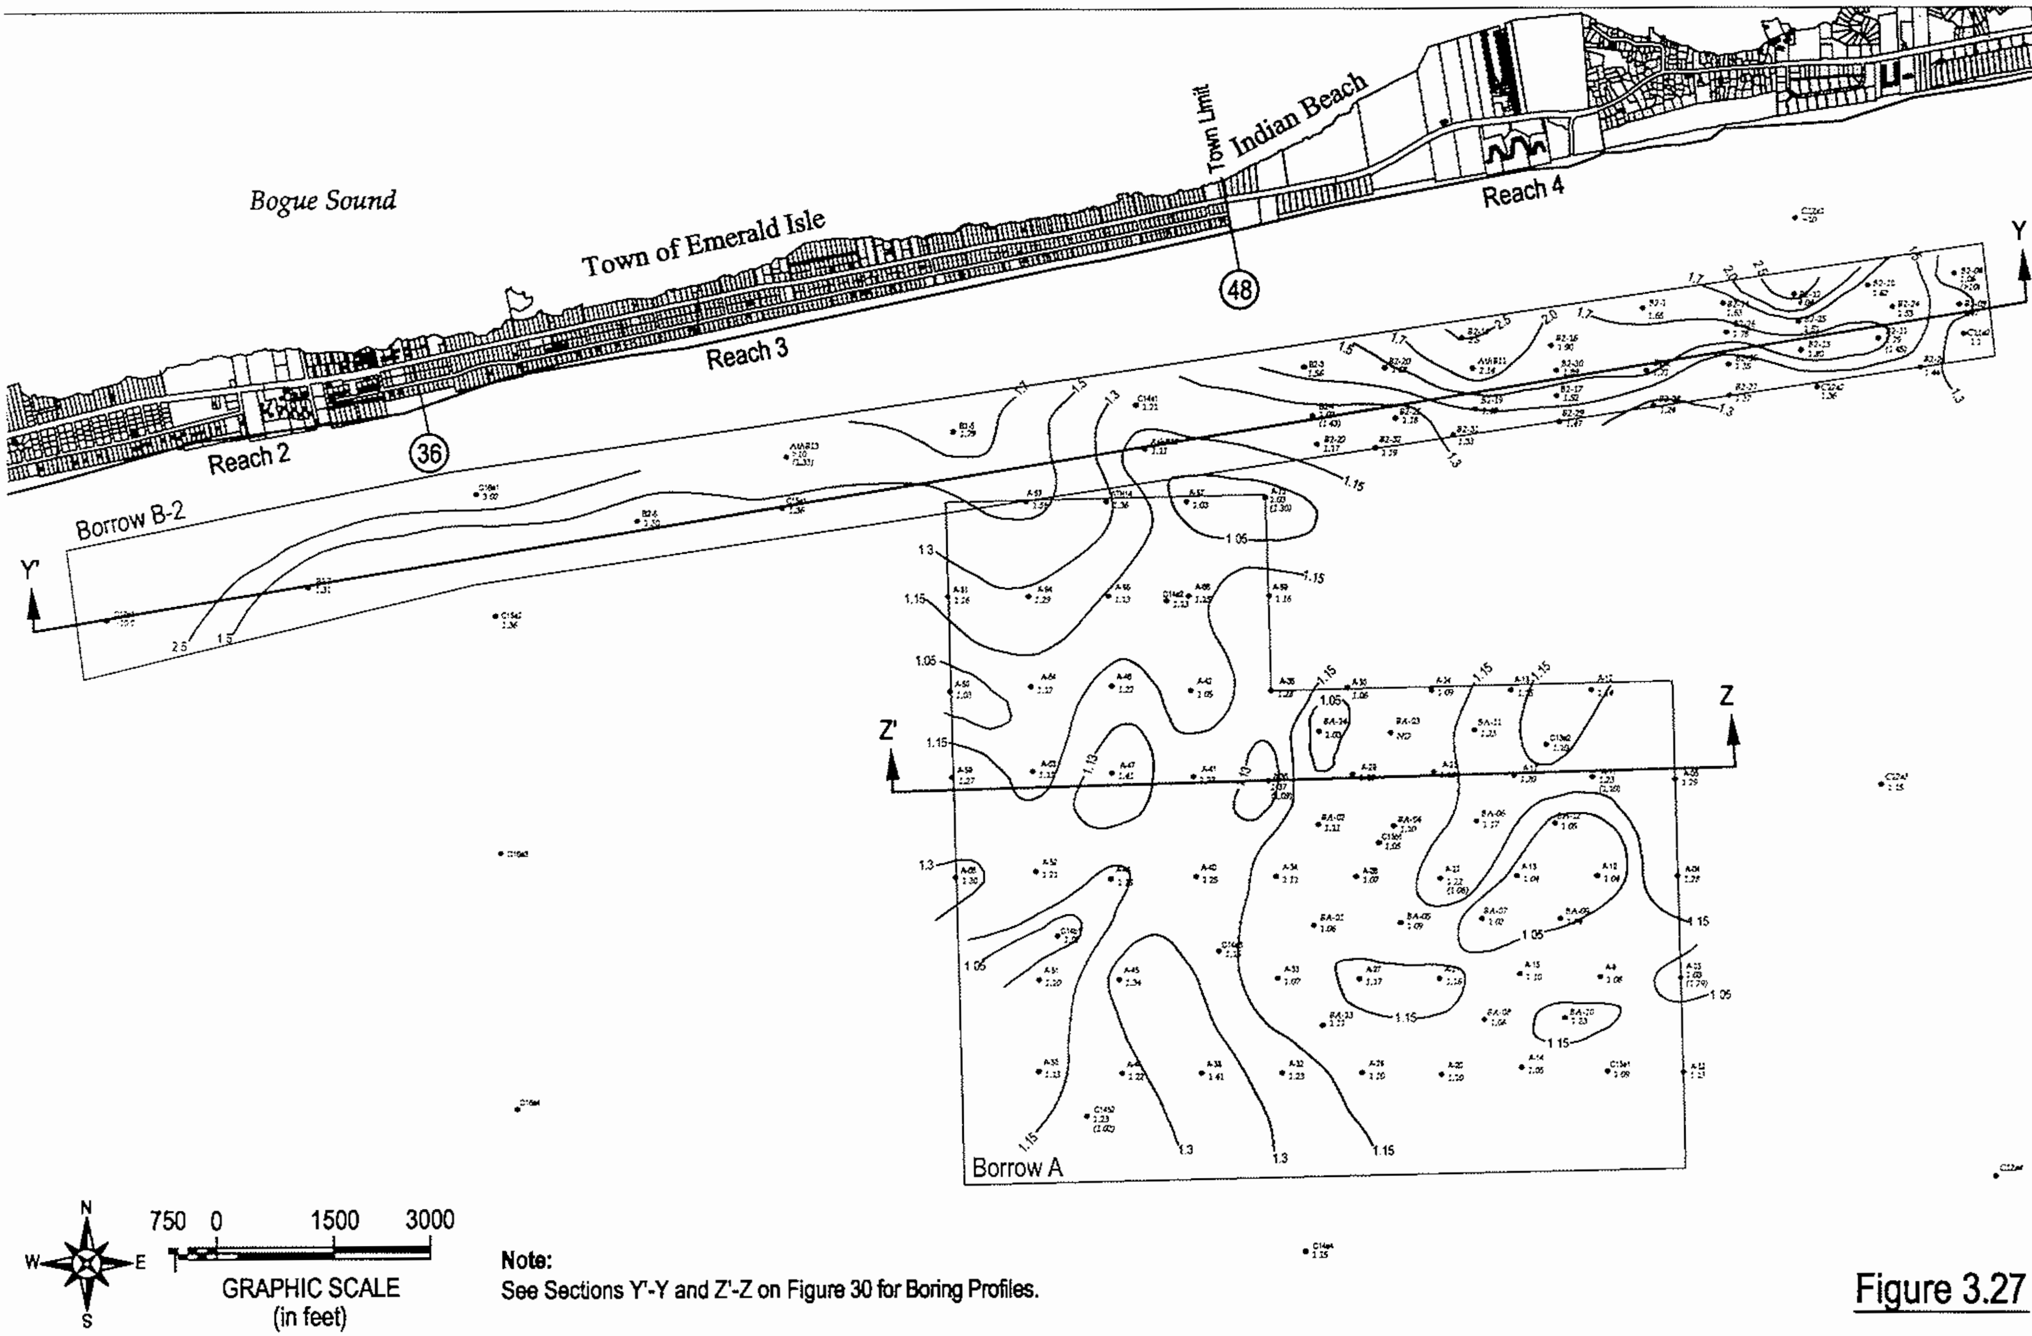
The confirmed borrow volumes represent the potential maximum volume of material that could be obtained from the indicated borrow areas. In keeping with best management practice, more source sediment must be confirmed so that some undisturbed areas can be left around each dredge cut to promote rapid recruitment of species after the project is complete. The above volumes assume 33 percent of the indicated Areas in A1 and A2 will not be dredged for purposes of wildlife recruitment, and 15 percent of the B1 and B2 will not be dredged for purposes of wildlife recruitment. Details of the Phase I excavation plan and anticipated Phase II plan are given in another section of the report.

Figures 3.27-3.29 show three typical cross-sections along borrow areas A, B1, and B2 – illustrating the sediments in the profile. Based on available borings, sediments are confirmed to approximately 10 ft in borrow areas B1 and B2 with more detailed confirmation in the upper 3-4 ft. Borrow area A is confirmed to ~5.5 ft with more detailed confirmation in the upper 2-2.5 ft. Based on these data and the project goal of limiting the depth of excavations to shallow cuts of the order 2-3 ft, a limit of ~3 ft for excavations in borrow areas B1 and B2 and ~2 ft for excavations in borrow area A has been set.

Applying the respective cut limits for each borrow area yields a total of ~8.7 million cubic yards. As noted in Table 3.5, these estimates assume that at least 15 percent of revised borrow areas B1 and B2 will not be dredged and at least 33 percent of revised borrow areas A1 and A2 will not be dredged. The purpose of leaving some undredged corridors running through each borrow area is twofold:

1) Undredged corridors leave undisturbed areas in close proximity to each cut such that natural recruitment of biota is accelerated after construction (Jutte et al 1999a,b).

2) The anticipated type of dredging equipment (hopper dredges) reportedly works more efficiently if gaps are left between each cut (E. Elefson, Weeks Marine, August 1999, pers. comm.).



Note:
See Sections Y'-Y and Z'-Z on Figure 30 for Boring Profiles.

Figure 3.27

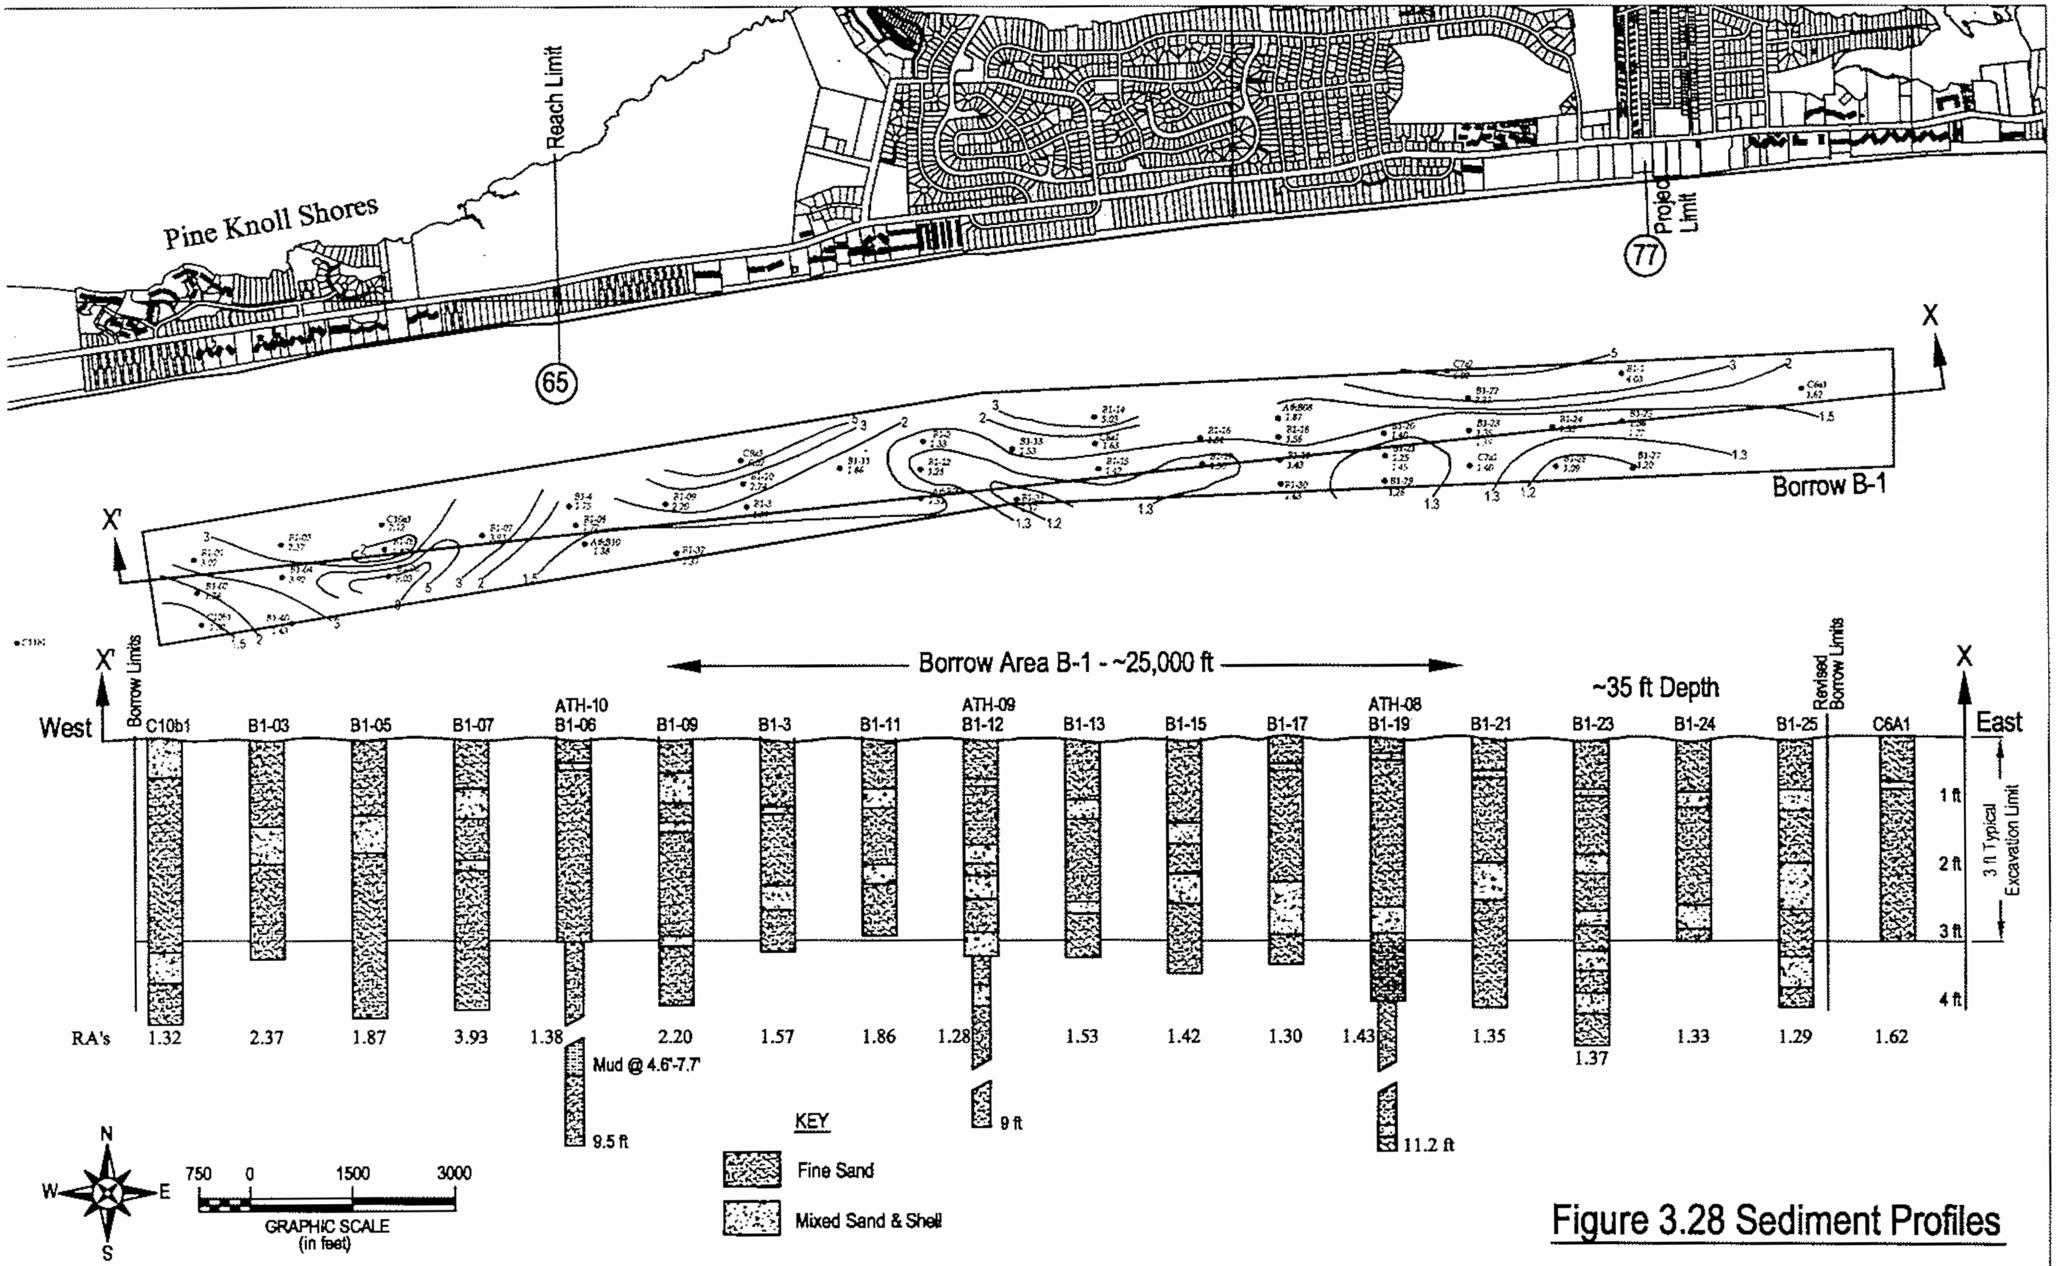


Figure 3.28 Sediment Profiles

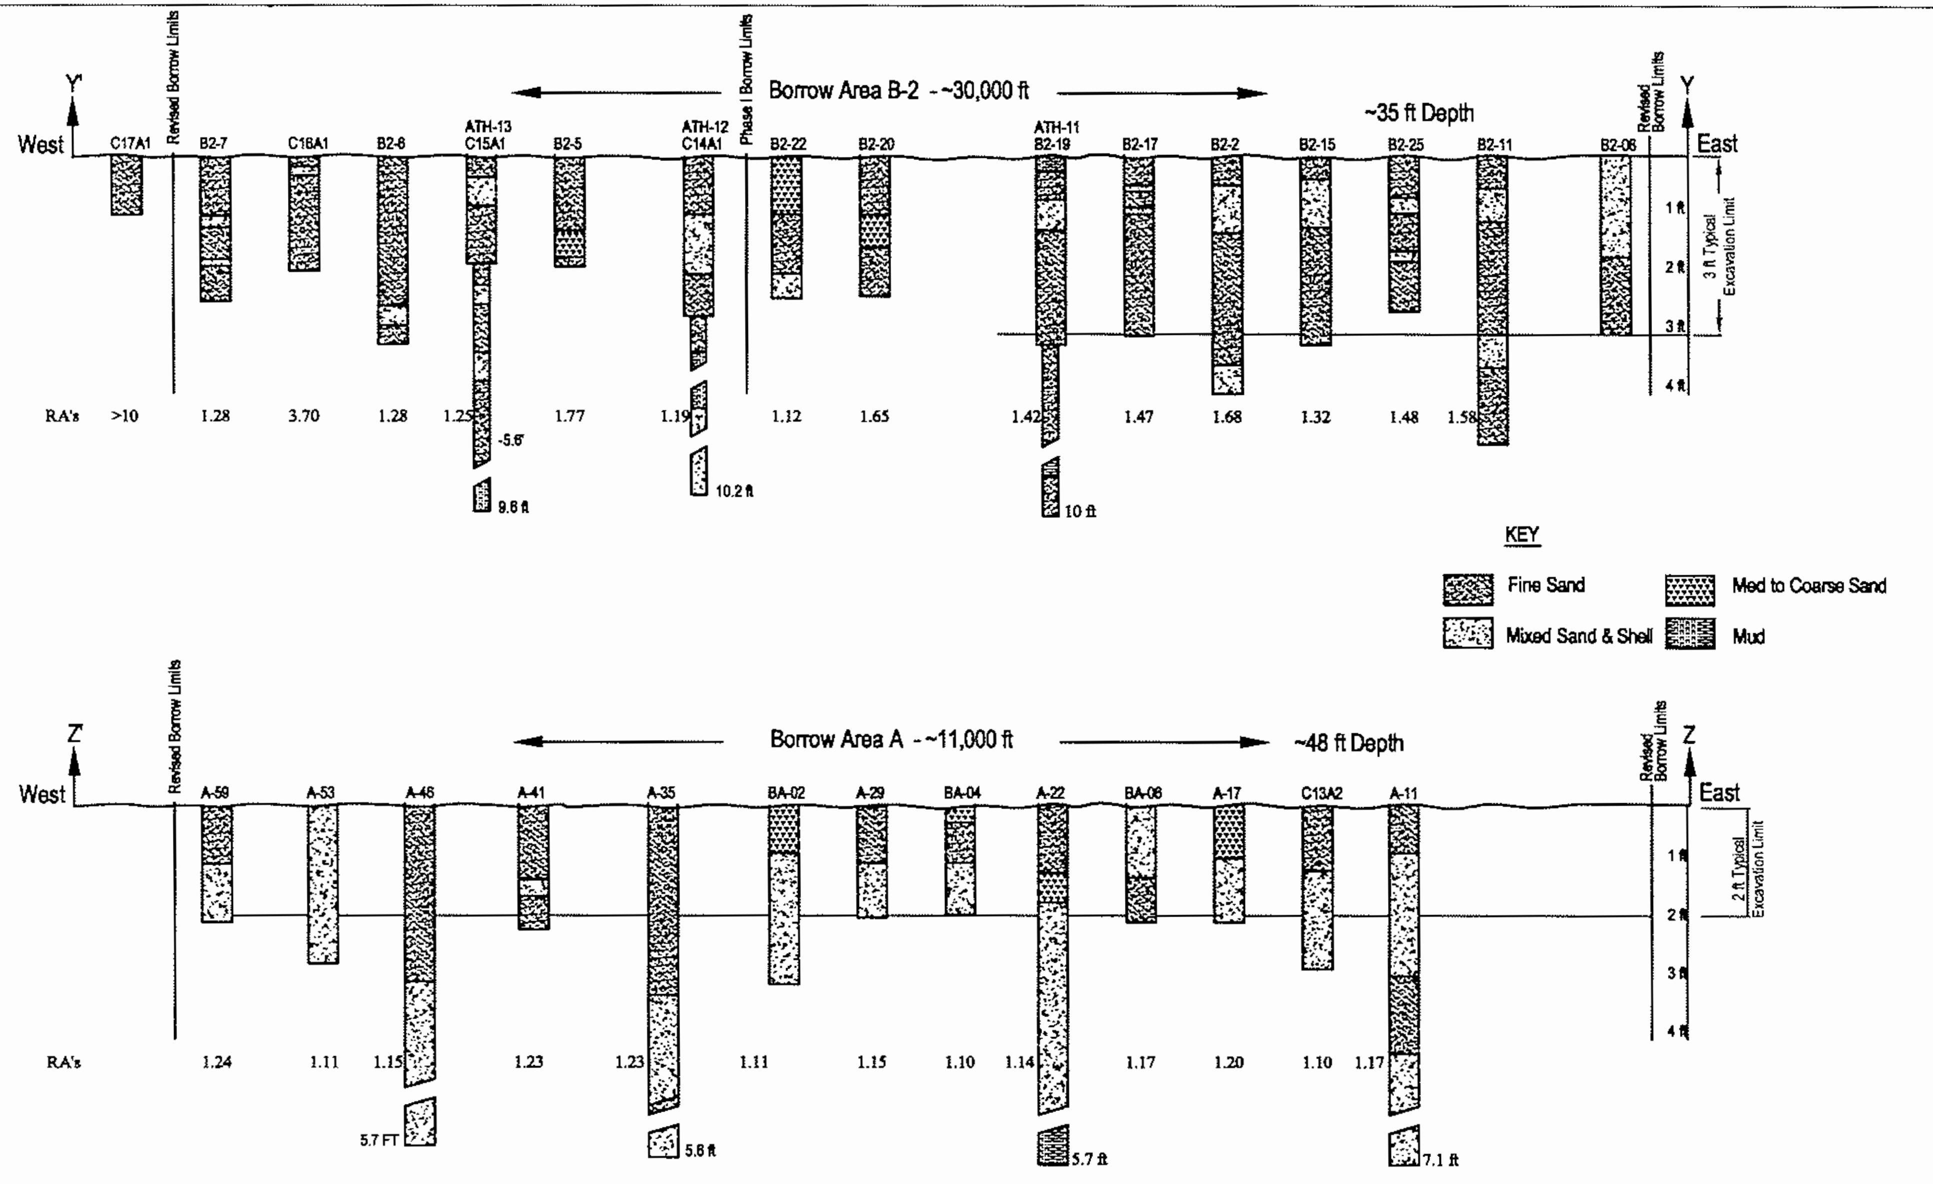

Figure 3.29 Sediment Profiles

The effect of these undredged corridors will be to reduce the total acreage impacted in the offshore area. A further reduction in impacted area will result if a lesser fill quantity is needed for the project than requested in the permit. Following standard practice, we have identified and confirmed approximately 25 percent more borrow area sediment than required (Figs 3.25-3.29 and Table 3.5). These factors are anticipated to reduce the total acreage impacted directly by excavations to ~731 acres in borrow area A* (A1 and A2), 330 acres in borrow area B1, and 530 acres in borrow area B2 (total ~1,591 acres or ~2.5 square miles).

[**NOTE: Borrow area A in this document refers to A1 and A2.*]

3.16.4.4 *Sediment Compatibility* – Groups of samples for each potential borrow area were compared with the native beach. Using the method of James (1975), borrow composites were compared with native beach composites to yield an overfill (R_A) factor for each borrow area (see Table 3.4). The results, using beach composites of 48 samples, show that the majority of samples have R_A's under 2.0. R_A's for revised borrow area A* were 1.15. Revised borrow areas B1 and B2 had slightly finer sands on average, yielding R_A's of 1.58 and 1.50 (respectively).

Upon further review of the sediment quality data and specific requirements of the project, it was determined that the optimal borrow sediment will be a combination of sands from borrow areas A* and B1 or A* and B2. Borrow areas B1 and B2 contain more fine sand and are slightly less stable for nourishment than borrow area A* (ie, approximately 33 percent of the B1 and B2 deposits will serve as overfill). The finer sands in these areas will migrate to the outer bar after placement and will build up the underwater profile (a desired outcome). Sediments in borrow area A* are slightly coarser than the native beach (lower end of the coarse sand range). These sediments will be more stable in the berm and beach face and will serve to improve the longevity of the dry beach.

As shown in Table 3.5, approximately 65 percent of the borrow sediment is anticipated to be derived from revised borrow areas B1 and B2. The remaining 35 percent would be excavated from borrow area A*. The purpose of combining sediments from borrow areas A* and B1 and B2 is to more closely match the native beach. Using these approximate proportions, composite grain-size distributions were developed for representative combinations of borrow areas A* and B1 or A* and B2 as detailed in previous correspondence (letter and attachments dated 19 June 2001 in response to 1 June 2001 comments from USFWS). Table 3.6 and Figure 3.30 provide example results. The use of statistical composites follows standard practice and is used to characterize the average size distribution that will result when sediments are delivered to the beach. Using 62 representative cores from borrow areas B1, B2, and A*, composite grain-size distributions for combinations of borrow areas A* and B1 and A* and B2 were computed. This simulates the effect of combining sediments during placement. The composite size distributions resulting from each combination yield overfill ratios of 1.25 to 1.3 (Table 3.6). Grain-size distribution curves for the composites are given in Figure 3.30. The native beach composite is given in Figure 3.31. Only 25-30 percent more borrow sand would be required in these cases to match the performance of the native beach. As NAS (1995) and experience suggest, borrow areas with R_A's under 1.5 are generally considered to be good matches with the native beach.

The selected borrow areas have several advantages:

1) They are in close proximity to the project site and will result in lower transportation costs and more rapid construction.
2) They contain a broad range of sediment sizes that fully encompass the natural variation that presently exists on the beach.
3) They have relatively low mud content (<4 percent on average).
4) They contain a sizable portion of granular material which will be more stable on the beach.
5) They are relatively free of large shell clasts. Most of the shell material consists of *Donax* sp., which is thinner walled and more friable than heavy shell such as *Crassostrea* sp.
6) They are situated in water depths of 30-50 ft, beyond the limit of normal sediment exchange with the beach.

The result of the above-listed refinements of the proposed borrow areas for the proposed project is to yield a beach-compatible sediment. Final plans and specifications for contractors will direct hopper dredges (the anticipated equipment) to alternate between borrow areas A and B1, or A and B2 in proportion to the volumes prescribed for each area. Construction will be monitored closely by the applicants' engineer with frequent sand sampling for quality control.

TABLE 3.6. Example composite overfill ratios for borrow areas B1 and A and borrow areas B2 and A, assuming combination of sediment to yield a more compatible fill. (Example to simulate combination of ~65 percent B1 and 35 percent of A or 65 percent of B2 and 35 percent of A.) See CSE response letter dated 19 June 2001 to USACE for more details. [*See Table 3.5 for definitions.]

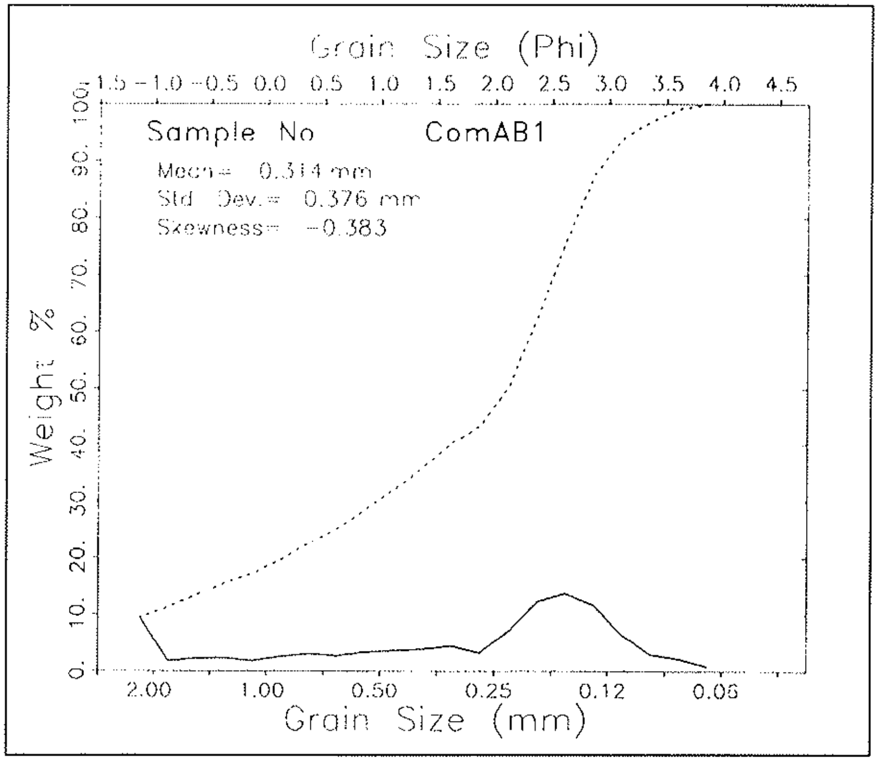

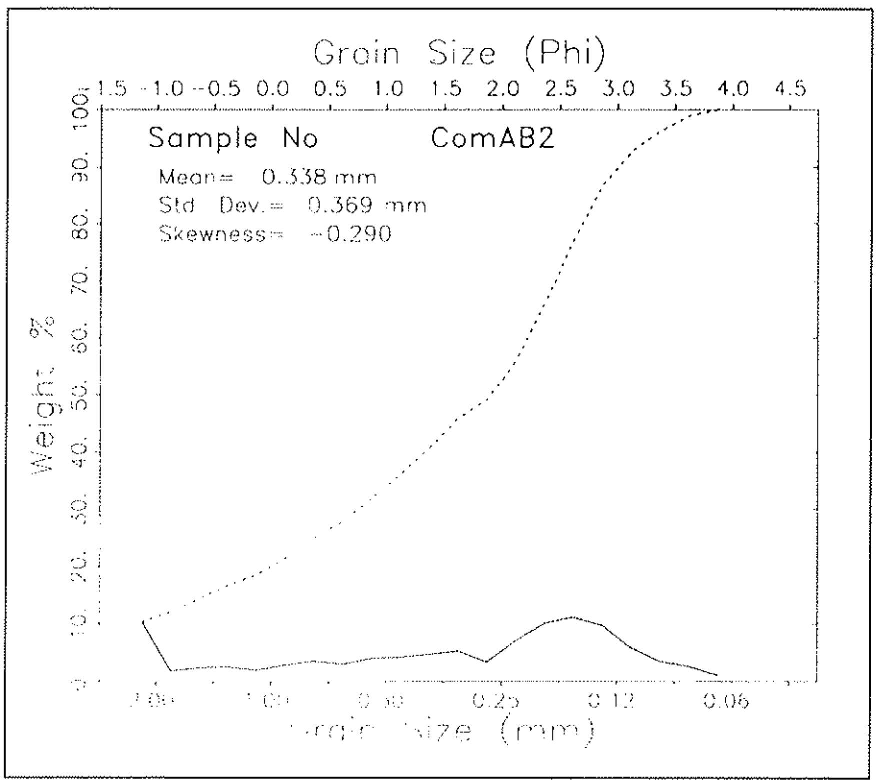

FIGURE 3.30. Example composite grain-size distributions for borrow areas A and B1 and A and B2, combining sediments in the approximate ratios as the indicated volumes in each deposit.

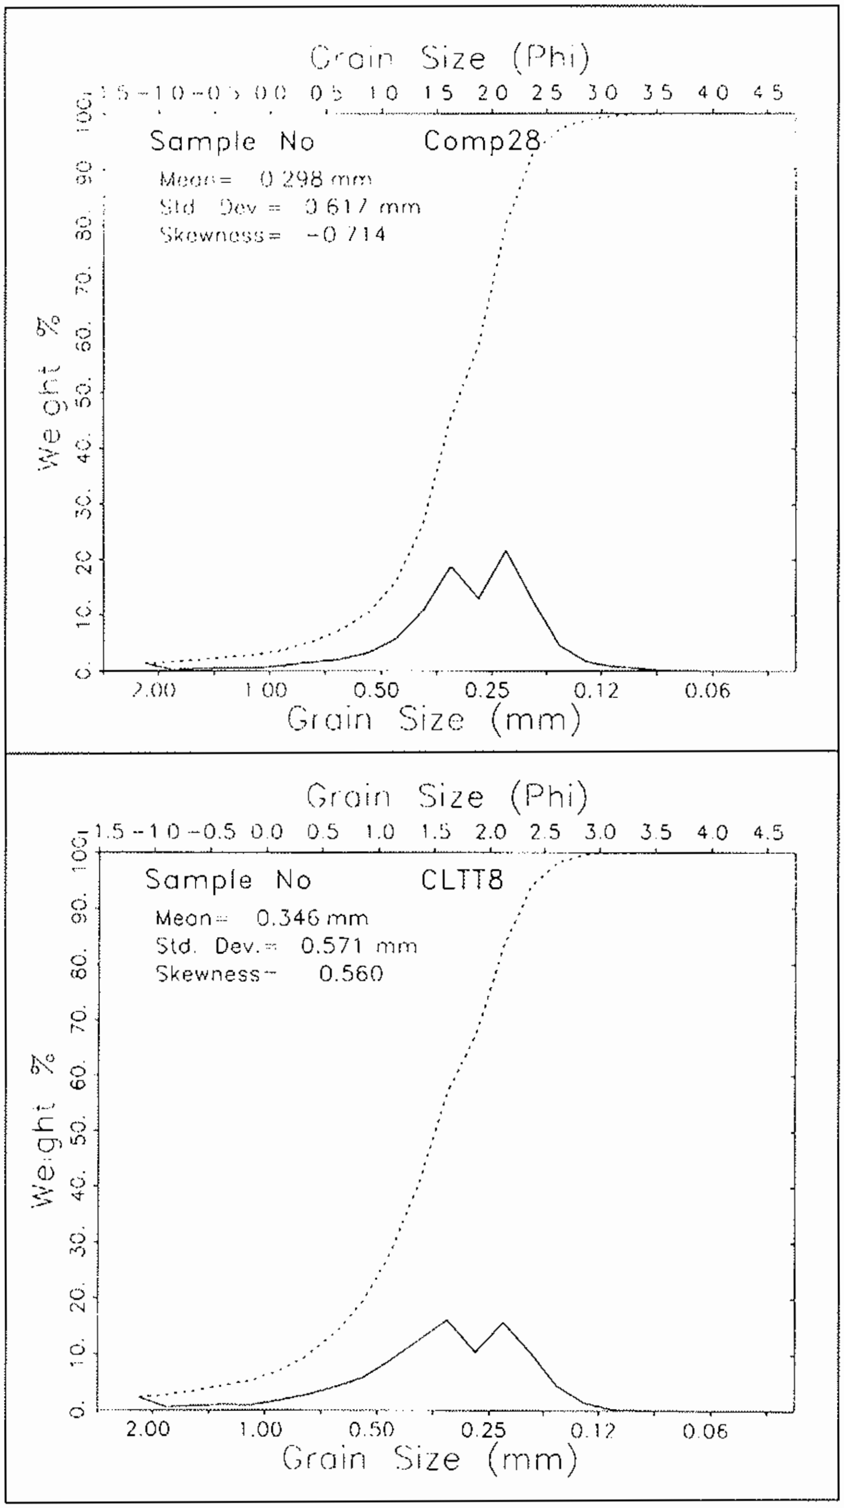

FIGURE 3.31. Example beach composites for Bogue Banks, based on 1999 and 2001 samples. Comp28 is a composite of dune, berm, beach face, and low-tide terrace (LLT) samples as detailed in Table 3.4. CLTT8 is a composite of eight LLT samples. Based on these results, borrow area sediments less than 0.12 mm (see Fig 3.30) are likely to represent the portion winnowed from the fill. The overfill ratios define this unstable portion as representing ~15-35 percent of the fill (ie, R_A's = 1.15 to 1.35).

4.0 ENVIRONMENTAL CONSEQUENCES

4.1 LAND USE IMPACTS

Nourishment of the Bogue Banks beach will not change the land use patterns. Development of the shoreline is governed by zoning regulations of the municipalities and County and by the CAMA Land Use Plans approved for each governmental entity. Ocean front development will remain primarily single family residences with patches of multi-family and hotel development. The beach nourishment project is consistent with the approved CAMA Land Use plans for Carteret County, and the Towns of Pine Knoll Shores, Indian Beach and Emerald Isle.

4.2 SOCIAL IMPACTS

The beach nourishment project will produce temporary and short-lived impacts on existing beach use, rental of property, and beach access only during construction. Impacts will be isolated to the immediate areas of construction at any particular time during execution of each phase of the project. This may adversely affect rentals for certain properties during the project. Similar impacts are believed to have occurred to properties in the project area as a result of five hurricanes since 1996 and the requirement to evacuate during storms. Following the project, the impacts of reduced rentals and beach use are expected to diminish. An improved beach is expected to attract people to the area, maintain rentals and beach use, and reduce the time for beach cleanup and recovery after storms.

4.3 ECONOMIC IMPACTS

The proposed project will provide ten-year benefits, substantially exceeding costs as described in Section 2 compared with the "no-action alternative" and the "abandonment and relocation alternative." The ratio of benefits to costs has not been calculated but is expected to greatly exceed 2:1, based on conservative assumptions (see Section 2). An accurate accounting of benefits and costs depends on the final cost of construction and the actual life of the nourishment which is not quantifiable until erosion rates of the fill are computed from surveys. The applicant has applied for a permit based on the expectation that the tangible as well as intangible benefits of the project greatly exceed the costs. A certain portion of the project budget will be recycled to the community by way of local purchases by the contractor of supplies (eg, fuel, machine parts, etc), lodging, and food. An estimated 95 percent of the project will be paid out of local (municipal) and 5 percent out of state funds (limited to the project area owned by the State of North Carolina in Reach 4). The project will restore and improve the public beach. This is expected to attract more visitors and contribute favorably to the local economy over a ten-year period. The project will reduce damages due to storms and the cost of repairs to the dunes (eg, beach scraping), walkovers, and existing shore-protection structures. The project is expected to sustain the tax revenues (ie, 43 percent) of the Carteret County receipts.

The USACE-Wilmington District reviewed the economics analysis given in the SEPA EIS and concluded that it was "adequate and thorough" (memorandum dated 18 May 2001 prepared by Bob Finch, economist). Additional economic information has been developed and incorporated into the present document in response to USACE comments.

4.4 CULTURAL RESOURCES IMPACTS

To determine the impact of the proposed dredging and beach fill operation on potentially significant submerged cultural resources, a remote sensing survey of the proposed borrow areas was conducted by Tidewater Atlantic Research, Inc. (TAR) of Washington (NC). The survey report prepared by TAR is provided in Appendix B. The survey was designed to locate and identify submerged cultural resources in the study areas, generate sufficient data to make an initial assessment of each target's significance, and provide insight into the necessity for avoidance or additional investigation. The survey was carried out between 7 and 13 December 1999. No magnetic or acoustic anomalies were identified in either borrow area A or borrow area B-1. In borrow area B-2, ten magnetic anomalies were identified near the western end of survey area. Seven of those targets contained signature characteristics indicative of submerged cultural resources. Because they could be associated with an historic shipwreck, either avoidance or additional investigation to positively identify the nature and significance of the material generating the seven anomalies was recommended. To avoid the areas of the seven anomalies identified by the survey, the western portion of borrow area B-2 has been eliminated as a potential source of sand for the proposed project.

The NC Department of Cultural Resources (NCDCR) has reviewed the project and has identified six archaeological sites along Bogue Banks beaches (letter dated 7 May 2001 from David Brook to Doug Huggett). NCDCR has recommended and the applicants agree to avoid the sites and report any evidence of unknown vessel remains in the course of construction. NCDCR will be contacted to inspect such discoveries, and work will cease in the immediate vicinity of found artifacts until cleared by NCDCR officials. While the possibility exists that a designated or unknown artifact may be exposed during construction operations, the proposed project is expected to benefit each site by the placement of additional sediment, further burying them and increasing their preservation.

4.5 UTILITY IMPACTS

There will be no permanent changes in utilities as a result of the project. The nourished beach is expected to provide an unquantified benefit to existing infrastructure and utilities near the beach in the form of increased protection during storms. Nearly all energy usage during construction will be self-contained on the dredge and via self-propelled equipment on the beach. There will be no significant demand on the local electrical grid. Purchases of diesel fuel will impact local suppliers by temporarily increasing demand. The construction workforce will number around 75 individuals who will not significantly alter the demand for water, sewer, electricity, transportation, or communication services.

Water Supply and Wastewater Systems — There are no activities associated with this project that will impact existing wastewater collection, treatment, or disposal systems. No activities of this project will impact potable water well sources or distribution systems on Bogue Banks or in Carteret County.

4.6 PHYSICAL ENVIRONMENT IMPACTS

4.6.1 Wetlands

No impacts to existing coastal wetlands or 404 wetlands will result from this project. No fill will be placed in 404 or coastal wetlands as part of this project.

4.6.2 Unique Agricultural Lands

The beach nourishment project will result in no impacts to agricultural lands, unique or otherwise.

4.6.3 Public Lands

The project will not reduce the existing public rights and use of the beach resources. The "Public Trust Doctrine" and the State Property Sovereignty Rules preserve the rights of all citizens of North Carolina for use of resources located below the mean high water line. Additionally, Carteret County and local municipalities will obtain permanent easements from oceanfront property owners within the project limits. The easements will grant access for construction and measurement, and will establish permanent rights for the public to cross lands above the mean high water line if those lands are created by filling operations financed with public funds.

Public Access to Beach Resources — Public access to the beach strand has been developed extensively by the Towns of Emerald Isle, Indian Beach and by Carteret County for the unincorporated area of Salter Path. As part of implementation of this project, the Town of Pine Knoll Shores is independently developing public access that will meet the USACE guidelines for public access to federally maintained beaches. Before construction begins, the county will require that all municipalities within the project limits meet the Corps of Engineer's guidelines for public access. In March 2001, the Town of Pine Knoll Shores secured oceanfront property that is improved to accommodate ~100 vehicles for the general public. This is consistent with a specific recommendation from the US EPA in a comment letter dated 13 April 2001 (reproduced in Correspondence Section).

4.6.4 Recreational and Scenic Areas

Construction of a ~100-ft-wide berm, dry beach area will enhance the beach by providing areas on the beach for activities during all tidal conditions. This is a benefit to Bogue Banks' communities which rely on the beaches and opportunities for beach activities to attract visitors.

The fall season is the peak period for surf fishing on Bogue Banks with activities tapering off during November and December. The beach restoration operations are scheduled to occur between the months of November and April. Surf fishing will not be limited along the beach except in the immediate vicinity of the discharge pipe and earthmoving equipment. Studies of recreational and commercial fisheries impacts in New Jersey (USACE–Burlas et al 2001) showed no significant change or decline in these activities as a result of a major nourishment project along 25 miles of the northern New Jersey shoreline. Some important fish species (such as kingfish) were attracted to the slurry discharge whereas others (such as bluefish) tended to avoid the discharge point.

4.6.5 Groundwater Quality

No action proposed as part of this project will have an impact on surficial or deep aquifer groundwater.

4.7 LITTORAL PROCESSES IMPACTS

4.7.1 Tides

Dredging borrow areas A, B1, and B2, and filling the beach between transects 8 and 77 will take place along the open coast, so no changes in tidal conditions will occur.

4.7.2 Hurricanes

Dredging the offshore borrow areas will not change hurricane surge levels, since surges are changes in water-surface elevations. The project will increase the shoreline protection from hurricanes because of the wider beach. A wider beach due to the project will protect dunes and lessen erosion by waves and surges generated by hurricanes. Currently there is very little distance between the base of the dunes and the water. In most reaches, peak monthly tides encroach on the toe of the foredune. During the 1999 hurricanes, the dunes on Bogue Banks retreated an average of about 15 ft, with some areas retreating more than 30 ft. In a few low-lying areas there was washover of the foredune and deposition in the swale between the first and second dunes. Since the toe of the dune is now close to the water, hurricane surge raises the water level sufficiently for waves to directly impact the dune toe and erode it away. Almost all areas of Bogue Banks have sufficiently high dunes to withstand 100-year surges. Existing narrow beaches allow waves to erode the toe, thus causing the entire dune to retreat, leaving vertical escarpments after storms.

4.7.3 Waves

Possible changes to waves caused by altering topography in the borrow areas was examined by use of wave shoaling models. The Wave Information Study database of waves from wind-wave models was used as a data source for the shoaling studies over borrow areas A, B1, and B2. Waves were shoaled over A, B1, and B2 for both existing and dredged conditions, with all results shown in Appendix G. The conclusions are: (1) there will be a temporary increase in wave heights for the sections of the island along the borrow areas of less than 1 percent or 0.1ft, and (2) error bars in the wave directional component of the database are very large. (The error can be seen in contradictory predictions of energy flux, depending on which versions of the WIS database are used.) Thus, error in the longshore energy flux predictions (used in estimating potential for longshore sediment transport) is many times larger than the model's predicted 8-9 percent increase in longshore energy flux caused by dredging the borrow areas. Any anticipated effects on wave changes are expected to be short-term and minimal.

4.7.4 Dimensions of Littoral Zone (Depth of Closure)

Appendix G analyzes the depth to which there is active motion of sediment. Different methods produced results varying between 13 and 30 ft below the mid-tide level (methods 1, 2, 4, and 6). Methods 3 and 5 were used to gauge the most extreme condition possible, the time of only a few hours duration when a hurricane was in the immediate vicinity and produces depth-limited waves of 7 meters. Methods 3 and 5 indicated seabed activity between 32 and 36 ft. Only during these extreme hurricane conditions does sediment move in the closest inshore borrow areas B1 or B2, and even then only in the most landward portion of the borrow areas. The conclusion is that sand in the borrow areas is not within the littoral system, but a relict of past events, such as lowered sea level and relict inlets. These results are further supported by beach profile surveys in June and September 1999 and June 2000 which generally show closure inside the –15 ft NGVD contour (CSE-Stroud 2001).

4.7.5 Littoral Transport

Effects of the dredging operation and the beach nourishment on longshore transport of sediment should be considered, since alterations in the transport patterns result in changes to the beach. The usual method for evaluating transport-pattern effects of topographic changes is to include the changes in a model which uses accurate measures of directional waves. Unfortunately, the usual data for computing the potential for long-shore sediment transport, measured directional waves, do not exist for this area.

As detailed in Appendix G on waves, the particular data set that was used for examining the effects of borrow-area dredging resulted in a 8-9 percent increase in longshore energy flux. However, comparisons of the different databases and their effects on littoral transport in Appendix G show that both direction and magnitude of transport are solely a function of which database is used. Thus error in the databases far exceed the numerical values of any predictions to the change in longshore energy flux.

The best indicator of effects of the nourishment on longshore transport is the behavior of the Corps' nourishment project at Atlantic Beach. When only one stretch of beach is nourished, there are often effects on the neighboring unnourished beaches. Usually the neighboring beaches receive benefits of nourishment sand moving out of the nourishment-project areas, regardless of whether they are on the net updrift or downdrift sides. The reason that updrift beaches also receive sand is that longshore transport occurs in both directions, at different times, and the beach is only updrift in a net-transport sense. Problems can occur, however, if the current patterns are so drastically altered that an already eroding neighboring beach suffers. There is some evidence (Roessler 1998) from detailed modeling of the current patterns at Atlantic Beach and Pine Knoll Shores that this has, in fact, happened. The obvious solution to such a problem is to not allow such drastic longshore variation in nourishment volumes, especially when a neighboring eroding beach receives no sand at all. The plan for the proposed project is to nourish all of the eroding unnourished parts of Bogue Banks, so this problem does not occur. The beach to the east of the proposed project (Atlantic Beach) is already nourished, and the beach to the west (Emerald Isle near Bogue Inlet) is slowly accreting (about 3 ft/yr). The project is expected to beneficially create a more uniform shoreline in terms of its recreational potential, storm protection, and beach habitat.

4.7.6 Erosion Rates

Uses of erosion rates in examining environmental impacts include:

- Erosion is one of the factors used in computing nourishment volumes, so the total impact to the borrow areas and nourishment areas depends on erosion rates.
- Erosion rates indicate how rapidly detrimental impacts of the "no action" alternative will affect the oceanfront properties, infrastructure, and tax base.
- After nourishment, erosion rates help to determine how long beneficial impacts will last, both for people, fauna, and flora (eg, increased dry beach width for turtle nesting).

The erosion rates summarized in Section 3 and Appendix G were one of the factors used to compute nourishment volumes for this project. The three components of the total nourishment volume are:

- *"Volume deficit"* is the sand needed to increase the beach volume up to some desirable level. The selected level for Bogue Banks is 175 cy/ft, which was the average volume in profiles of Atlantic Beach prior to 1999 hurricanes. The details of computing this volume goal are described in Section 3 and in the last section of Appendix G entitled "Beach Erosion Analysis Used to Determine Nourishment Requirement." This component is the largest volume of the three components.

- *"Advance nourishment"* is the volume determined from the erosion rates that is necessary to advance the beach enough to counteract the anticipated future erosion. Various scenarios were computed, and for this project, the ten-year protection was selected. This does not mean that in ten years the nourishment sand will be gone. Rather in ten years, the "advance nourishment" component of the project will be gone. That is, ten years after the project construction the beach will have eroded back to the still healthy Atlantic Beach-type volume of 175 cy/ft. Of course, if erosion is currently higher than the historical average, as some have argued, then the beach will erode back to the 175 cy/ft Atlantic Beach profile sooner than in ten years. The quality of historical data is inadequate to accurately predict the time over which advance nourishment will erode.

- *"Overfill ratio"* is a ratio of how many cubic yards from a borrow area will be needed to produce one cubic yard of material that matches the native beach sand. These ratios have been computed for the different borrow areas, so the total amount of material placed on a section of beach will depend on which borrow areas are used. Section 3 of this report details which borrow areas will be used and in what proportions.

Duration of beneficial impacts of the project (protecting oceanfront properties, providing a recreational beach, increasing habitat for beach fauna) depend on erosion rates. The erosion rates and selected nourishment volumes show beneficial impacts well in excess of ten years, since the "volume deficit" component of the project is the largest component. As an example, the central reach of Emerald Isle has erosion rates that are roughly average for the island. Duration of the project using a safety factor of two (to account for 100 percent uncertainty in computed erosion rates) is (10 yrs/2)(766,958 cy nourishment)/ (226,902 cy advance nourishment) = 17 years. (Note: This computation would be modified only slightly by modifications in the phasing and advance nourishment quantities detailed in Section 2.4 of this report.

4.7.7 Sediment Compatibility

The sediments on the beach are admixtures of sands and shell fragments. Mud has been winnowed out because it is unstable in the surf zone. Compared to fine sand beaches along the southern coast of North Carolina, Bogue Banks beaches have a much broader size distribution ranging from pockets of coarse, granular sediment in the step or lower beach face to fine sand in undisturbed foredunes and the outer bar. Seaward of the outer bar along the lower foreshore to about -30 ft, sediments are finer still as shown in Corps navigation studies for Morehead City Harbor and for disposal projects along Atlantic Beach (eg, USACE 1992, 1993). Sediments in borrow areas B1, B2, and A were, at one time, littoral sediments. They exhibit a similar gradation in sizes with the primary difference being a broader, flatter distribution because of the presence of slightly more shell and small percentages of mud.

The accepted standard for quantifying compatibility is the overfill factor, R_A (CERC 1984). This is a measure of how similar a borrow sediment is to the native beach. Section 3 reports R_A's for individual borrow samples ranging from <1.02 to >10.0 with means of about 1.15 in revised borrow area A, 1.58 in revised borrow area B1, and 1.50 in revised borrow area B2. As shown in Section 3, it is possible to obtain sediment that more closely matches the native sediment distribution in terms of grain size distribution, percent shell and percent coarser material by alternating excavations between borrow area A* and borrow areas B1 and B2 in proportions of approximately 1:2. This yields a composite R_A of about 1.3-1.35. Shell content for an example composite of 62 borings is approximately 32 percent (see Table 3.5 and Appendix E). A further advantage of the borrow areas chosen is the slightly broader size distribution than the native sediment. This is important from an engineering standpoint because it means the borrow sediment will be more stable and last longer, a primary goal of the project. Borrow areas with narrow size distributions will generally not perform as well even if the mean grain size matches the native sediment (USACE 1995a).

The example composite size distribution of 62 borings from borrow areas A, B1, and B2 is expected to be modified favorably after placement on the beach because of the following factors:

- Construction by hopper dredge (the 95 percent most probable dredging method) will eliminate nearly all mud before pump-out onto the beach (D. Hussin, Great Lakes Dredge & Dock, pers. comm., April 2001), thus shifting the mean grain size to a slightly coarser value.

- Shell material in the cores contains high proportions of friable thin shell (eg, *Donax* sp.) which is expected to be broken into smaller shell hash fragments in the swash zone, narrowing the size distribution.

- Natural sorting in the littoral zone of a broad distribution of sediments will maintain the distinct difference between the offshore bar (fine sand), beach face (medium to coarse sand and shell), and dune (fine sand). Presently, there are portions of the profile such as the horns of beach cusps containing >70 percent shell material.

Unlike some Southeast coast barrier islands, the native beach along Bogue Banks contains a broad size distribution. The proposed borrow areas have been selected to provide sediments that are compatible with the native beach.

As part of the postproject monitoring plan, the applicants plan to obtain yearly sediment samples from a minimum of six beach transects and conduct textural analysis for comparison with the prenourishment condition. Grain-size data will be prepared using the same methods and parameters reported herein for prenourishment samples. The results of these sediment tests will be included in annual monitoring reports of project performance and will be submitted to regulatory and resource agencies for review.

The USACE-Wilmington District has reviewed the geotechnical data for the project (memorandum dated 17 August 2001 from Ben Lackey to Mickey Sugg) and has concluded that the proposed borrow material is ". . . of a quality that would be recommended for U.S. Army Corps of Engineers beach projects."

4.7.8 Alteration of the Beach Profile

The shape and slope of beach profiles evolves in relation to wave energy and sediment grain size (Bascom 1951; Komar 1976). Tide range also plays an important role because it controls the elevations over which waves act on the profile. Where sediments are uniform across the foreshore, there tends to be less topography, particularly in the fine to very fine sand ranges. In settings like Bogue Banks, where there is a relatively broad range of sediment grain sizes, profiles tend to have more complex morphology. Bars and troughs are more common, and berms tend to be more mobile (Hayes 1976). By using a graded deposit of similar-sized sediments from borrow areas A, B1, and B2, the nourished profile is expected to adjust to a morphology similar to the existing beach. Nourishment will displace the profile seaward (including the offshore bar and trough) and not simply infill the trough as depicted on reference cross-sections in the permit application (Appendix A-2).

Evidence from other studies (eg, USACE 1995) suggest that if a narrow, borrow size distribution is used, the resulting profile will be more uniform. This is not what is desired for the proposed project because the existing profile contains complex cross-shore topography. The profile illustrations in the permit application are idealized to show the relative scale of the fill sections. These are easier to visualize than a complex profile that is expected to develop across the littoral zone to closure depth (approximately −30 ft NGVD) after the fill has time to equilibrate.

The applicants will conduct annual profile surveys of the beach and inshore zone to document the evolution and fate of the nourishment. Profiles will be compared with prenourishment surveys and evaluated for unit-width volumes, volumetric change, beach widths, slope changes, and longshore advection. Annual reports on the performance of the project will be prepared and submitted to the regulatory agencies.

4.7.9 Chemical Alteration and Cementation of the Fill Material

None of the sediments to be dredged and placed on the beach are highly reactive. While calcium carbonate material breaks down much faster than quartz and feldspar, the process is not rapid. Shell fragments from the borrow area generally require many decades to centuries to break down completely and dissipate from the beach. Meanwhile, new shell material is forming in situ through normal biological processes. Cementation is not likely to occur, because the fill will be placed within the active surf zone and will not contain high proportions of muddy material. Hydraulic fills have the advantage of producing a slurry that runs down the profile during construction. Fine-grained material is selectively sorted and winnowed in the surf during placement. Reports of sites (eg, Edisto Beach, SC, as quoted in USFWS correspondence dated 1 June 2001 to Col James W DeLony) where cementation may have occurred generally involved placement of unwashed sediments above the spring swash line. [Note: The problem at Edisto Beach was mitigated by bulldozing the berm seaward and leaving it at a lower elevation so that subsequent wave swash could rebuild the profile to a more natural configuration (CSE, unpublished data)] Hardpan is generally not a problem with hydraulic fills, which are placed without containment berms. To avoid future problems, compaction tests will be performed along the backshore, comparing with natural conditions and tilling the berms if compaction becomes a problem.

The postproject sediment and analysis that will be performed by the applicants are detailed in Section 4.12.7. Shell content will be measured as part of this effort following the same methodology as preproject sampling.

4.7.10 Alteration of the Borrow Area

The planned dredging depth is specified such that similar sediments will be left exposed below each cut. As noted on Figures 3.27-3.29, borrow areas B1 and B2 are dominated by fine sand but become coarser in the composite due to the presence of mixed sand and shell layers of varying thickness. Borrow area A is much more variable with surficial sediments ranging from fine sand to granular material. Underlying sediment at 2 ft is similarly variable such that the excavations in borrow area A will maintain a distribution of substrate sediments like the ones that presently exist at the surface. Diver observations indicate that intermittent patches of fluid mud exist and appear to migrate into and out of the proposed borrow areas. Of ~150 cores from the designated borrow areas, only three (B2-19, A-24, A-54) had a surficial layer (typically upper 0.3 ft) of soupy mud. Such unconsolidated mud is expected to dissipate quickly during excavations and wash out of the hopper or through the surf zone. Consolidated mud, by contrast, has the potential to form mud rollers during placement and produce chronic releases of clays as mud rollers are abraded. The proposed borrow areas have been chosen because they lack significant sections of consolidated clays (see Figs 3.27-3.29).

As part of the applicants' monitoring of the project, representative sediment samples will be obtained in the excavated sections of the borrow area at approximately 20 percent of the previously sampled stations in Years 1, 2, and 3 after construction. Samples will be analyzed and compared with the prenourishment condition to document changes in the substrate.

4.8 WATER QUALITY AND TURBIDITY IMPACTS

Temporary increases in turbidity are associated with both dredging operations and the washing of fine sediments by waves on the nourished beach. The applicants received a 401 Water Quality Certification on 23 March 2001. The certification references General Water Quality Certification Number 3274 as the applicable standard for the project.

Published measurements of turbidity during beach nourishments are rare. Reference (USACE 1993, p 6) is made to turbidity measurements for pipeline discharge of nourishment sediment on Atlantic Beach. Turbidity was a function of distance from the discharge pipe. Measurements ranged up to 250 NTUs in the vicinity of the pipe, but decreased rapidly with distance. That sediment pumped from Brandt Island had a much higher overfill ratio and mud percentage than the borrow areas proposed for this project, so turbidity is expected to be lower for this project.

A fairly comprehensive set of measurements was made for another project with mud percentages more similar to the one proposed here by Hanes (1994). Table 5 in that publication lists measured turbidities for times during and after nourishment and for both the project area and a control site uninfluenced by the nourishment. Turbidities were not measured in the immediate vicinity of the discharge pipe, but rather seaward of the breakers along the nourished stretch of beach. Values are listed for surface, mid-depth, and near bottom in the water column. The control site must have had slightly different conditions, because the after-nourishment numbers showed an average ratio of 0.6 of nourishment site to control site. (The nourished area had less turbidity than the control site well after construction.) But the numerical values were low for this post-construction period: 2.8 to 4.4 NTUs for the nourished area and 4.4 to 9.2 for the control site.

Natural turbidities are usually lower in Florida, where this study occurred, than they are in North Carolina. During construction the nourishment area showed turbidities averaging 50 percent higher than the control site, but again the numerical values were low, ranging between 4.6 and 7.5 NTUs in the nourishment area. These studies show that for turbidities associated with nourishment:

- Turbidities may be quite high in the immediate vicinity of discharge. However, the WQC standard pertains to "outside the area of construction or construction related discharge."

- Neither of the two studies showed turbidities exceeding 25 NTUs outside the discharge area.

- Outside the discharge area, but in the ocean along the same stretch of beach, turbidities increased about 50 percent, but the reported increases are less than 10 NTUs.

- Natural variation in turbidities associated with storms is larger than these increases outside of the discharge area.

Increases in sedimentation associated with nourishment are of concern because of possible impacts on benthic fauna. In the Hanes (1994) study sedimentation rates of fine sediments were compared between the nourished and control sites. The ratio of sedimentation rates between nourished and control was 0.8 before nourishment, 1.3 during, and 1.1 after. Numerical values were in the 15-25 mg/cm^2/day range for all sites. Statistical computations (the Binomial Sign test) which test for the probability that the observed differences were the result of random chance resulted in the conclusion (p 3029) that "there were no significant differences in fines sedimentation rates." Significant differences were observed in sand sedimentation rates, but the wave heights were one-third higher at the nourishment sites with 75 percent higher energies. That increased energy between the sites "is probably the reason for the relatively higher sand sedimentation rates."

Other anecdotal evidence suggests that the impact of the proposed project on turbidity will fall well within the natural range occurring along Bogue Banks in the surf zone and around the borrow areas.

The SEPA EIS for the project (CSE-Stroud 2001) did not elaborate on background turbidity off Bogue Banks because such information is highly site- and time-specific. Turbidity varies by several orders of magnitude and varies exponentially down the water column. A full accounting of suspended-sediment distribution is well beyond the scope of projects such as this. Based on diver observations during the collection of over 200 cores under fair-weather conditions (eg, seas at <4 ft), the following can be stated anecdotally:

- There was generally zero visibility at the bottom between the 15 ft and 30 ft contours (ie, landward of any borrow areas).
- Maximum visibility for any station sampled at any time at the bottom was no more than 15 ft.
- Typical visibility at the bottom was less than 2 ft.
- Visibility was greatest in borrow area A where a portion of the bed was floored with granular-shelly sediments and average depths are ~48 ft.
- The exposed surficial sediments off Bogue Banks between the 15 ft and 50 ft contours are highly variable and include areas with a nepheloid layer of soupy mud which is easily resuspended, areas with coarse granular material free of mud in the upper 1-3 ft, and areas with all sizes in between.
- Turbidity around the surf zone and inshore area has been observed by CSE personnel during beach surveys to fluctuate by orders of magnitude. Surface waters close to shore experience high turbidity events in storms and during periods of strong onshore breezes as evidenced by zero visibility and the chocolate brown color of the water. This is attributed primarily to resuspension of fines from the bed because there are no major rivers discharging nearby.

The sediments that will be released into the water column by dredging and nourishment are expected to be the same as occur naturally. They were once part of the active littoral zone when sea level was lower. They contain similar admixtures of sands, silts, clays, and carbonate material. Persistent turbidity results when discrete clay-sized particles are in suspension. Silt and fine sand have settling velocities orders of magnitude faster than clay. Clay-sized material will be a fraction of the "mud" fraction which will total an estimated 4 percent of the borrow material (see Appendix E).

Low percentages of mud are ubiquitous in the nearshore zone off Bogue Banks and account for the chronic resuspension during storms and large seas. The proposed project is not likely to produce permanent elevated turbidity levels because the amount of clay-sized material that will be mobilized by dredging an approximate 2.5-square-mile area is dwarfed by the volume of free mud on the ocean floor over other sections of the inner shelf in this locality. The applicant has chosen the borrow areas so as to avoid areas off Bogue Banks that have higher concentrations of mud on the sea floor.

It is possible to assess the relative magnitude of turbidity released by the project with the background levels by a simple volume accounting. Based on casual observations, high turbidity levels are observed to occur naturally as a result of resuspension of clays and silts at the bed. A typical suspended-sediment concentration one meter above the bed in zero visibility conditions is estimated to be approximately 1 gm/liter (1 kg/m^3). To produce this concentration over the 16.8-mile project area within 2 miles of the beach in the lower ~1 m of the water column would require ~2 million cubic meters of mud. The proposed project will release ~10 percent of this quantity in the form of mud. Because the source of mud released during nourishment is derived from the same source that produces resuspension, there will be no net change in mud content in the nearshore zone as a result of the project.

The mud that will be released during the planned excavation will be released incrementally, thus reducing its overall impact compared to resuspension of free mud in the nearshore zone. Therefore, mud released by the project is expected to make up only a small fraction of the total volume. Turbidity changes associated with the project are expected to be difficult to distinguish from the background suspended sediment load.

Other data on turbidity associated with beach nourishment are given in Burlas et al (USACE July 2001) for the northern New Jersey project conducted by the USACE-New York District. The results of measurements over six, 3-4 day periods in 1997 found:

- ". . . the effects of beach fill operations on short-term turbidity conditions appear to be limited to a relatively narrow swath (less than 500 m) of beach front."
- ". . . observed concentrations appeared to decline rapidly with dispersal through the surf zone."

- "The maximum NTU values measured near the fill operations do not appear to be outside the range that organisms would be exposed to during periods of high wave energies."
- Except in the immediate swash zone, "the magnitude of elevation (of turbidity) above ambient conditions appears to be negligible."
- "Measured TSS concentrations outside the swash zone seldom exceeded 25 mg/ℓ, which is comparable to concentrations that many of the dominant fish and invertebrate species of the northern New Jersey shore experience in estuaries."

NOTE: It is not possible to convert TSS units to NTUs with confidence because one is a direct measure (TSS) where the other (NTUs) is an indirect measurement dependent on site-specific calibration and detailed knowledge of the suspended sediment characteristics. For one study in Brevard County (Florida), Raymond and Antonius (1997) correlated average turbidity readings of 92 NTUs with TSS values averaging about 110 mg/ℓ (ie, approximately 1:1 correspondence).

Beach and Sternberg (1992) using OBS sensors estimated the mean background suspended sediment concentration 54 cm above the bed on an Oregon Beach to be ~500 mg/ℓ. Kana (1979) calculated the "washload" of suspended sediment (ie, particles <0.063 mm) to average less than 50 mg/ℓ on two South Carolina beaches near Charleston. Total suspended sediment (including sand-sized particles) fluctuated by three orders of magnitude (from ~50 mg/ℓ to 25,000 mg/ℓ) in the surf zone at Bulls and Capers Island (SC) under a variety of daily (nonstorm) conditions based on over 1,000 in-situ TSS samples. Kana and Ward (1980) found a similar three-order range of natural variations in total suspended sediment in the Duck (NC) surf zone under fair-weather and northeast storm conditions. These studies indicate the natural concentration of suspended solids in the surf zone greatly exceed the EPA criteria of 25 NTUs.

One study that does suggest turbidity can be higher during nourishment is Reilly and Bellis (1978). Based on only two TSS samples from the surf zone during nourishment at Fort Macon State Park (~6 miles east of the proposed project area), they found concentrations one order higher than a reference beach at Emerald Isle (~1.7 g/ℓ and 4.7 g/ℓ versus 0.10 g/ℓ and 0.09 g/ℓ). The authors noted these high readings may have been due to the presence of a high percentage of clay in the dredged material because it was derived from a channel-deepening project associated with the Morehead City navigation project. The sampling by Reilly and Bellis (1978) is considered inadequate to draw conclusions because it involved only four discrete samples.

Other research conducted by Schubel (1977), the Corps' dredging research program, and others show limited and short-lived increases in turbidity due to dredging. Schubel's studies were in the Chesapeake Bay where the dredged sediments were muddier. The consensus of studies to date regarding turbidity in the nearshore is that suspended sediment varies by orders of magnitude under the normal range of conditions and that "the spatial scales of elevated turbidity conditions associated with beach fill operations are relatively small (USACE-Burlas et al 2001).

The majority of the proposed project will be constructed over 5 miles from Bogue Inlet and 7 miles from Beaufort Inlet. Emerald Isle west is considered the least likely reach to be completed and will require the smallest fill sections given its condition (see Section 2 of this report). The project will leave a one-mile or greater buffer from the end of the project (Reach 1) to Bogue Inlet. This is expected to prevent a measurable rise in turbidity in Bogue Sound because of (1) the exponential decay in turbidity with distance from the nourishment discharge point and (2) the low percentage of mud in the borrow areas. Emerald Isle west (Reach 1) will introduce ~50,000 cy total mud into the water column out of about 1 million cubic yards scheduled for that reach. It is anticipated that the majority of this quantity will be returned to the borrow area during dredging operations because a hopper dredge will be required for that reach. (A pipeline dredge will only be economical if an alternate borrow area is located outside of borrow areas A, B1, or B2, such as the shoals of Bogue Inlet.)

4.9 NATURAL RESOURCE IMPACTS

4.9.1 Impacts to Offshore Resources

Fish, plankton, and other motile animals in the vicinity of the borrow areas during dredging are least likely to be affected during dredging, because of their ability to avoid the disturbed areas. Fish species have been observed to leave the area temporarily during dredging operations and return when dredging ceases (Pullen and Naqvi 1983). A study of nearshore borrow areas after dredging offshore of South Carolina revealed no long-term impacts to fisheries, both fish and planktonic organisms, as a result of the dredging (Van Dolah et al 1992). Creation of new habitat and the uncovering and suspension of food that attract fish during dredging have been attributed to dredging offshore borrow areas (Naqvi and Pullen 1982). Dredging of the bottom sediments in the borrow areas can be expected to attract fish over the short term (after the dredge leaves) as a result of suspension of bottom material. Impacts to fishery resources will occur with removal of benthic organisms (food source). These impacts are expected to be minimal with the recolonization (return) of the benthic organisms. Impacts to anadromous fish and other estuarine-dependent organisms are not expected to be significant or long term, since construction-related activities in the offshore borrow areas would be localized.

Benthic organisms in the immediate area being dredged will be largely eliminated during dredging. However, initial recolonization of the dredged areas by opportunistic species is expected to occur soon after cessation of any dredging activities. Further recovery is expected from recolonization from migration of benthic organisms from adjacent areas and by larval transport. Monitoring studies of post-dredging effects and recovery rates of borrow areas indicate that most borrow sites show significant recovery by benthic organisms approximately one year after dredging (Naqvi and Pullen 1982; Bowen and Marsh 1988; Van Dolah et al 1992; USACE-Burlas et al, 2001). To encourage recolonization by organisms from undisturbed substrates, the borrow areas will not be "swept clean." Undisturbed corridors will be left between dredge furrows such that an estimated 15 percent of borrow areas B1 and B2 and 33 percent of borrow area A will be available for recruitment. The proposed depth of excavation is 3 ft or less so as to minimize changes in the bottom topography.

4.9.2 Impacts to Special Aquatic Sites

Hard bottom is found offshore of Bogue Banks away from the borrow areas. The only hard bottom encountered was at two stations off western Emerald Isle (C18a1 and C18a2). A thin (<1 cm) veneer of silt was present at those sites and was easily resuspended. Because these areas did not contain beach-quality sand, they were abandoned in favor of more promising sites. The hard bottom detected is more than 20,000 ft from the Phase I reaches at Pine Knoll Shores and Indian Beach and about 4,500 ft off the central Emerald Isle reach in water depths greater than 30 ft. Excavations in the borrow areas will involve shallow dredge cuts so as to avoid any underlying hard bottom as documented by approximately 140 borings in the proposed borrow areas. Fill along the beach is not expected to produce any adverse impacts on hard bottom because of the distance offshore and the depth of water beyond the normal limit of littoral transport.

4.9.3 Impacts to Nearshore Resources

In view of the high mobility of fish, it is expected that fish will leave nearshore areas in close proximity to the nourishment on the beach. However, USACE-Burlas et al (2001) documented attraction to active construction areas by certain species such as kingfish on the New Jersey coast. Impact on fishing resources in the nearshore zone will be minimized simply by the fact that sand-placement operations will take place at any one location for only a few days and then move further along the beach. Short-lived increases in turbidity will occur during the fill placement operation (a few days at each location) and will alter the water column conditions sufficiently that it causes most mobile species to leave the area. Return is expected to be rapid. Studies have found that speed of return of mobile species is more dependent on the return rate of their prey than on the rapid return of normal turbidity levels.

4.9.4 Impacts to Intertidal Resources

Impacts on intertidal macrofauna in the immediate vicinity of the nourishment project are expected as a result of discharges of nourishment sediment on the beach. A study by Reilly and Bellis (1983) was conducted on Bogue Banks and is used as a seminal study on beach projects throughout the southeastern United States. "The Ecological Impact of Beach Nourishment with Dredged Materials on the Intertidal Zone at Bogue Banks, North Carolina" concluded that beach nourishment virtually destroys existing intertidal macrofauna, but that recovery is rapid once the pumping operation ceases. In most cases, recovery occurs within one or two seasons following the sediment placement. Reilly and Bellis stated, ". . . a speedy recovery largely depended on recruitment from pelagic larval stocks." Most species fell into this category. The few that did not, and recruited instead from neighboring beaches, were slower to recover. Recent Florida, South Carolina, and New Jersey studies of nourishment impacts suggest that beach recovery rates are typically measured in weeks to months rather than months to years (RK Van Dolah Aug'99, pers comm). The New Jersey experience is documented in USACE-Burlas et al (2001) who found that benthic populations generally recovered to predredging conditions in 2-6 months. The South Carolina experience is documented in Jutte et al (1999).

4.9.5 Impacts to Beach and Terrestrial Resources

The project will introduce new sediments to the littoral profile seaward of the base of existing dunes and escarpments. Therefore, it is not expected to have an adverse impact on dune and terrestrial resources. It will add beach-quality sediment to the existing beach profile and mix with native sediment under normal littoral processes. Placement by hopper dredge is expected to reduce the percentage of mud below the average of ~4 percent that occurs in borrow areas prior to discharge on the beach. Fine-grained sediments will be further sorted during placement and subsequent fill adjustment with most washing seaward into the surf zone in the slurry discharge. Upon completion, the dry beach will provide fine sand for aeolian transport and natural nourishment of the foredune.

Project construction will result in disturbance and removal of some of the existing vegetation along the seaward side of the existing dune. Dune stabilization with vegetative planting will take place only in the isolated sections of the project where new dunes are built. Most of the project has vegetated dunes. The project is intended to widen the base of the dunes and the beach face, not build up the dune itself. Thus, replanting makes sense only for those areas where new dune will be built. The Reilly and Bellis (1983) study that focused on the intertidal zone also encompassed dry-beach sampling. Most species, including all of the larger organisms such as crabs, recruited from pelagic larvae and thus recovered rapidly (one or two seasons). The project will provide beneficial impacts in the form of creation of additional dry beach and foredune habitat.

4.10 THREATENED AND ENDANGERED SPECIES IMPACTS

In accordance with the requirements for federal review of the proposed project, the following section has been prepared. Threatened and endangered species for eastern North Carolina are given in North Carolina Heritage Program data and in Wynne (1999) for species migrating along the coast.

The presence of threatened and endangered species in the project area depends on the availability and abundance of appropriate habitat. Because the Bogue Banks nourishment project area does not contain any freshwater or forested areas, the eastern cougar, American alligator, red-cockaded woodpecker, and roughleaf loosestrife are not likely to be found at this site and will not be affected by the proposed actions.

Listed species that could potentially be located at Bogue Banks during the proposed action are the finback whale, humpback whale, right whale, sei whale, sperm whale, West Indian manatee, piping plover, roseate tern, green sea turtle, hawksbill sea turtle, Kemp's ridley sea turtle, leatherback sea turtle, loggerhead sea turtle, and seabeach amaranth.

Species assessments follow.

4.10.1 Right Whale, Finback Whale, Humpback Whale, Sei Whale, and Sperm Whale

Effect Determination – Of the five species of whales being considered, only the right whale and humpback whale would normally be expected to occur within the project area during the construction period. Therefore, the other species of whales are not likely to be affected. Since sections of this beach area have received fill material in the past, this project will not significantly alter nearshore physical conditions. While some food resources may be initially affected by either dredging activities or burial associated with the beach nourishment, most invertebrates are expected to reestablish quickly from adjacent unaffected areas or through recruitment processes. Furthermore, the presence of a hopper dredge in this area should pose no more of a collision threat to migrating whales than normal commercial ship traffic. As prescribed in the NMFS 26 July 2001 and the September 1997 Regional Biological Opinion to reduce the potential for accidental collision, a whale observer with at-sea large whale identification experience will be present on the hopper dredge from the beginning of hopper dredge use through April 30 to conduct daytime observations. Because habitat conditions and food supplies will be maintained in their current states and the potential for accidental collisions with hopper dredges will be minimized, it has been determined that the proposed project is not likely to adversely affect these whale species.

4.10.2 West Indian Manatee

Effect Determination – Because the proposed dredging work is currently scheduled to occur during the time of year when manatee populations are expected to be minimal, it is unlikely that there will be any manatees in the project area during the proposed project. Therefore, it has been determined that the dredging of the borrow areas and the subsequent beach nourishment are not likely to adversely affect the West Indian manatee. All conditions as prescribed in the NMFS Regional Biological Opinion (September 1997) will be implemented to insure protection of these species.

4.10.3 Piping Plover

Effect Determination – Within Bogue Banks, only the west end of Emerald Isle has been documented to support piping plovers. This area is not located within the project boundaries and will not be affected by beach nourishment or dredging activities. Therefore, the proposed project is not likely to adversely affect the piping plover. After the project, some nourishment sand is expected to migrate west into the Bogue Inlet area and contribute to the maintenance and possible enhancement of sandy spit habitat. Thus, the project could benefit this species by potentially expanding plover habitat over the ten-year life of the project.

4.10.4 Roseate Tern

Effect Determination – The roseate tern has never been observed within the project site. Bogue Banks is most likely too large and too developed an island to provide appropriate habitat for the roseate tern. Additionally, when the tern is observed in North Carolina, it is mostly during summer months, when the project is not scheduled to occur. Therefore, the project is not likely to affect the roseate tern.

4.10.5 Hawksbill, Leatherback, Kemp's Ridley, and Green Sea Turtles

Effect Determination – The hawksbill, leatherback, and Kemp's ridley sea turtles do not regularly nest along North Carolina coasts. The green sea turtle nests sporadically in North Carolina but has not been observed nesting in the project area. Therefore, beach nourishment activities are not likely to adversely affect any of these sea turtle species. However, all of these species migrate within North Carolina waters throughout the year, mostly between April and December. Hopper dredges will be used to dredge material from borrow areas located within these migratory waters and transport it to the shore. Construction activities are planned to occur between November and April to avoid the majority of nesting and migrating turtles. However, because turtles may be found in the offshore area within this time period, dredging activities may occur during moderate levels of sea turtle migration.

Hopper dredges move rapidly over the bottom sediments and can injure or kill juvenile turtles lying on the sea bottom. To prevent adverse effects to these species, all precautionary measures and conditions prescribed in the Regional Biological Opinion (25 September 1997) will be implemented pursuant to Section 7 of the ESA under NMFS purview. Observers will be on hopper dredges for the periods prescribed by NMFS to document any takes of turtle species and to ensure that turtle deflector dragheads are used properly.

4.10.6 Loggerhead Sea Turtle

Effect Determination – The proposed project could potentially affect loggerhead sea turtles in three ways. First, dredging activities proposed to occur offshore may occur in areas used by migrating juveniles. The act of dredging material with a hopper dredge may adversely affect juvenile turtles. Second, nourishing the beach with the fill material may affect nesting activities by altering nesting habitat. If the beach becomes too hard through the compaction of deposited nourishment sediments by construction equipment, it could present a physical barrier to turtle nest digging. Furthermore, beach nourishment may influence physical characteristics of beaches such as sand-grain size and shape, silt-clay content, sand compaction, moisture content, porosity/ water retention, gas diffusion rates, and color of sand grains which could alter the temperature of the beach. These factors could reduce reproductive success of nests laid in nourished areas (Crain et al 1995, Ackerman 1996). The applicants plan to alleviate impacts to nesting sea turtles in the project area by implementing steps that are now common practice or commonly listed as conditions on permits (to be determined by regulatory agencies), such as sediment quality monitoring, compaction tests, leveling scarps in the fill, and monitoring for nests. The third way the project could potentially affect loggerhead sea turtles is by increasing the area of stable dry beach (nesting habitat) and reducing the frequency of dune escarpments and beach scraping.

With the implementation of NMFS conditions during aquatic measurements and USFWS conditions when on land, loggerhead species are not expected to be adversely affected by this project. By planning to perform the majority of the project during off-season months, monitoring beach hardness, and relocating nests found in unsuitable habitat if project completion delays occur, impacts to nesting loggerhead sea turtles will be minimized. In addition, NMFS and ACOE hopper dredge protocol will be followed to minimize impacts to migrating loggerheads caused by dredges. However, because of the possibility of missing a sea turtle nest during the nest monitoring program, inadvertently breaking eggs during relocation, or injuring a migrating loggerhead with a hopper dredge, it has been determined that the project is not likely to adversely affect the loggerhead sea turtle.

Turtle Sightings Addendum – Records of public offshore sightings of various turtle species are maintained for Onslow and Raleigh Bays by the National Marine Fisheries Service in Beaufort, North Carolina. Records of public sightings were provided by Joanne B. McNeill and are given in Appendix E (Table 1) of the biological assessment report (CSE 2001) for the period April 1988 to April 2001. There were 1,233 recorded offshore sightings of sea turtles at various life stages, sizes, and species during the period of record. A summary of Onslow Bay sightings by month is listed below. The asterisk indicates dredging month for beach nourishment.

Month	No. of Sightings	Month	No. of Sightings
Jan*	0	Jul	84
Feb*	18	Aug	108
Mar*	12	Sep	79
Apr*	69	Oct	127
May	445	Nov*	103
Jun	173	Dec*	15
		TOTAL	**1233**

Reports of observed, estimated stranded lethal take levels of sea turtles at various life stages show that, by a considerable margin, trawling activities result in the highest levels of sea turtle mortality. Dredging and channel maintenance activities by the Army Corps of Engineers over the period evaluated accounted for the takings of 100 turtles in the Atlantic region. Comparatively, trawling accounted for 14,450 takings in the Atlantic and

Gulf of Mexico regions (NOAA 2001, Table 2 of Appendix 2). No data are provided for takings resulting from beach nourishment and other beach disturbing activities. Table 2 of the referenced NOAA report is provided in Appendix E of the biological assessment report (CSE 2001). It is the intent of this project to follow the same protocol for turtle protection employed by the Corps of Engineers for dredging and channel maintenance projects. Following that protocol and performing the proposed work in the period indicated should result in a similar conservative impact to both offshore and beach bound turtle populations.

4.10.7 Shortnose Sturgeon

Effect Determination – It is unlikely that the shortnose sturgeon occurs at the offshore dredging sites (F. Rohde 2000, pers comm; 26 July 2001 letter by NMFS). However, should it occur, its habitat would be only minimally altered by project construction and maintenance. This species feeds on a wide variety of invertebrates and while some food resources may be initially affected by either burial associated with beach nourishment, most invertebrates will quickly reestablish from adjacent unaffected areas or through recruitment processes. Although hopper dredges have been known to impact shortnose sturgeons, this species is not likely to be present in the project area and, therefore, impacts from dredges are not anticipated to occur. Because of the unlikelihood of shortnose sturgeon being present in the project area and because of the precautions being taken with the hopper dredges, it has been determined that the actions of the proposed project are not likely to affect the shortnose sturgeon.

4.10.8 Seabeach Amaranth

Effect Determination – Since dredging of the borrow areas will be done offshore, no impacts to amaranth plants will occur from this action. Furthermore, since beach nourishment will occur in winter months, when amaranth exists as seeds, immediate impacts from filling will be reduced. However, deeply burying existing seeds could negatively affect the amaranth population in later seasons. Assuming that seeds are located in the general position of former parent plants observed in past surveys, they may be covered by proposed beach nourishment activities. Research on the consequences of beach nourishment to amaranth seeds is somewhat inconclusive. The USACE (1995b) found that amaranth at Masonboro Inlet was more abundant in areas that recently received dredged material. In addition, 1995 survey data from the NC Natural Heritage Program found a section of Bogue Banks that was used as a disposal zone in 1994 had an increase in population from 100 to 7300 plants. Dredging activities could uncover buried seeds and allow them to germinate in deposited areas. (This benefit is unlikely to occur during this project if dredged material is supplied from areas offshore that do not contain amaranth seeds.) In contrast, Hancock (1995) concluded that amaranth seedlings generally do not emerge from depths of sand greater than 1 cm. Therefore, the added sand may be detrimental if placed on top of seeds. However, the beach nourishment that is to take place along the coast of Bogue Banks will occur on areas suffering from erosion and should ultimately expand potential habitat for the plant species.

The USACE has instituted a long-term seabeach amaranth monitoring program at every beach in North Carolina which routinely receives dredged material from federally funded projects. The program is to be conducted until such a time that enough data are available to allow a reasonable prediction of the actual impacts of each planned disposal action on the species in the future. After this beach nourishment project is complete, the project area will be monitored by the applicant to see if and where seeds survived. Within a few monitoring seasons, these data will help predict ultimate impacts of beach nourishment on amaranth at Bogue Banks and will be made available to the Corps' monitoring program. The project is not likely to adversely affect seabeach amaranth, provided measures as stated in USFWS letter dated 20 September 2001 are followed.

4.10.9 Summary Effect Determination

This assessment has examined the potential impacts of the proposed project on listed species of plants and animals which are, or may be, present in the project area. Both primary and secondary impacts to habitat have been considered. With the implementation of NMFS conditions during aquatic measurements and USFWS conditions when on land, it has been determined that the project is not likely to adversely affect the hawksbill sea turtle, leatherback sea turtle, Kemp's ridley sea turtle, green sea turtle, loggerhead sea turtle, and seabeach amaranth.

4.10.10 Summary of Protective and Mitigative Measures

To minimize impacts to nesting sea turtles and vegetative-stage seabeach amaranth, work is planned to occur during the winter months with contingencies in place for project completion beyond this period. Furthermore, sand will be placed in areas suffering from erosion, minimizing impacts to suitable sea turtle nesting habitat and expanding potential habitat for seabeach amaranth. All material will be monitored to determine beach hardness and areas where the post-disposal beach is harder than 500 CPU's will be tilled.

If any work on the project occurs between May 1 and 1 November, a beach monitoring and nest relocation program for sea turtles will be implemented. This program will include daily patrols of disposal areas at sunrise, relocation of any nests laid in areas to be impacted by fill placement, and monitoring of hatching success of the relocated nests. Sea turtle nests will be relocated to an area suitable to both the USFWS and the NC Wildlife Resources Commission's Sea Turtle Coordinator.

To reduce impacts from hopper dredges to whales, fish, and sea turtles that may be in the area of proposed dredging, NMFS and ACOE hopper dredge protocol will be followed. An observer will be present on the hopper dredge to document any takes of sea turtle species, except when water temperatures are cold enough to ensure that sea turtles will not be present (during January and February), to watch for and alert the dredge operator of whales in the area (from the beginning of hopper dredge use through March 31 for daytime observations), and to ensure that turtle deflector dragheads are used properly. Limits on take set by the USACE will be strictly followed.

Based on existing biological opinions for beach nourishment and discussions with federal resource agencies between May and August 2001, it is anticipated the following monitoring of the project will be performed.

1) *Condition Surveys* – Profile surveys for volumetric erosion changes to -15 ft NGVD or closure depth – pre and post dredging; annually for minimum for five years; ~100 profile lines.

2) *Environmental Sampling Surveys* – Borrow areas and beach as proposed by CSA plan 23 August 2001 with revisions as required by resource agencies (see Section 5.0 and Appendix A-4).

3) *Seabeach Amaranth Surveys* – Annually for minimum of 3 years in July/August.

4) *Beach Compaction Tests* – Annually prior to 1 April at 500 ft spacing along upper beach (two or three positions along profile), three replicates each at 6-inch, 12-inch, and 18-inch depths via cone penetrometer. Tilling will be performed if measurements exceed USFWS compaction criteria (typically 500 psi).

5) *Sediment Sampling* – Annual postnourishment beach and borrow area sampling at ~15 stations to compare post dredging/beach fill sediment quality with predredging condition.

6) *Turtle Nest Monitoring* by community observers (ongoing in season) to document numbers and success rates of nests/hatchlings.

4.11 VISUAL IMPACTS

The proposed project will improve the aesthetic quality of the Bogue Banks shoreline by widening the recreational beach, reducing the frequency and need for beach scraping, and allowing natural dunes to develop and become vegetated. The nourishment will decrease the slope of the land between the existing foredune and the low-tide line, thus softening the edge along the coast. Native vegetation is expected to propagate down the face of the dune over time as the dunes are fed finer sand compared to that which has been scraped into place after storms over the past five years.

Construction activities will detract from the natural vistas and provide temporary disruption over ~1-2 mile reaches at any given time. Upon initial placement, sediments from the ocean bottom will be darker than the existing beach. Experience indicates that sediment mixing and bleaching to the natural colors of sand and shell material will occur rapidly over the course of several weeks.

4.12 CONSTRUCTION IMPACTS

4.12.1 Air Quality

Discharges of pollutants into the air will occur as a result of the operation of dredging equipment offshore and earth moving equipment on the beach. The discharges will be temporary and localized and are not expected to result in any significant impact to ambient air quality standards along Bogue Banks or in Carteret County. The emissions from the portion of the project authorized by this permit fall below prescribed *deminimus* levels and, therefore, no Clean Air Act conformity determination is required.

4.12.2 Noise Levels

Dredging equipment in the ocean and earthmoving equipment on the beach will result in increased noise levels in the vicinity of the equipment during beach building operations. Beach filling and shaping operations will progress down the beach at a rate of about 500 ft per day ensuring that no single location will experience increased noise levels for more than several days.

4.12.3 Hazardous Materials and Waste

No action proposed as part of this project will cause an intentional discharge of hazardous materials or general waste into the environment. Insignificant discharges of hazardous substances could possibly occur as a result of operation of mechanical equipment on the dredging platform or by earthmoving equipment operating on the beach. State and federal regulations place a high burden of responsibility on the owner and operator of such equipment to prevent hazardous discharges. Regulations for reporting and dealing with discharges are administered by the US Coast Guard. As part of their normal operations, Coast Guard personnel will conduct safety inspections of vessels and equipment operating in the coastal waters. Those inspections include identification of possible discharges of hazardous substances. Contractors will be required to dispose general waste according to existing laws and regulations of the local municipalities, Carteret County, the State of North Carolina, and the United States.

4.13 CUMULATIVE IMPACTS

The Council on Environmental Quality (CEQ) defines cumulative impact as:

> *the impact on the environment which results from the incremental impact of the action when added to other past, present and reasonably foreseeable actions regardless of what agency (Federal or non-Federal) or person undertakes such other actions. Cumulative impacts can result from individually minor but collectively significant actions taking place over a period of time.* 40 CFR 1508.7

This assessment of cumulative impacts of the proposed action is based on recent analyses by the USACE for the proposed Dare County (NC) nourishment project. It will first focus on impacts of dredging from the proposed ocean borrow sites, and second on impacts of placement of sand material on the beach.

This assessment is also based on review of an Environment Report prepared for and published by the U.S. Department of the Interior, Minerals Management Service, entitled "Use of Federal Offshore Sand Resources for Beach and Coastal Restoration in New Jersey, Maryland, Delaware, and Virginia," dated November 1999 (DOI 1999). The potential cumulative impacts of dredging operations for beach nourishment can be considered with respect to time-crowded perturbations, and space-crowded perturbations, as defined below.

- Time-crowded perturbations – repeated occurrence of one type of impact in the same area.
- Space-crowded perturbations – a concentration of a number of different impacts in the same area.

4.13.1 Dredging Impacts

With dredging offshore areas for beach nourishment sand, there is a concern for potential cumulative impacts as a result of repeated dredging in the borrow area within short periods of time such that the benthic community, in particular, may not have sufficient time to recover. Dredging in subsequent areas close to one another may result in impacts to potential adult recruitment to the dredged area, further lengthening recovery time (DOI, 1999).

4.13.1.1 ***Site-Specific Impacts*** – Plans for potential use of borrow sites A, B1 and B2 for project construction are shown on Figures 2.1, 3.25 and 3.26. Under the proposed plan all borrow areas (2810 acres available) would be used up to three times during cold-month construction windows only. Only a portion of the available area would be dredged for the project construction, directly impacting about 1650 acres (2.58 square miles). Dredging would be conducted over three phases (yearly dredging windows). The impacts of this activity on ocean invertebrates are discussed in section 4.9. Assuming that the borrow areas are not impacted after three phases are complete by continued dredging, unusually high sedimentation rates, or some other disturbance, a natural succession of species composition should occur, potentially restoring the area to its original levels of abundance and biomass within 1-2 years (Jutte et al 1999; USACE-Burlas et al 2001).

Excavation, performed in three phases, would average about 550 acres per year over a three year period. There will be no subsequent maintenance dredging under the proposed project. Assuming a two year recovery period, an estimated 50% of the dredged area (~825 acres) may experience time-crowded perturbation for the anticipated three-season dredging period. After completion of the project, this would no longer produce cumulative impacts.

4.13.1.2 *Local Impacts* – Cumulative impacts from space crowded perturbations would occur at a local scale, resulting from the use of A, B1 and B2 for project construction. Based on a 3-Year construction schedule, the largest area of effect would be at year 2002 when 700 acres (42.4% of project area in Phase I) are in recovery. After 2002 the area in recovery would range between 295 (Phase II) and 483 acres (Phase III).

4.13.1.3 *Statewide Impacts*

Existing Sites – There is only one existing North Carolina ocean borrow site. It is located in the nearshore ocean off of Kure Beach (about 70 miles South). Dredging requirements are about 766,000 cy every three years. Assuming that the addition of the proposed project would cause an increase in impact area apportioned over the 3-year construction period of the project,(~550 acres/year),the cumulative impact area from space crowded perturbations statewide is estimated to be about 800 acres, then decline to ~255 acres/year after year three.

Potential Sites – The USACE-Wilmington District is in the early reconnaissance planning stage of the Dare County Beaches (Hatteras to Ocracoke portion) Study. While no details are available at this stage and any assumptions are highly speculative, consideration of potential beach nourishment that may come from this study was considered prudent for a worst case assessment. Public concerns have identified
6 "hot spots" of beach erosion where potential beach nourishment is proposed. It is assumed for this analysis that 10 miles of beach nourishment could occur as early as 2008. This project could cover about 70% of the beach area (14.2 miles) proposed for the Bodie Island portion of the study area with a resulting use of approximately 260 acres annually for borrow.

4.13.1.4 Project Vicinity Impacts

There are no known similar projects within a ~50 mile radius of the project area.

The following tables graphically illustrate the relationship of the proposed borrow areas to the available habitat in the area. The available habitat area is estimated by multiplying the shoreline length of the area of consideration, by the distance from the shore of the offshore limit of proposed borrow areas. It is recognized that other methods could be used to establish an area of available habitat, but this method is considered to be both reasonable, and conservative, given the broad geographic range of the species discussed.

Local Cumulative Impact Area (A, B1 & B2)

Impact Area		Available Habitat			% Impacts	
Proposed	Potential	Shoreline length	Offshore Extent	Area-Acres, Square Miles	Proposed	Potential
1650 acres (2.58 sq. mi.)	0 acres (0 sq. mi.)	16.8 miles	3 miles	32,400 ac. (50 sq mi)	5.1%	0%

Project Vicinity Cumulative Impact Area (~50 mile radius) A, B1, B2
Ocracoke Island to North Topsail Beach

Impact Area		Available Habitat			% Impacts	
Proposed	Potential	Shoreline length	Offshore Extent	Area-Acres, Square Miles	Proposed	Potential
1650 acres (2.58 sq. mi)	0 acres (0 sq.mi)	100 miles	3 miles	192,000 ac, (300 sq.mi.)	0.9%	0%

Statewide Cumulative Impact Area
Kure Beach NC, Dare County (Hatteras to Ocracoke)

Impact Area		Available Habitat			% Impacts	
Existing & Proposed	Potential	Shoreline Length	Offshore Extent	Area-Acres,Square Miles	Existing & Proposed	Potential
2096 acres (3.28 sq. mi)	706 acres (1.1 sq.mi)	320 miles	3 miles	614,400 acres (960 sq mi)	.3%	0.1%

4.13.2 Summary of Dredging Impact on Significant Resources

Based on comments from resource agencies including National Marine Fisheries Service, Fish and Wildlife Service, NC Division of Marine Fisheries, NC Marine Fisheries Commission and others, the primary concern with the proposed use of the offshore borrow sites A, B1 and B2 is the potential for adverse impacts on important commercial fish species. The concerns are given in the correspondence section and include potential impacts to benthic food sources, impacts due to turbidity and impacts due to altered substrate.

The following EA sections describe potential impacts associated with this and other similar projects that are pertinent to this analysis.

3.14 Marine Resources
4.0 Environmental Impacts
4.7.7 Sediment Compatibility
4.8 Water Quality and Turbidity Impacts
4.9 Natural Resource Impacts
4.9.1 Impacts to Offshore Resources
4.9.2 Impacts to Special Aquatic Sites

4.9.3	Impacts to Nearshore Resources
5.0	Environmental Commitments and Mitigation
App A-1	Correspondence
App C	UNC-IMS Environmental Monitoring Study
App D	Essential Fish Habitat Report

Concern for fish species has been raised regarding turbidity, entrainment and other impacts related to operational activities. These impacts are discussed in the EA sections listed above, and were considered in preparation of this cumulative impact analysis. Of particular concern to the agencies is a cumulative degradation of habitat with an associated loss of benthic food resources. These are primary issues addressed in this analysis.

Resource Threshold Levels – There are no known and established thresholds regarding the extent of ocean bottom that can be disturbed without significant population level impacts to fisheries. Therefore, a comparison of cumulative impacts to established thresholds is not made. It is clear from the above analysis however, that the potential impact area is small relative to the area of available similar habitat on a local, vicinity and statewide basis. It is expected that there is a low risk that the direct and cumulative impacts of the proposed action and other known similar activities would reach a threshold with potential for population level impacts on important commercial fish stocks. The following discussion provides support for this conclusion.

The DOI (1999) reports that

> *The pelagic/anadromous fisheries include those marine species that are free-swimming or highly migratory and therefore can avoid the areas of dredge activity. Direct impacts to this fishery could result from noise, entrainment, gill clogging, depletion of benthic food sources, and loss of relict shoal areas that may be utilized as navigation points for some migratory marine species (T. Goodger, NMFS, pers. comm., April, 1999). The importance of benthic communities in marine food webs leading to exploitable yields of pelagic and anadromous fish is widely recognized. Decimation of benthic community populations could result in a depletion of food source for the pelagic species (e.g., red drum, weakfish, silver hake) that rely on these organisms for sustenance (Newellet al. 1998a). Yet, the mobility of these fish species enables them to avoid the dredging operational areas and obtain food sources in other unaffected forage areas incurring insignificant adverse impacts to the fishery (T.Goodger, NMFS, pers. comm., April, 1999). There is also evidence that dredging operations may benefit fish species that feed within the water column by suspending food material (Courtenay et al. 1972). Bordering regions of dredge activity could provide suitable fishing grounds due to the resuspension of food particles. Spawning, egg dispersal, and juvenile development for these species occurs inshore and away from the study area resulting in minimal impacts to the stresses already imposed upon future stock abundance.*

This is further supported by recent studies in New Jersey by the USACE Burlas et al (2001) report that certain species (eg kingfish) were attracted to the dredge slurry in New Jersey, whereas others (eg bluefish) tended to avoid areas where active dredging was occurring. In regard to physical habitat alterations it is expected that alterations in depths and bottom sediment will be minor for the proposed project because of the shallow depth of excavations and the fact that the underlying sediments closely match the surficial sediments. The election to restrict dredging to shallow cuts results from indications in other jurisdictions that recovery rates of benthic organisms in borrow areas tend to be more rapid compared with deep cuts (Dr. RK Van Dolah, SC DNR, pers comm, August 1999). Site modifications are expected to be within the range of tolerance by the species utilizing the areas and, although man-altered, consistent with natural variations in depth and sediment within the geographic range of the wintering grounds and EFH for these species.

It is acknowledged that some uncertainty regarding these potential impacts exists and therefore the proposed project plan includes preconstruction and postconstruction monitoring. The details of the monitoring plan are given in Appendix A-4 and are being developed in coordination with the concerned fisheries agencies.

4.13.3 Beach Impacts

Three major sources of beach impacts are considered in this cumulative assessment. These include local maintenance activities, disposal of dredged material from navigation projects and disposal of dredged material from offshore borrow areas for beach nourishment.

4.13.3.1 *Local Maintenance Activity*

Under the existing condition the project area is subjected to repeated and frequent maintenance disturbance by individual homeowners and local communities following major storm events. These efforts are primarily made to protect adjacent shoreline property. Such repairs consist of dune rebuilding using sand from beach scraping. Limited fill and sandbags are generally used to the extent allowable by CAMA Permit. Such activities occur not only in the project area but also along all other developed North Carolina beaches. These frequent maintenance efforts could keep the natural resources of the barrier island ecosystems from reestablishing a natural equilibrium with the dynamic coastal forces of the area.

4.13.3.2 *Beach Disposal*

Throughout North Carolina, maintenance dredging of navigation channels places sand along the state's shoreline. The placement of such material occurs within the 320 miles of beachfront along the North Carolina coastline. Maintenance activities are summarized below by mileage and maintenance schedule. The summary differentiates between beach disposal and nourishment. This breakdown is necessary to delineate between material placed in the swash zone versus on the upper beach and dune system. Calculations are based on estimated actual mileage used during any given disposal event. For instance, an approved 5-miles of ocean beach may be designated for disposal; however, during a given event only 0.4 to 1 mile of beachfront may be impacted. The assessment is made based on a 16-year period (2000-2015) and area impacts are discussed relative to the total length of North Carolina shoreline habitat available (320 miles).

Federal navigation projects have specific dimensions which are set by their authorizing documents and which remain constant until such time as their authorizations are modified through acts of Congress or specific authorities delegated to the Chief of Engineers. However, natural accumulation of sediment in the channels and harbors of these projects reduces their effective dimensions and impairs safe, predictable, and economic navigation. Therefore, maintenance dredging must be accomplished periodically in order to remove the shoals and restore the dimensions. Amounts of shoal material vary from year to year in response to the forces of nature, so dredging and disposal quantities and disposal lengths will vary likewise. Lengths reported are based on normal conditions.

Beach quality sand is a valuable resource that is highly sought by beach communities to provide wide beaches for recreation and tourism, as well as to provide hurricane and wave protection for public and private property in these communities. When beach quality sand is dredged from navigation projects, it has become common practice of the USACE to make this resource available to beach communities, to the maximum extent practicable. Placement of this sand on beaches merely represents return of material which eroded from these beaches, and is, therefore, replenishment with native material. The design of beach placement sites is very simple, generally starting at the high tide line and proceeding seaward, with a crest elevation not exceeding mean high water. Widths of beach placement zones generally reflect the wishes of the local government relative to the choice between a long, narrow beach or a shorter, wider beach.

4.13.3.3 *Beach Nourishment*

The proposed project is considered a typical beach nourishment project, although the length is greater than existing North Carolina projects. The impacts of the proposed project are littoral processes impacts discussed in Section 4.7. The impacts of beach disposal on other North Carolina beaches are considered to be similar to those described herein. The degree of cumulative impact would increase proportionally with the total length of beach impacted.

The North Carolina ocean beach (320 miles) can be divided based on the potential that a beach nourishment project will be proposed for various reaches. The Coastal Area Management Act (CAMA) applies to all North Carolina Coastal Counties. Proper beach nourishment or disposal or local maintenance as described above is generally regulated under CAMA and Corps permitting authorities alone, and for this analysis, are labeled CAMA protected. Approximately 37 percent of North Carolina beaches are in this category. It could reasonably be expected that any developed and eroding beach in this category is likely experiencing local maintenance and may be considered for disposal or nourishment in the future. Other North Carolina ocean beach areas are unlikely to be considered for beach disposal. These are beaches within the Coastal Resources Barrier System (CBRS) (19 percent), or beaches that are owned and managed by either the state (4 percent) or federal government (40 percent), primarily as national or state parks.

CRBA restricts the expenditure of federal funds in designated areas. The large majority of existing or projected disposal and nourishment projects described below are federal, with less than 2 percent of the activities conducted by private groups. While most CRBA lands are undeveloped, local maintenance activities would be expected in any developed portions. Federal and State parks allow highly restricted disposal under special use permit and conduct nourishment only as required to protect resources, such as at Assateague Island as described above. Only ~10 percent of all existing or projected disposal/nourishment in North Carolina are on beaches within this category. Of that number, 8 percent are potential nourishment projects in the early planning stage, which are highly speculative but included for worst case analysis.

This analysis quantifies these impacts in terms of the percent of North Carolina beach affected on an annual and total basis by sand disposal for maintenance of federal navigation channels, and existing, proposed or potential beach nourishment projects. Activities of others are also considered.

4.13.3.4 *Statewide Impacts*

The following summaries are statewide impacts as calculated from information available from the USACE which shows Wilmington District activities. In addition similar activities by others exist or are proposed and considered in this assessment. These activities include Figure 8 Island where private beach nourishment has occurred on about 2 miles of beach on 4 occasions between 1985 and 1999. The same area may be impacted by disposal as early as 2001 for inlet relocation. The Marine Corps currently proposes beach nourishment on about 1 mile of West Onslow Beach. Future nourishment of this site is possible.

Disposal Activities

- Average/year – 8.0 miles or 2.5 percent of total NC ocean beach (320 miles)
- Minimum for any year – 3.5 miles or 1 percent of total NC ocean beach
- Total beach affected is 22.4 miles or 7.0 percent of total NC ocean beach

Existing Beach Nourishment

- Average of 2.9 miles or 1 percent of North Carolina ocean beach
- Minimum of 0 (possible that no beach nourishment in any given year)
- Total beach affected 9.8 miles which is 3 percent of NC ocean beach
- Inclusion of Figure 8 Island (2 miles) – total beach affected 11.8 miles or 3.7 percent of North Carolina beach

4.13.3.5 *Proposed Beach Nourishment*

These numbers are highly speculative and subject to change. Includes best guess for projects that are in early study phases, i.e. study requested but not funded, & reconnaissance. Appendix A-5 contains additional information on proposed USACE nourishment projects.

- Average of 16.9 miles or 5.3 percent of North Carolina ocean beach
- Minimum would be 0 (possible none would occur in a given year)
- Maximum of 85.0 miles which is 26.6 percent of North Carolina ocean beach
- Inclusion of Onslow Beach (1 miles) and Kitty Hawk North (2.2 miles) – total beach affected 88.2 miles or 27.5 percent of North Carolina ocean beach

4.13.3.6 *Cumulative (disposal and nourishment projects existing and future)*

- Average annual impact from existing disposal and nourishment 11.0 miles, 3.4 percent of North Carolina beach.
- Maximum impact (worst case) from existing beach disposal and nourishment activities 32.2 miles, 10.1 percent of North Carolina ocean beach.
- Average impact from existing disposal and nourishment projects and proposed projects 27.8 miles, 8.7 percent of North Carolina ocean beach.
- Maximum impact (worst case) from Wilmington District existing disposal and nourishment and potential beach nourishment 119.4 miles, 37.3 percent of North Carolina ocean beach.
- Inclusion of Onslow Beach (1 miles) and Figure 8 Island (2 miles) – total beach affected 122.4 miles or 38 percent of North Carolina ocean beach.

It should be noted that only Onslow Beach and Atlantic Beach (where the Wilmington district has occasionally disposed dredge spoils from the Beaufort Inlet/Morehead City Navigation Project) are situated within 25 miles of the proposed project shoreline. There are an estimated 80 miles of protected shoreline east and north of Beaufort Inlet that are not likely to require any nourishment activities and about 15 miles of protected shorelines west of the project area that are not likely to require any nourishment activities.

It is interesting to note that ~5 percent of the North Carolina ocean beach is not regulated beyond CAMA and the Corps and is not proposed for beach nourishment or disposal. The future of this area is undetermined. Due to extreme development pressure, however, these are likely to be developed in the future unless additional protection is provided at a state or Federal level.

Beach disposal/nourishment activities are relatively limited under the base condition, 34 miles (~10 percent). These activities could potentially increase to 122 miles as early as 2013; over a threefold increase in the next 13 years. Incrementally, the proposed project would account for ~10 percent of the increase.

4.13.3.7 *Project Level Impacts* (16.8 mile project area)

a. Local Maintenance:
   - Under existing conditions approximately 15 miles (90 percent) are expected to experience frequent local maintenance, in the form of beach scraping and bulldozing, etc.
   - With the proposed project, 16.8 miles (100 percent) would be restored to conditions approaching those of about 20 years ago (circa 1980). The proposed project would increase the beach width and sand volume available on the beach to respond to the full range of littoral processes and normal beach cycle. Natural dune building is expected as a result of the influx of new sediment thus reducing the need for local maintenance activities. Experience indicates that beach disposal projects along Atlantic Beach in 1986 and 1994 by the Wilmington District significantly reduced local maintenance activities as well as storm damage compared with unnourished areas of Bogue Banks as detailed in Section 3.4. After

the project, for a period of approximately 10 years, local maintenance activities are expected to be reduced to about 10 percent of present levels (i.e. ~2 miles of shoreline).

b. Disposal Activities: None

c. Existing Beach Nourishment: None

d. Proposed Beach Nourishment: 16.8 miles or 67 percent of Bogue Banks ocean shoreline

e. Cumulative Impacts:
- 16.8 miles or 67 percent of Bogue Banks area proposed for nourishment
- Remainder ~6 miles or ~25 percent subject to USACE navigation channel and disposal activities

4.13.3.8 ***Vicinity Impacts*** [50 Miles North and South of the project (100) miles]

a. Local Maintenance:
- Under existing conditions, ~20 miles (20 percent) are expected to experience frequent local maintenance
- With project 16.8 miles (17 percent) would be nourished one time with negligible maintenance for ~10 years

b. Disposal Activities: 5 miles or .05 percent of the ocean beach in the project vicinity

c. Existing Beach Nourishment: None

d. Proposed Beach Renourishment: 16.8 miles, or 17 percent of study area proposed for nourishment

e. Cumulative Impacts:
- Existing condition includes 5 miles of beach disposal
- With all proposed and existing disposal and nourishment impacts, 21.8 miles or 22 percent of the beaches in the vicinity would be impacted.

4.13.4 Summary of Beach Disposal Impact on Significant Resources

Based on comments from resource agencies and others, the primary concern with the proposed beach disposal is the potential for adverse impacts on important commercial fish species due to disposal impacts on larvae and indirect impacts to fish and birds due to impacts on beach invertebrates. The concerns are typified by comments from the NCDMF for similar projects.

> *The Division is concerned with the adverse impacts that will occur from the project. Biological resources will be affected by dredging of material for initial project construction and by placement of material on the beach. These impacts will reoccur as the area is renourished. As stated in the document the surf zone and the nearshore waters are utilized by kingfishes, spot, croaker, bluefish, weakfish, spotted sea trout, summer flounder, striped bass, spiny dogfish, Atlantic sturgeon and other commercially and recreationally important species.*

The following EA sections describe potential impacts associated with this and other similar projects that are pertinent to this analysis.

4.9.4	Impacts to Intertidal Resources
4.9.5	Impacts to Beach and Terrestrial Resources
4.10.6	Loggerhead Sea Turtle
4.10.8	Seabeach Amaranth
4.10.10	Summary of Protective and Mitigative Measures

Concern for fishery resources have been raised regarding turbidity impacts. These impacts are fully discussed in EA Section 4.8 listed above and were considered in preparation of this cumulative impact analysis. Of particular concern to the agencies is a cumulative degradation of habitat with an associated loss of benthic food resources for fish and birds. These are primary issues addressed in this analysis.

Resource Threshold Levels – There are no known established thresholds regarding the extent of ocean beach that can be disturbed by beach disposal/nourishment without significant population level impacts on birds and fisheries that rely on the beach invertebrates for food. Therefore, a comparison of cumulative impacts to established thresholds is not made. A relatively small portion of North Carolina beaches is presently affected by these activities, about 11 percent. With the proposed action the impact area would increase to 15 percent. The existing and proposed sites are distributed in northern and southern parts of the state with existing nourishment sites in New Hanover County and a proposed action in Dare County. It is unlikely that cumulative impacts from space crowded perturbation are occurring or will occur with the construction of this project because the adjacent barrier islands are wilderness preserves (e.g. Bear Island, Shackleford Banks, Cape Island, Core Banks). The analysis suggests that the potential impact area from the proposed and existing actions is small relative to the area of available similar habitat on a vicinity and statewide basis. These areas are expected to recover food resources, which should continue to be available. It is expected that the risk that the direct and cumulative impacts of the proposed action and other existing similar activities, would reach a threshold with high potential for population level impacts on important commercial fish stocks and birds is low. The following discussion provides support for this conclusion.

DOI (1999) reports that

> *As with benthic organisms living in borrow areas, benthic organisms are significantly impacted by beach nourishment activities (Nelson 1985; Van Dolah et al. 1992). These impacts, however, are considerably shorter in duration than the impacts observed in offshore borrow areas. Because benthic organisms living in beach habitats are adapted to living in high energy environments, they are able to quickly recover to original levels following beach nourishment events; sometimes in as little as three months (Van Dolah et al. 1994; Levison and Van Dolah 1996). This is again attributed to the fact that intertidal organisms are living in high energy habitats where disturbances are more common. Because of a lower diversity of species compared to other intertidal and shallow subtidal habitats*

(Hackney et al. 1996), the vast majority of beach habitats are recolonized by the same species that existed before nourishment (Van Dolah et al. 1992; Nelson 1985; Levison and Van Dolah 1996; Hackney et al. 1996). Rakocinski et al.

The above comments are further supported by results of a seven-year monitoring program for the northern New Jersey project which found that the typical time to complete recovery of benthic populations on the beach after nourishment were 2-6 months (USACE-Burlas et al 2001).

It is acknowledged that some uncertainty regarding the rate of repopulation of food organisms and the potential for reduced population levels due to continual sand deposition exists. The proposed project plan therefore includes preconstruction and postconstruction monitoring of beach fauna. The details of the monitoring plan are given in Appendix A-4 and will be developed in coordination with the concerned fisheries agencies.

4.14 ENVIRONMENTAL COMMITMENTS AND MITIGATION

Commitments – The environmental goal of this project is to avoid and minimize adverse impacts to the extent practicable. These commitments have been divided into two categories: offshore dredging and beach disposal.

Offshore Dredging and Beach Disposal – These activities will be conducted before, during, and/or after construction.

1) No expansion of borrow area will be made._Excavation depths will be restricted to 4 ft or less in areas B1 and B2, and 3 ft or less in A.

2) Agency concerns regarding use of offshore borrow sites within an area that is wintering grounds and Essential Fish Habitat (EFH) for important commercial and sport species indicate that some additional monitoring is justified. The applicant will address these issues through the development and implementation of an integrated monitoring plan as described in Appendix A-4. The first preproject sampling has already been performed in June 2001. The second preproject sampling is scheduled for November 2001. Postproject sampling will be performed as described in Appendix A-4. The applicant will provide results of the sampling and coordinates for excavated portions of all borrow areas to the resource agencies so the areas can be considered for sampling as a part of the other research activities.

3) The applicant proposes to conduct additional physical and environmental monitoring of the project including seabeach amaranth surveys, beach compaction surveys, beach profile surveys, and sediment sampling to document changes along the beach and in the borrow areas, as detailed in Section 5.

5.0 COMMENTS AND COORDINATION

5.1 PLANNING AND COMMUNITY MEETINGS THROUGH JUNE 2001

The proposed project results from planning and community meetings initiated by the Carteret County Beach Preservation Task Force* in 1997. The task force was convened partly in response to accelerated erosion during Hurricanes *Bertha* (1996) and *Fran* (1996). Following is a chronology of the project through June 2001.

1996	– Hurricanes *Bertha* and *Fran*
1997-1999	– Periodic public meetings of Beach Preservation Task Force
August 1998	– Hurricane *Bonnie*
May 1999	– Initiate shoreline erosion assessment
June 1999	– Beach and inshore survey
	– Initiate sand search
September 1999	– Shoreline assessment and preliminary beach restoration plan
	– Plan presented to the community (CSE Baird-Stroud 1999)
	– Hurricanes *Dennis* and *Floyd*
18-22 September 1999	– Post-*Floyd* beach surveys and damage assessment
12 October 1999	– Interagency scoping meeting with USACE, USFWS, NMFS, NCDCM NCDMF, municipal officials
	– County commission presentation
November 1999	– Initiate project design and surveys
	– County contracts with CSE Baird (now Coastal Science & Engineering LLC) to engineer project
	– County contracts with UNC-IMS (Dr Peterson) to initiate environmental monitoring
1 November 1999	– Coordination meeting with county council, public forum
2-3 November	– Coordination meeting with NMFS (Sechler and Hardy), UNC-IMS (Peterson and Wells)
10 November 1999	– Coordination meetings with FEMA (post-*Floyd*)
November-December 1999	– Offshore geotechnical, cultural resources, and environmental surveys
6 January 2000	– Public forum on project – Pine Knoll Shores

---

*Carteret County Beach Preservation Task Force Members (1999)

Carl Huff (chairman, Harkers Island)
Bill Donnelly, Jr. (Atlantic Beach)
Grady Fulcher (Pine Knoll Shores)
Jack Goldstein (Indian Beach Hospitality Assn.)
Thomas R. Hoover, Jr. (councilman, Emerald Isle)
Reese Musgrave (mayor, Pine Knoll Shores)
Prof. Mike Orbach (director, Duke Marine Lab)
Bill Price, II (Pine Knoll Shores)
Jonathan Robinson (county commissioner)
Richard Stanley (Chamber of Commerce, Beaufort)
Sam Stell (county commissioner, Emerald Isle)
Roy Stevens (Ports Committee, Morehead City)
Dr. Ruth E. Sweeney (North Carolina Shore & Beach)
Prof. John Wells (director, UNC Marine Lab)
James N. Willis, III (Atlantic Beach)

and ex-officio members:
Karren Brown (park director, U.S. Park Service)
Jody Merritt (superintendent, Fort Macon State Park)
Robert Murphy (county manager, Carteret County)

February-March 2000	–	Numerous newspaper articles, television and radio pieces describing project and upcoming county funding referendum
6 March 2000	–	Draft SEPA EIS submitted to NCDCM/NCDENR
7-9 March 2000	–	Three community forums on project at White Oak Elementary School, Atlantic Beach Town Hall, and Smyrna Elementary School
19 March 2000	–	Community forum at Broad Creek Community Center
21 March 2000	–	County funding referendum fails
April-May 2000	–	SEPA EIS coordination meetings with NCDENR agencies
June 2000	–	Second annual beach/inshore survey
August-September 2000	–	SEPA EIS coordination meetings with North Carolina agencies – comments and responses
September 2000	–	Town of Pine Knoll Shores assumes responsibility for planning for Reaches 5 and 6 of county project
	–	UNC-IMS submits environmental monitoring report (Appendix C of SEPA EIS)
October 2000	–	Town of Pine Knoll Shores contracts with Coastal Science & Engineering LLC (CSE) to design Reaches 5 and 6
31 October 2000	–	Revised draft SEPA EIS with approvals from NCDENR agencies submitted to North Carolina Clearinghouse
November 2000	–	Supplementary geotechnical surveys and coastal process measurements (November 2000 to May 2001)
December 2000	–	Town of Indian Beach contracts with CSE to design Reach 4
January 2001	–	Supplementary geotechnical surveys
9 January 2001	–	Public hearing on Pine Knoll Shores bond referendum
24 January 2001	–	Permit application submitted to USACE and NCDCM for project by Carteret County
13 February 2001	–	Community forum on project – Pine Knoll Shores Town Hall
14 February 2001	–	Community forum on project – Indian Beach Town Hall
27 February 2001	–	Community forum on project – Pine Knoll Shores Town Hall
6 March 2001	–	Pine Knoll Shores funding referendum passes
16 March 2001	–	Public notice on permit application ID 200000362 published
26 March 2001	–	Town of Pine Knoll Shores and Town of Indian Beach meet with USDA to discuss requirements for project financing under a Rural Development Loan
April 2001	–	Two federal agencies (NMFS, USFWS) request that USACE require new EIS under NEPA after state reviews and approvals of Final SEPA EIS.
	–	Applicants request waiver of NEPA EIS requirement because *no federal grants* will be involved
	–	Applicants retain Coastal Science Associates Inc (CSA) (Dr Bart Baca) to conduct pre and postproject environmental monitoring surveys
2 April 2001	–	UNC-IMS resigns from project
4 April 2001	–	Final SEPA EIS complete under state review
24 April 2001	–	Indian Beach funding referendum passes
25 April 2001	–	Draft environmental monitoring plan submitted to USACE for review (revised in May and June)
11 May 2001	–	Federal interagency meeting (with USACE, USFWS, NMFS) to discuss remaining environmental assessment requirements – additional beach sampling requested by USFWS

May 2001	– Towns of Pine Knoll Shores and Indian Beach contract with CSE to perform additional beach sampling as required by USFWS
24 May 2001	– Additional sediment data submitted to USFWS – no material change in results from SEPA EIS data
6 June 2001	– USDA submits Class II environmental assessment on the project
14 June 2001	– USFWS requests stand-alone "Biological Assessment" on which to base their required biological opinion – information in SEPA EIS to be incorporated into report
June 2001	– CSA completes first of two preproject environmental samplings in borrow areas and along beach
5 July 2001	– Biological Assessment Report submitted to USACE, USFWS, and NMFS

The preceding chronology documents extensive public involvement in the proposed project since 1997. To date, the following have occurred.

- Over a dozen meetings of the Carteret County Beach Preservation Task Force.

- Approximately ten community forums and information meetings convened by Carteret County; the municipalities of Pine Knoll Shores, Indian Beach, and Emerald Isle; and citizens groups including CAST (Citizens Against Sand Tax).

- Three community funding referendums:
  - Carteret County failed because of opposition to funding formula by residents of the mainland.
  - Town of Pine Knoll Shores passed by a margin of ~2:1.
  - Town of Indian Beach passed by a margin of ~8:1.

- Two interagency scoping meetings (October 1999 and May 2001).

- Numerous articles and letters in local and regional newspapers.

- Several television and radio programs including call-in shows.

In addition, the applicants have made available for public review and comment copies of all reports associated with the project. Copies of the SEPA EIS and project reports have been distributed to nongovernmental organizations such as the North Carolina Coastal Federation for review and comment.

5.2 COMMENTS AND RESPONSES

The correspondence section of this document includes copies of comments and responses by various federal, state, and other organizations/individuals. The final state EIS under the state's SEPA review process incorporates revisions to the project and responses to comments from all corresponding state agencies.

Following submittal of the final SEPA EIS (4 April 2001), the applicants received additional comments from federal agencies and others. Responses to these comments were subsequently submitted to the USACE and are included in the correspondence section.

5.2.1 Federal Agencies

5.2.1.1 *U.S. Environmental Protection Agency*

The U.S. Environmental Protection Agency (EPA) provided comments by letter dated 13 April 2001 from William L. Cox to Colonel James W DeLony (USACE) during the commenting period. The applicant responded to comments and concerns by letter from Dr. Timothy W. Kana (consultant for the applicants) to Colonel James W DeLony on 25 April 2001, and by additional analyses and proposed mitigation measures detailed in the Biological Assessment Report and present EA. The EPA expressed concerns about the project as follows, and recommended that the concerns be addressed prior to project authorization.

A) The EPA recommended that other alternatives and a 50-year planning time frame be considered. The applicant addresses this concern in the EA with additional discussion of each alternative. Given the existing density of development, the proposed plan is considered the only practicable solution at this time. The applicant proposes to monitor the performance of the project over the first decade of its lifetime and reevaluate the economics of each alternative before implementing additional projects. In addition, the USACE-Wilmington District initiated planning in 2001 for a long-range project for Bogue Banks under a cooperative agreement with local sponsoring agencies. Results of this study will include detailed economics analyses of alternatives, and estimated costs and benefits over a 50-year design life.

B) The EPA expressed concern regarding coordination of the project with multiple political jurisdictions. The phasing and coordination of the project among the three municipal sponsors and Carteret County (co-applicant) are described in detail in the EA (Section 2.4) and in the applicant's response to comments.

C) The EPA expressed concern regarding nonpoint-source runoff and land planning. The applicant addresses this concern in the response to comments by stating there is relatively little drainage toward the ocean along Bogue Banks. Most drainage over the barrier island is directed toward the lagoon or directly into the groundwater table by percolation.

D) The EPA expressed concerns regarding impacts to hard bottom communities. The applicant addresses this concern in the EA and in responses to comments. There is presently no hard bottom believed to be in close proximity to the borrow areas and beach areas that fall within the zone of active littoral transport.

E) The EPA recommended that all agency comments be addressed in the completion of the state EIS for the project, prior to authorization. The applicant has addressed the EPA concerns and other federal and state agency concerns in the final SEPA EIS (dated 4 April 2001), various responses to comments (see correspondence section), the Biological Assessment Report, and the present EA.

5.2.1.2 *U.S. Fish & Wildlife Service*

The U.S. Fish & Wildlife Service (USFWS) provided comments at an interagency meeting on 11 May 2001 and by letters dated 1 June 2001 and 20 September 2001 from Garland Pardue to Colonel James W. DeLony. The applicant responded to comments and concerns by letter from Timothy Kana (consultant to the applicants) to Dr. Garland Pardue on 24 May 2001; by submission of a Biological Assessment Report dated 5 July 2001 (prepared by Coastal Science & Engineering, LLC, Consultant to the applicants) under the NEPA review process; and by letters from the applicants to Colonel James W. DeLony dated 21 September 2001 (Mr. Pete Allen, Carteret County), 24 September 2001 (Mayor Reese Musgrave), 24 September 2001 (Mayor Buck Fugate), and 24 September 2001 (Mr. Frank Rush, Emerald Isle Town Manager). The USFWS found the project is not likely to adversely affect any Federally-listed endangered or threatened species provided certain conservation measures are implemented as follows:

A) The project must be conducted between November 16 and April 30.

B) All fill material placed on beaches must be sand that is similar to that already existing at the beach in both coloration and grain size distribution and be free of construction debris, rocks, organic materials other foreign matter and shall not contain, on average, greater than 10 percent fines and shall not contain, on average, greater than 5 percent coarse gravel or cobble, exclusive of shell material.

C) A daily, early-morning sea turtle nest monitoring program must be implemented.

D) Sand compaction along the back beach must be monitored prior to 1 April for three subsequent years after fill placement and tilling to 36 inches depth be performed if results show compaction exceeds USFWS criteria as listed in their 20 September letter.

E) Sand compaction along the back beach must be measured prior to fill placement.

F) Visual surveys for escarpments in the fill must be made immediately after fill placement and prior to 1 April for three subsequent years, and grading be performed as necessary according to USFWS protocols as listed in their 20 September letter.

G) Seabeach amaranth surveys must be conducted before and after fill placement for a period of three years, and the general location of plants protected by a buffer zone.

H) No construction equipment or pipes shall be stored on the beach from 1 May through 15 November.

The applicants have agreed to all of the above conservation measures.

The USFWS also expressed concerns about the adequacy of sediment sampling for purposes of defining the native beach, and sediment compatibility, particularly with regard to grain size distribution, color, shell content and angularity of shell material. The applicant addressed these concerns by performing additional beach sampling and analyses (see letter and attachments dated 24 May 2001 from TO Kana to Garland Pardue, Biological Assessment Report dated 5 July 2001, and the present EA) and the above referenced correspondence. The applicant has also addressed these concerns by the following design parameters and restrictions.

1) Dredging will be restricted to those portions of borrow areas A, B1 and B2 having sediments that most closely match the native beach in terms of size distribution, shell content and overfill ratios. The areas will also fully comply with the guidelines given in USFWS comment letter dated 20 September 2001. Overfill ratios for all of area B1 and B2 were originally calculated to range from 1.97 to 2.16 as detailed in the SEPA EIS (Section 3.16.4). Additional borings were obtained which allowed delineation of selected areas within B1 and B2 that yield overfill ratios ranging from 1.50 to 1.58. Overfill ratios in borrow area A range 1.14-1.15 (Biological Assessment Report dated 5 July 2001, Table 5).

2) The contractor will be required to alternate excavations in A and B1 or A and B2 such that sediments from the two areas will be mixed on the beach. In so doing, the average overfill ratio will range 1.25-1.30 thus more closely matching the size distribution of the native beach (Biological Assessment Report, Table 6).

3) It is anticipated the project will be constructed by hopper dredge because of the requirement to alternate between borrow areas. Hopper dredges tend to wash the sediments and discharge some of the fines prior to pumping onto the beach. The net result is a reduction of mud discharged into the surf zone, and a narrowing of the grain size distribution upon placement. This is expected to have the effect of improving the match of grain sizes between the nourishment sediment and the native beach, and reducing the overfill ratios of the resulting fill.

4) Sediment color is expected to be the same as the native beach because the source sediments in the borrow areas have the same composition as beach sediments (i.e. predominantly quartz sand and calcium carbonate shell material). Sediments residing in borrow areas tend to be darker because of the reducing environment that exists and the fact that small percentages of silts and clays will tend to color the entire deposit. After mud, which gives borrow sediments their initial dark appearance, is winnowed during excavation and transfer to hopper dredges and further winnowed in the surf zone, the remaining sand and shell material will bleach on the beach. Bleaching is expected as a result of exposure of the fill to sunlight and the oxidizing conditions that occur in the intertidal and subaerial beach zone.

5) Shell content and angularity is expected to be modified as a result of placement in the surf zone. The dominant shell material in A, B1 and B2 consists of thin-walled Donax species. Such shell material will be subject to intense abrasion processes in the surf zone and is expected to be broken into smaller

fragments and rounded over time. The result is expected to be a reduction in the percentage of coarse shell material exceeding 2 mm diameter, a further narrowing of the sediment grain size distribution, and a closer match with the native sediment grain size distribution.

5.2.1.3 *National Marine Fisheries Service*

The National Marine Fisheries Service (NMFS) provided comments dated 20 April 2001(letter from Andreas Mager to Colonel James W. DeLony) during the commenting period, and subsequently on 25 June 2001 (Section 7 Endangered Species Consultation from Andreas Mager, Jr. to Colonel James W. DeLony), on 26 June 2001 (Joseph E. Powers to Colonel James W. DeLony), and 26 September 2001 (Andreas Mager, Jr. to Colonel James W. DeLony). The applicants provided responses to NMFS comments by letter dated 30 April 2001 from Timothy W. Kana (consultant for the applicants) to Colonel James W. DeLony; by letter dated 17 August 2001 from JW Forman (consultant for the applicants) to Colonel James W. DeLony; and by submission of a draft Essential Fish Habitat (EFH) Assessment Report on 10 May 2001, and submission of a Biological Assessment Report dated 5 July 2001 (both prepared by Coastal Science & Engineering, LLC, Consultant to the applicants). The EFH is provided in Appendix D of the present EA.

The NMFS concluded (letter dated 26 June 2001 from Joseph E. Powers to Colonel James W. DeLony) that a hopper dredge(s) will likely be used for most of the proposed activities and that the 25 September 1997 Regional Biological Opinion establishes adequate protocols and monitoring requirements to minimize adverse effects on listed species of concern.

The applicant agrees to abide by the NMFS 1997 Regional Biological Opinion monitoring, terms and conditions, including maintenance of endangered species observers on board the dredge during the prescribed periods.

Other issues of concern raised by NMFS and the applicants' response include the following.

A) NMFS expressed concern regarding sediment compatibility and the percentage of shell material in the proposed borrow areas. The applicant has addressed these concerns in the EA and final project plans and is proposing to combine sediments from borrow areas A, B1 and B2 during construction in such a way as to closely match the existing grain size distribution on the beach. This will entail alternating hopper loads from borrow areas A and B1/B2 at a ratio of approximately 1:2 (See above responses regarding USFWS concerns).

B) NMFS expressed concern regarding the scale and phasing of the project. The applicant has clarified the scope and schedule of work in the Biological Assessment Report (5 July 2001) and in the present EA.

C) NMFS expressed concern regarding resuspension and transport of fill material to or around hard bottom areas. The applicant addressed this concern in the Biological Assessment Report, in the EA (Section 4.8 and 4.9.2) and in responses to comments.

D) NMFS requested revisions to the applicants' proposed environmental monitoring plan and preliminary results of the June 2001 borrow area and beach sampling. The applicant submitted environmental monitoring plans (prepared by Coastal Science Associates, Inc, consultant to the applicants) on 18 April 2001, 28 May 2001, July 2001, and 23 August 2001; and submitted preliminary results from June 2001 samplings in August 2001. NMFS accepted the applicant's proposed environmental monitoring plan with conditions by letter dated 26 September 2001 (from Andreas Mager, Jr. to Colonel James W. DeLony).

E) NMFS expressed concern that the proposed borrow sediment may result in compaction that hampers sea turtle nesting (letter dated 26 September 2001). The applicant has addressed this concern by agreeing to perform compaction monitoring and till the beach according to existing protocols and requirements prescribed by USFWS as well as the state permit for the project.

5.2.2 State and Local Agencies

5.2.2.1 *North Carolina Division of Coastal Management*

The North Carolina Division of Coastal Management (NCDCM) issued a Coastal Area Management Act (CAMA) permit on 5 October 2001. The permit acknowledges the project is consistent with the North Carolina Coastal Management Program provided thirty-nine (39) conditions are met. A copy of the state permit is given in front of the permit application in Appendix A-2. The permit expires on 31 December 2004. Following are some key provisions of the permit.

A) Prior to beach nourishment, the existing mean high water line and the first line of stable vegetation must be surveyed.

B) Nourishment activities may be carried out one time under the permit using borrow areas A, B1 and B2.

C) The dredging operation shall relocate to other areas of the borrow area in the event non-compatible material is encountered.

D) A low protective dune must be pushed up if the nourished area has no protective dune at the time of construction such that the slurry will not run toward existing development. A plan for sand fences or dune plantings must be submitted to NCDCM prior to installation.

E) Endangered species protection measures must be implemented including observers on hopper dredges, use of beach compatible sediment, beach tilling, and grading of escarpments.

F) Biological monitoring must be performed according to NCDMF protocols and requirements.

G) Cultural resources at identified sites must be avoided.

H) A preconstruction conference shall be scheduled with the contractor and NCDCM prior to initiation of dredging activities.

5.2.2.2 *North Carolina Department of Environment and Natural Resources*

The North Carolina Department of Environment and Natural Resources(NCDENR), Division of Water Quality (DWQ) issued a 401 Water Quality Certification for the project on 23 March 2001 (letter from Kerr T Stevens to Robert Murphy, Carteret County Manager), stating that the proposed project (beach fill) is covered under General Water Quality Certification Number 3274. DWQ recommended that the CAMA Permit be conditioned to address all issues raised in the SEPA EIS. The CAMA permit is conditioned accordingly.

The North Carolina Wildlife Resources Commission (NCWRC) submitted comments on the draft SEPA EIS by letter dated 27 April 2000 from Franklyn McBride to Melba McGee (NCDENR). These comments were addressed by the applicants in a letter from J.W. Forman (consultant to the applicants) to Franklyn McBride dated 13 September 2000 and by way of a revised draft SEPA EIS and project plan. NCWRC responded by letter dated 24 October 2000 stating that the information in the revised SEPA EIS addressed their concerns provided the project is scheduled to avoid peak biological activity of invertebrates.

The North Carolina Division of Parks and Recreation (NCDPR) submitted comments on the draft SEPA EIS by letter dated 13 April 2000 from Stephen Hall to Melba McGee (NCDENR). These comments were addressed by the applicants in a letter from J.W. Forman (consultant to the applicants) to Stephen Hall dated 13 September 2000 and by way of a revised draft SEPA EIS and revised project plan. DPR responded by letter dated 30 October 2000 stating that the information provided in the revised SEPA EIS and in the applicant's response has addressed each of their concerns to their satisfaction.

The North Carolina Division of Marine Fisheries (NCDMF) submitted comments on the draft SEPA EIS by letter dated 18 April 2000 from David Taylor and James P. Monaghan to Melba McGee (NCDENR). These comments were addressed by the applicants in a letter from J.W. Forman (consultant to the applicants) to James P. Monaghan dated 13 September 2000 and by way of a revised draft SEPA EIS and revised project plan. DMF responded by letters dated 2 October 2000 to Melba McGee and 27 September 2001 to Doug Huggett (Division of Coastal Management) stating that DMF recommends approval of the project provided four (4) conditions are met:

A) Benthic sampling at each beach station should be conducted during the same portion of the tidal cycle.

B) Additional revisions (unspecified) be made to the environmental sampling design before Phase II and Phase III are implemented.

C) The dredging window for the project shall be 16 November to 15 April.

D) Phase I dredging and pumping shall begin at the eastern end of the project.

Regarding the timing of benthic beach sampling, the applicant's consultant (Coastal Science Associates, Inc.) performed pre-project sampling in June 2001 with all samples collected within 1.5 hours of published low tide (Dr. Bart Baca, pers comm. 4 October 2001). Given the large number of beach samples (several hundred) that are being required by the resource agencies (NCDMF and NMFS), it is not practicable to collect all samples at the exact same time. Tide range is relatively low along Bogue Banks which means the water level does not fluctuate significantly for a couple of hours around low tide when sampling is normally scheduled for logistical reasons.

5.2.2.3 *North Carolina Clearinghouse*

The North Carolina Department of Administration: No Comment

The North Carolina Department of Cultural Resources, State Historic Preservation Office provided comments dated 7 May 2001 by letter from David Brook to Doug Huggett (Division of Coastal Management) and Colonel James W. DeLony listing six (6) archeological sites along the project area and a requirement to avoid these sites. The applicants responded by letter from Timothy W. Kana (consultant to the applicants) to David Brook dated 18 May 2001 and by way of the EA and revised project plan. The CAMA permit is conditioned to require avoidance and protection of the designated sites.

5.2.3 Organizations

5.2.3.1 *Environmental Defense*

The Environmental Defense (ED) provided comments dated 13 March 2001 by letter from Michelle Duval and Daniel J Whittle to Doug Huggett (Division of Coastal Management). The same comments were provided by letter dated 12 April 2001 from Michelle Duval and Daniel Whittle to Mickey Sugg (USACE). The applicants responded by letter dated 4 April 2001 from Timothy W. Kana (consultant to the applicants) to Doug Huggett (Division of Coastal Management) and by letter dated 27 April 2001 from Kana to Mickey Sugg. The applicants also responded by way of the Biological Assessment Report, the EA and the revised project plan. Environmental Defense expressed the following concerns.

A) The ED expressed concern about cumulative and long term impacts. The applicant addressed these concerns in the above referenced correspondence and in the EA.

B) The ED requested clarification regarding how project success would be defined. The applicant addressed this concern in the above referenced correspondence and in the EA documenting design criteria for a "10-year" project based on historical erosion data and beach fill performance at Atlantic Beach among other factors.

C) The ED requested additional consideration and analysis of alternatives. The applicant addressed this concern in the EA and the above referenced correspondence.

D) The ED requested that the project sponsors fund a monitoring program. The applicants are funding a comprehensive, multi-year monitoring program that will periodically sample organisms and quantify changes in beach volumes and sediment quality.

5.2.3.2 *University of North Carolina*

The University of North Carolina (UNC) provided comments by letter dated 15 March 2001 from Charles H. Peterson to Doug Huggett (Division of Coastal Management). The same comments were provided by letter dated 13 April 2001 from Charles H. Peterson to Mickey Sugg (USACE). The applicants responded by letters dated 3 April 2001 from Timothy W. Kana (consultant to the applicants) to Doug Huggett, and dated 27 April 2001 from Kana to Sugg. Additional correspondence is provided in the present EA between Charles Peterson and representatives of the applicants (Section O. in correspondence section). UNC expressed the following concerns.

A) UNC expressed concern that the applicant was not committed to a scientifically rigorous before and after environmental monitoring of the project. The applicants have committed to performing environmental monitoring following established sampling protocols as detailed in the environmental monitoring plan contained in Appendix A-4 of the present EA. The consultant to the applicants for biological monitoring (CSA-Dr. Bart Baca) has completed over a dozen such monitoring projects in Florida, South Carolina and elsewhere. CSA's results have been submitted to resource agencies in those jurisdictions and been accepted as a basis for evaluating rates of recovery of benthic populations. An example report for Daufuskie Island (SC) is given at the back of Appendix A-4.

B) UNC requested a programmatic state EIS be prepared to address cumulative impacts. The applicant responded to this concern in the above referenced correspondence and in the EA.

C) UNC expressed concern regarding the sediment quality. The applicant responded to this concern in the above referenced correspondence, in the Biological Assessment Report, in the EA, and in revisions to the project design whereby borrow areas A and B1/B2 will be combined in a ratio of approximately 1:2 such that the closest practicable match of borrow and native sediment can be obtained. The resulting overfill ratios are expected to average approximately 1.3. The resulting mixture of sediment from borrow areas A, B1 and B2 is expected to closely match the native grain size distribution, percentages of fines and coarse material, and percentages of shell after fill placement and adjustment.

D) UNC requested the period of construction be restricted to 1 December through 31 March. The applicant responded to this concern in the above referenced correspondence.

5.2.3.3 *North Carolina Coastal Federation*

The North Carolina Coastal Federation (NCCF) provided comments by letter dated 12 April 2001 from Jim Stephenson to Mickey Sugg (USACE). The applicants responded by letter dated 27 April 2001 from Timothy Kana (consultant to the applicants) to Mickey Sugg and by way of additional analyses and explanations contained in the Biological Assessment Report and the EA. NCCF expressed the following concerns.

A) NCCF expressed concern that the SEPA EIS did not adequately address alternatives. The applicants responded to this concern by providing additional information and cost comparisons regarding alternatives in the Biological Assessment Report and the EA.

B) NCCF requested the period of construction be restricted to 1 December through 31 March. The applicant responded to this concern in the above referenced correspondence

C) NCCF expressed concern that the environmental monitoring plan was inadequate. The applicant responded to this concern in the above referenced correspondence, the Biological Assessment Report, and the EA.

D) NCCF requested more study of sand suitability for nourishment. The applicant has responded to concerns regarding sediment compatibility in the above referenced correspondence, the Biological Assessment Report, the EA and the revised project plan.

E) NCCF requested the applicant address the issue of cumulative impacts. The applicant responded to this request in the above referenced correspondence and the EA.

F) NCCF listed seven (7) policies their organization recommends regarding beach nourishment. The applicant responded to these guidelines in the above referenced correspondence.

5.2.3.4 *Other*

Citizen Don E. Morris (Newport, NC) provided comments toDoug Huugett (NCDCM) by letter dated 6 February 2001, and to Mickey Sugg (USACE) on 10 April 2001. Mr. Morris expressed concern about public hearings in regard to the SEPA EIS, about beach access along the project area, about beach scraping, and about sea level rise. The applicant addressed these concerns in correspondence dated 27 April 2001 (letter from Timothy Kana, consultant to the applicants, to Mickey Sugg (USACE).

No other comments requiring responses were received from concern citizens.

5.3 ENVIRONMENTAL MONITORING PLAN (see Appendix A-4)

The applicants have committed to performing environmental monitoring of the project and have initiated sampling. The applicants propose to perform semi-annual monitoring of the borrow areas (and adjacent control sites) and the beach (and adjacent control sites) following established methodology and protocols for Southeast (US) nourishment projects (cf, Van Dolah et al 1992). Two sampling months have been established (June and November) for purposes of quantifying impacts and recovery of biota due to the nourishment project. The first preconstruction sampling was performed in June 2001; the second is scheduled for November 2001.

Postconstruction sampling will be performed in June and November 2002 following completion of Phase I. This sampling will also yield prenourishment sampling for Phase II. Postconstruction sampling will continue in June and November 2003 and June and November 2004, and so on until recovery is demonstrated (as described below).

The applicants for Phase I (Town of Pine Knoll Shores and Town of Indian Beach) retained the firm of Coastal Science Associates Inc (CSA) (Dr Bart Baca, Jacksonville FL) to conduct the surveys and analyses. A preliminary sampling proposal dated 18 April 2001 was submitted to NMFS and North Carolina Division of Marine Fisheries (NCDMF) around 25 April. The proposal was discussed at an interagency review meeting on 11 May and was subsequently revised and resubmitted around 28 May. Comments on the revised monitoring plan were submitted to the USACE on 3 June by Dr. Charles Peterson (consultant to NCDMF). Further discussions on the monitoring plan were conducted at NMFS (Beaufort NC) on 20 June. A second revised environmental monitoring plan was submitted by CSA on 26 June.

CSA proceeded with the June 2001 sampling such that baseline conditions could be defined. Sampling followed established protocols for projects of this type. CSA's third revised proposal and preliminary results of the June 2001 sampling were submitted to the resource agencies on 23 August and are given in Appendix A-4.

The purpose of the environmental monitoring is to document the species living in and utilizing the borrow sites and project beach before and after construction and to document whether and when biological populations return to normal levels. The applicants' proposed biological monitoring plan is designed to:

- Quantify the changes in benthic populations in the borrow areas.

- Quantify the changes in benthic populations along the beach.
- Compare impacted areas with unnourished areas.
- Obtain semiquantitative data on fish populations and foraging habits in the surf zone.
- Monitor the recovery and population of ghost crabs and turtle nests in the project area.
- Monitor the occurrence of seabeach amaranth in the project area.

The duration of postproject sampling will be determined by NCDMF in consultation with NMFS. The applicants anticipate performing semi-annual sampling until one or two monitoring periods after construction demonstrate recovery of biota to preproject conditions (cf. conditions # 24-26 of the CAMA permit Number 124-01, letter dated 20 September 2001 from USFWS-Garland Pardue to Colonel James W. DeLony, and letter dated 26 September 2001 from NMFS-Andreas Mager, Jr. to Colonel James W. DeLony). Based on studies of previous nourishment projects, recovery of the beach is expected within one year of construction, and recovery of the borrow areas within two years of construction.

In the July 2001 Biological Assessment, the applicants outlined a commitment to perform up to ten samplings with the first five sponsored by the Towns of Pine Knoll Shores and Indian Beach (in connection with Phase I) and the second five to be funded by Emerald Isle (in connection with and subject to funding authorization for Phase II and III construction).

5.4 SUMMARY OF MITIGATION MEASURES

Based on comments and concerns from the above referenced correspondents and agencies, the applicant proposes to perform the following mitigation measures as required under North Carolina CAMA Permit 124-01 (Appendix A-2) and recommended by USFWS (letter dated 20 September 2001) and NMFS (letter dated 26 September 2001).

1) Semi-annual biological monitoring of borrow areas, beach-fill areas and control areas as detailed in Appendix A-4 and the referenced documents in this section.

2) Perform the work during cold weather months specifically between 16 November and 15 April. Any work required during any portion of the month of April will be reviewed with NCDCM and USACE officials prior to implementation. No work will be performed between 1 May and 15 November.

3) The project will be completed one time with no subsequent renourishment without modification of the permit.

4) All excavations will be confined to the designated areas of borrow area A, B1 and B2 and restricted to the upper 3-4 feet of section in the deposit as detailed in the CAMA permit and the present EA.

5) Temporary dikes will be used to retain and direct the discharge of dredged material along the beach as detailed in the CAMA permit.

6) Only beach quality sand with similar grain size as the existing beach will be used for nourishment. The dredge will move to other sections of the borrow area if non-compatible sediment is encountered.

7) Construction will be monitored by representatives of the applicants at all times.

8) Equipment will be removed from completed sections of the project area as soon as practicable once final grading and profile shaping is completed.

9) The contractor will be required to access the beach by way of existing accesses and restore same to their pre construction condition after use.

10) A low protective dune will be constructed in areas where there is none prior to construction so as to prevent dredge slurry from running landward into developed areas.

11) Dune disturbance will be kept to a minimum and the landward edge of construction be restricted to the area marking the approximate toe of the existing dune at the time of nourishment.

12) Dune fencing and revegetation will be performed in consultation with NCDCM officials.

13) Prior to beach nourishment, exposed remnants of or debris from failed erosion control structures will be removed by the permittee.

14) Nourishment will begin at the eastern end of the project to minimize impacts to the stop net fishery as prescribed in the CAMA permit.

15) An observer will be present on board hopper dredges to monitor takes of sea turtles or other endangered species according to protocols established by NMFS.

16) Beach quality sand suitable for sea turtle nesting and having a similar grain size as the native beach will be used.

17) Beach compaction will be monitored prior to construction and prior to turtle nesting season, and tilling will be performed to a depth of 36 inches as necessary following protocols established by North Carolina Wildlife Resources Commission and USFWS.

18) The post-nourishment beach will be monitored for escarpments and regraded as necessary following protocols established by resource agencies and described in CAMA permit 124-01.

19) The applicant will submit an Erosion and Sedimentation Control Plan at least thirty (30) days prior to the beginning of any land disturbing activity.

20) The contractor will be instructed to avoid cutural resource sites identified in NCDCR correspondence and in CAMA permit 124-01 and will otherwise safeguard any unearthed remains that my occur as a result of the project.

21) The applicant and its contractor will schedule a pre-construction conference with NCDCM representatives prior to initiation of work and review the terms and conditions of the permit.

22) The applicant will perform annual monitoring of the project to track its performance in terms of profile durability and sediment transport out of the area, and document sediment quality.

23) The applicant will submit annual monitoring reports to resource and regulatory agencies documenting the findings of environmental monitoring, and project performance surveys.

This document constitutes my Finding of No Significant Impact, Statement of Findings, and incorporates the applicant's October 19, 2001 "Environmental Assessment Bogue Banks Beach Nourishment Project Carteret County North Carolina" as my Environmental Assessment.

This permit action is being taken under authority delegated to the Wilmington District Engineer by the Secretary of the Army and the Chief of Engineers by Title 33, Code of Federal Regulations, Part 325.8, pursuant to:

__X__ Section 10 of the Rivers and Harbors Act of 1899.
__X__ Section 404 of the Clean Water Act.
______ Section 103 of the Marine Protection, Research and Sanctuaries Act.
______ Section 4(e) of the Outer Continental Shelf Lands Act of 1953.
__X__ Section 401 of the Clean Water Act. Water Quality Certification issued by the North Carolina Division of Water Quality.
______ Section 402 of the Clean Water Act. National Pollutant Discharge Elimination System (NPDES) permit issued by the North Carolina Division of Water Quality.
__X__ Section 307 of the Coastal Zone Management Act. Consistency concurred/CAMA permit issued by North Carolina Division of Coastal Management.
__X__ Conforms to the Section 404(b)(1) Guidelines, (40 CFR 230, FR 24 DEC 80).
______ Conforms to the Ocean Dumping Criteria (40 CFR 220-229, FR 11 JAN 77).

Project Description:

Carteret County, Pine Knoll Shores, Indian Beach, and Emerald Isle are proposing to conduct a beach nourishment project on Bogue Banks Island adjacent to the Atlantic Ocean. Specifically, the project boundary will encompass a 16.8-mile stretch, starting at the Atlantic Beach/Pine Knoll Shores Town Limit and terminating near Shipwreck Lane in Emerald Isle, approximately 1.0 mile east of Bogue Inlet. The project has been segmented into three (3) phases and six (6) separate reaches. Phase (1), which consists of Reaches 4, 5, and 6, will include Pine Knoll Shores and Indian Beach Town Limits and the community of Salter Path. This work, conducted from November 2001 to April 2002, will start at the Atlantic Beach/Pine Knoll Shores Town Limit and continue 7.1 miles (approximately 37,600 linear feet of beach) to the Salter Path/Emerald Isle Town Limit. Approximately 3.06 million cubic yards will be used for this phase. The second phase is expected to be constructed from November 2002 to April 2003, and will envelope a 3.0-mile stretch (approximately 15,700 linear feet of beach). The project boundary for this phase includes 2,800 feet of Reach 2 and all of Reach 3, starting at the Salter Path/Emerald Isle Town Limit and terminating at 30th Street. Approximately 1.68 million cubic yards of material will be used for this phase. Phase 3, which is comprised of Reach 1 and the remainder of Reach 2, includes a 6.7-mile stretch (approximately 35,400 linear feet) from 30th Street to Shipwreck Lane. The amount of material used in this phase is estimated at 1.96 million cubic yards.

Plans show the use of approximately 6.7 million cubic yards of material for the entire project. Typical fill sections would add approximately 44 to 113 cubic yards per linear foot of beach and advance the shoreline 50 to 125 feet. The scope of the work consists of utilizing three offshore borrow sites, A, B1, and B2, as a source of dredge material to nourish the beach. Borrow Site A is located approximately 3.0 miles offshore from the Indian Beach/ Emerald Isle Town limits (Reach 3 & 4) and contains approximately 3.1 million cubic yards of usable material. The total area of this borrow site is approximately 1,460 acres. Borrow Site B1 is positioned approximately 2,500 linear feet offshore of Pine Knoll Shores (Reaches 5 & 6). Comprising 2.2 million cubic yards of usable material, this borrow area is approximately 520 acres in size. Borrow Site B2 is located approximately 2,000 linear feet offshore between Borrow Site A and the mainland. This borrow area contains approximately 3.4 million cubic yards of usable material and encompasses an 830 acre area.

Equipment used in the nourishment activity will be a hydraulic dredge. Of these dredges, there is a 95 percent probability that the work will be accomplished using a hopper dredge. The hopper dredge will make cuts 2.0 feet deep in the borrow Site A and 3.0 feet deep in Borrow Sites B1 & B2, with a 1.0 foot margin of error. Once the dredge is full to capacity, the material is transported to a buoyed pipeline anchored near shore and pumped via submerged pipeline to the dry beach. The dredged material will be deposited in an area between the foredune and a temporary dike that will be constructed 150-200 feet seaward of the foredune. This will allow the coarser material to settle out within a contained system while the finer sediment washes into the surf zone. As the material is disposed on the beach, bulldozers will be used to spread the material to an elevation of +7.0 feet NGVD. The dimensions of the beach profile will vary contingent upon site-specific deficits. Daily operations will work within 500 to 1,000 linear foot of shoreline. Upon completion of a section, the submerged pipe and equipment will be relocated to the next section.

The purpose of the project is to restore the recreation beach and its associated habitats in the chronic erosion areas of Bogue Banks, and to preserve property values and the tax base of Carteret County. The shoreline has been severely damaged within the last five years from hurricanes and winter storms, and is expected to show increasing erosion problems that will affect over 395 threatened dwellings if the nourishment project is not completed. This section of Bogue Banks Barrier Island generates critical tourist and tax revenue and the continuing erosion is expected to threaten this valuable public economic resource for Carteret County. The proposed nourishment project is to ensure short and long term protection of this resource.

Environmental Setting:

Bogue Banks is a 25-mile long barrier island that traverses east and west with a southward facing ocean shoreline. The island is between two major tidal inlets, Bogue Inlet to the west and Beaufort Inlet, a major commercial inlet, to the east. Bogue Inlet drains the White Oak River and western Bogue Sound while Beaufort Inlet drains the Newport River, eastern Bogue Sound and portions of the North River. Bogue Sound borders the north side of the island while Onslow Bay of the Atlantic Ocean flanks the south side. Of the 80 miles of Carteret County barrier island shoreline, Bogue Banks is the only developed area.

Environmental Impacts:

(Reference the October 19, 2001 "Environmental Assessment Bogue Banks Beach Nourishment Project Carteret County North Carolina", as "EA" in this document, for details on environmental impacts incurred with this project):

Impacts are expected within the borrow sites, intertidal, and onshore areas. Benthic sessile organisms, predominantly polychaete worms, inhabiting the areas to be dredged will be removed with the use of the hopper dredge or other hydraulic dredges. Once extracted and pumped onto the beach, these organisms will be buried and eliminated. However, impacts to benthic organisms will be minimized with the hydraulic dredge cutting to shallow depths of only 2-3.0 feet and leaving undisturbed strips within the borrow sites. It is anticipated that benthic recolonization of the borrow sites will occur in a range from a few months to 2.0 years.

For benthic invertebrates, such as mole crabs, amphipods, isopods, coquina clams, and polychaete worms, living nearshore and in the intertidal zone, impacts will be immediate. These organisms will be smothered with the placement of dredged material on the beach. However, several studies (as documented in the "EA") have shown benthos populations recovering within 6.5 months after completion of beach nourishment projects. With these results, impacts are expected to be short term.

With the expected short-term impacts to the benthic communities, it is anticipated this will result in some affects to demersal organisms since benthos organisms are a predominant food source, and, in turn, affect pelagic species that feed on demersal species. These organisms, specifically spot, croaker, sea mullet, summer flounder, menhaden, and shrimp species, contain an important commercial value for the fishing industry. However, these impacts are expected to be short lived due to the fact that the borrow area comprise of only 3 percent of the ocean bottom for Bogue Banks Barrier Island. These organisms are mobile, and have the ability to retrieve food and inhabit the surrounding undisturbed ocean bottom and water column. Additionally, the project will take place in three separate phases. This is expected to allow portions of the borrow areas in Phase 1 to recoup some of the losses during a 6.5 month period prior to undertaking Phase 2, likewise with Phase 2 and 3.

Additional impacts to both demersal and pelagic dwellers are expected from the resulting turbidity of the dredging and disposal operation. Turbidity, or suspended particulates, will damage respiratory structures of larvae and juvenile fish inhabiting the borrow sites and the intertidal areas. Additionally, the turbidity is expected to affect feeding activities, in the immediate area, for fish species relying on sight to detect their prey. Although these impacts are unavoidable, the severity of the suspended sediments can be reduced contingent on the percentage of fines (silts and clays) or mud content in the material dredged (NC and Army Corps of Engineers target materials with <10% mud content as a general guideline). The material to be extracted from borrow sites are the following: 1) Borrow Site A contains a mean grain size ranging from 0.51mm to 0.54mm (coarse sand), 2) Borrow Site B1 has a mean grain size averaging 0.28mm (medium sand), and 3) Borrow Site B2 results show an average mean grain size of 0.313mm (medium sand). All three borrow areas contain a percent mud content averaging 3.1 to 4.0. With these results along with natural turbidity occurrences, it is expected that long-term turbidity from the project will not occur; therefore, these impacts should be minimal.

To further protect against any unexpected long-term impacts to the pelagic, demersal, and benthos communities, a comprehensive monitoring plan will be implemented to detect any measurable changes during and upon completion of the three-phased project. The monitoring plan was coordinated with the National Marine Fisheries Service (NMFS) and the North Carolina Division of Marine Fisheries (DMF) to verify its adequacy. The results of the monitoring will not only allow for a post-construction evaluation of this beach nourishment project, but will aid in evaluating future beach nourishment proposals.

With the disposal of material onshore, minor impacts to dry beach wildlife are expected. The dry beach, including the foredune, is utilized mostly by bird species, such as seagull species, pigeons, starlings, sparrows, and black birds. These opportunistic species are accustomed to human populations and are expected to adapt to changes posed by the dredging operation. The project is expected to provide a short-term abundance of invertebrate food source, which will benefit many bird populations, specifically the gull species. Other beach wildlife impacted by the project is a scattered population of ghost crabs along the foredune, and small rodents that live among the vegetated portions of the dune. These impacts are expected to be short term due to the severity of past hurricane damage along these portions of the dry beach and foredune. In fact, these impacts should be negated since additional habitat for these organisms will be created and may result in increasing populations.

Although short-term impacts are expected, long term affects on the mentioned inhabitants of the project area are expected to be minimal. To ensure these impacts are minimal, the work will be restricted to a winter and early spring dredging window. Additionally, a monitoring plan will be implemented immediately to measure any short-term and possible long-term affects on the benthic and demersal populations within the offshore borrow sites and the onshore disposal area.

In regards to threatened and endangered species that occupy or may utilize the area, the species of concern are the whales, Right, Finback, Humpback, Sei, and Sperm; the sea turtles, Hawksbill Leatherback, Kemp's Ridley, and Green; the West Indian Manatee; the Shortnose Sturgeon; the Piping Plover; the Roseate Tern; and the Seabeach Amaranth. To ensure that these species are "not likely to be adversely affected", Section 7 consultation was initiated with both the US Fish and Wildlife Service (USFWS) and the NMFS Protective Resource Division pursuant to the Endangered Species Act. We determined that the species that may be affected were the whales, the turtles, the sturgeon, and the seabeach amaranth. However, through informal consultation with both Federal agencies, conservation measures will be implemented during and after the completion of the project to ensure that the project is "not likely to adversely affect" any of the listed species. In the period from 1996 to present, over (215) CAMA beach bulldozing permits were issued for chronic erosion from Pine Knoll Shores to Emerald Isle, in contrast to (2) CAMA permits for pre-1996 nourished Atlantic Beach. This, and other, pre-documentation of the project site and post documentation from Atlantic Beach nourished area demonstrate that the nourishment is likely to benefit seabeach amaranth populations and sea turtle nesting habitat.

<u>**State Comments**</u>:

1. The North Carolina Division of Water Quality issued 401 General Water Quality Certification Number 3274, dated March 23, 2001, for the authorization to conduct the entire 16.8 miles Bogue Banks Beach Nourishment Project with the following condition:

DWQ staff recommended that the CAMA Permit be conditioned to address all issues raised in the EA or EIS.

2. Coordination with the North Department of Cultural Resources revealed the presence of six archaeological sites along Bogue Banks. To avoid damage to these sites, the coordinates of each one has been sent to the applicant by letter dated June 29, 2001. None of these sites are located within the borrow or disposal areas. In a July 25, 2001 telephone conversation with Mr. Chris Southerly of the Archaeology Underwater Department, he stated that the agency does not object to the project, in fact, beach nourishment provides additional sand material that further protects any site located on the beach. This no objection statement is reiterated in their June 29 letter.

3. The North Carolina Division of Coastal Management determined the project to be consistent with the North Carolina Coastal Area Management Act, by letter dated October 5,

2001, provided the following conditions are met:

a. In addition to the permittee listed above, the Towns of Pine Knoll Shores, Indian Beach and Emerald Isle have all submitted documentation requesting that their municipalities be added as co-applicants to Carteret County's permit application. Consequently, these three Towns are hereby added to this permit as co-permittees, and as such are bound by all permit conditions contained herein.

Beach Nourishment Activities

b. Prior to the initiation of any beach nourishment activity above mean high water (MHW) within the limits of the permittee's jurisdiction (e.g. Pine Knoll Shores), easements from all property owners within that specific community must be obtained.

c. Prior to the initiation of any beach nourishment activity, the existing mean high water line and the first line of stable natural vegetation used as the reference point for measuring future oceanfront setbacks must be delineated and the line approved by representatives from the Division of Coastal Management. The approved lines must be surveyed in and the survey submitted to Division. If nourishment activity for a particular community is not initiated within sixty (60) days and/or there is a major shoreline change prior to the commencement of beach nourishment of beach nourishment, a new survey must be conducted.

d. In order to protect threatened and endangered species and to minimize adverse impacts to offshore, nearshore, intertidal and beach resources no beach nourishment activity may occur from April 1 to November 15 of any year without prior approval from the North Carolina Division of Coastal Management in consultation with the NC Division of Marine Fisheries and the NC Wildlife Resources Commission.

NOTE: The permittee is advised that there may be additional timing restrictions placed on the authorized project by the U.S. Army Corps of Engineers as part of the Federal permit process. Nothing in this State Permit should be construed as overriding or superceding any such Federal permit requirement.

e. This permit authorizes beach nourishment activities to be carried out one (1) time along the entire reach of the requested project area. Any request to carry out additional activities within an area where nourishment activities have been completed will require a modification of this permit.

f. All excavation activities must take place within one of the three borrow areas (A, B1, and B2) as shown on the attached workplat drawings. Excavation from borrow area A shall not exceed –3' below existing contours while excavation from borrow area B1 and B shall not exceed –4' below existing contours.

g. Temporary dikes must be used to retain and direct flow of material parallel to the shoreline to minimize surf zone turbidities. The temporary dikes shall be removed and the beach graded in accordance with approved profiles upon completion of pumping activities within each specific area.

h. Only beach quality sand shall be used for beach nourishment purposes. Furthermore, sand of similar grain size to the existing beach will be used to reduce any changes in physical characteristics of the beach.

i. Should the dredging operations encounter any non-beach compatible sand, the dredge shall immediately cease operation and move to an approved area where suitable material does exist.

j. The seaward nourishment limit varies among the six nourishment plan reaches. However, the seaward nourishment limit for each reach must be conducted in accordance with the approved work plats labeled Nourishment Plan Reach 1 through 6, each dated January 19, 2001 except for reach six which is dated August 29, 2001.

k. In order to prevent leakage, dredge pipes shall be routinely inspected. If leakage is found and repairs cannot be made immediately, pumping of material shall stop until leaks are fixed.

l. Once a section is complete, piping and heavy equipment shall be removed or shifted to a new section and the area graded and dressed to final approved slopes.

m. Land-based equipment necessary for beach nourishment work shall be brought to the site through existing accesses. Should the work result in any damage to existing accesses, the accesses must be restored to pre-project conditions immediately upon project completion in that specific area.

n. Where oceanfront development exists at elevations nearly equal to that of the native beach, a low protective dune will be pushed up along the backbeach to prevent slurry from draining towards the development.

o. Dune disturbance shall be kept to a minimum. Any alteration of existing dunes shall be coordinated with the Division of Coastal Management as well as the pertinent property owner. All disturbed areas must be restored and revegetated immediately following project completion in that specific area.

p. The applicant has committed to the installation of dune fencing and plantings where appropriate. Any such proposal involving sand fence installation shall be submitted to the Division of Coastal Management for approval to insure that such installation does not impede public access or emergency vehicles and does not endanger nesting sea turtles. Any derelict sand fencing shall be immediately removed from the beach.

q. Prior to any beach nourishment activity, all exposed remnants of or debris from failed erosion control structures must be removed by the permittee.

r. The permittee shall begin dredging and pumping at the eastern end of the project to minimize impacts to the stop net fishery, unless consultations with the Division of Marine Fisheries indicate otherwise.

Endangered Species Protection

s. An observer shall be present on the hopper dredge except during the colder months of January and February to document any takes of sea turtles or other endangered species. Any encounters with threatened or endangered species will be recorded and reported to the Division of Coastal Management, the Wildlife Resources Commission, the U.S. Army Corps of Engineers and the U.S. Fish and Wildlife Service. In addition, a turtle deflector draghead shall be properly used.

t. Only beach quality sand suitable for sea turtle nesting, successful incubation and hatchling emergence shall be used for beach nourishment purposes. Furthermore, sand of similar grain size to the existing beach will be used to reduce any changes in physical characteristics of the beach that may affect nest survival.

u. In accordance with commitments made in the EIS prepared for this project, immediately after completion of any phase of the beach nourishment project, and prior to the next three nesting seasons, beach compaction shall be monitored and tilling shall be conducted as necessary to reduce the likelihood o impacting sea turtle nesting and hatching activities. All tilling must be done to a depth of 36 inches and must be completed no later than May 1. An annual report on the beach compaction monitoring shall be provided to the Division f Coastal Management and the NC Wildlife Resources Commission by June 1st of each year in which monitoring takes place.

v. Should any work take place within the sea turtle nesting period of May 1st to November 15th, sea turtle crawl and nest monitoring will take place each morning. Any necessary nest relocations will be coordinated with the NC Wildlife Resources Commission and carried out by qualified personnel prior to the construction of that project section.

Biological Monitoring Requirements

w. The sampling procedures and protocols described in the August 31, 2001 sampling design submitted by Coast Science Associates will be carried out for the 2001-02 dredging window only. Prior to the initiation of activities any future dredging windows, a sampling design shall be developed in coordination with the N.C. Division of Marine Fisheries (DMF) that further satisfies DMF concerns. A copy of this monitoring protocol, as well as written approval of its acceptance by the DMF, must be provided to the Division of Coastal Management prior to initiation on dredging during these future dredge windows. All conditions and stipulations of this modified monitoring plan must be strictly adhered to.

x. For each sampling period (i.e. June and November), benthic sampling at each beach station shall be conducted during the same portion of the tidal cycle. Beach benthos, especially

Donax spp., migrates along the beach face in response to water level. Sampling all five locations along the transect as close together temporally as possible will prevent sampling the same group of animals twice.

y. Unless altered herein, the permittee shall implement the biological sampling and monitoring program outlined in Appendix C of the Environmental Impact Statement prepared for this project.

Post Nourishment Beach Sediment Monitoring

z. Beach compaction shall be monitored and tilling shall be conducted in any areas where the post nourishment beach is harder than 500 CPU's. The monitoring and tilling shall also be done in accordance with Condition (U) of this Permit.

Sedimentation and Erosion Control

NOTE: An Erosion and Sedimentation Control Plan will be required for this project. This plan must be filed at least thirty (30) days prior to the beginning of any land disturbing activity. Submit this plan to the Department to Environment and Natural Resources, Land Quality Section, 127 Cardinal Drive Extension, Wilmington, NC 28405.

Cultural Resource Protection

aa. The N.C. Department of Cultural Resources (NCDCR) has identified six archaeological sites along the Bogue Banks Reaches. These sites are listed as follows:

001BBB- Iron Steamer Pier Wreck Site
002BBB- Gun Emplacement Site
003BBB- Salter Path Site
004BBB- Cupulo Site
005BBB- Emerald Isle Pier Wreck Site
006BBB- Ocean Reef Site

The exact locations of these six sites may be confirmed by contacting a representative of the NCDCR at (919) 733-4763. All authorized work shall avoid these areas unless prior approval is obtained from NCDCR.

bb. As referenced in the text addendum to the permit application, the western portion of Borrow Area B-2 shall be avoided due to the presence of 10 magnetic anomalies.

cc. There exists the possibility that the authorized activities may unearth a beached shipwreck. Should such a finding occur, the permittee shall immediately move to another area. The NCDCR Underwater Archaeology Branch must also be contacted at (910) 458-9042 to determine appropriate response procedures.

General

dd. The permittee and/or his contractor shall schedule a pre-construction conference with a Division of Coastal Management representative prior to the initiation of any dredging activities. No attempt will be made by the permittee to prevent the full and free use by the public of all navigable waters at or adjacent to the authorized work.

ee. The authorized activity must not cause an unacceptable interference with navigation.

ff. The permittee shall comply with all U.S. Coast Guard regulations.

gg. All commitments made during the environmental review process as found in the Final Environmental Impact Statement must be adhered to, including the basic procedures described in the sampling design dated August 31, 2001 and with the associated Biological Monitoring Proposal.

hh. This permit does not grant any property rights or exclusive privileges to the permittee.

ii. The permittee shall obtain any necessary authorizations or approvals from the USACOE prior to initiation of permitted activity. All conditions of this Federal approval must be adhered to, including the commitment made by the permittee to provide public access consistent with Federal regulations and policies.

jj. The permittee and/or his contractor shall provide for proper storage and handling of all oils, chemicals, hydraulic fluids, etc., necessary to carry out the project.

kk. This permit does not authorize any permanent or long-term interference with the public's right of access and/or usage of all State lands and waters.

NOTE: This permit does not eliminate the need to obtain any additional state, federal, or local permits, approvals or authorizations that may be required.

NOTE: The permittee is advised that the State of North Carolina claims title to all lands raised above the mean high water line.

NOTE: Future nourishment activities may require a modification of this permit. Contact a representative of the Division at (252) 808-2808 prior to the commencement of any such activity for this determination.

NOTE: The permittee and/or his contractor are urged to meet with a representative of the Division prior to project initiation.

NOTE: The N.C. Division of Water Quality has authorized the proposed project under General

Water Quality Certification No. 3274 (DWQ Project No. 010324), which was issued on 03/23/01.

Federal Comments:

1. In an April 13, 2001 letter, US Environmental Protection Agency (EPA) disclosed particular aspects of the project that concerned that agency. First, EPA believes that the applicants should evaluate and formulate a long-range solution, specifically a 50-year planning time frame, instead of a 10-year design. Second, it is their belief that the implementation of this large project by four separate municipalities may result in the following difficulties: coordination of dredging sites, ensuring compliance with the permit, and ensuring that most of the municipalities will complete the project. Other concerns and measures expressed are providing mitigation for project impacts in near-shore areas by municipalities reducing stormwater runoff to these areas, revising and improving land use plans, acquiring undeveloped lots for green space, and potential impacts to nearshore hardbottom.

The applicant selected a 10-year plan due to the presence of over 395 structures, including single family, condominiums, and mobile homes that were identified as endangered in a post-Hurricane Floyd survey and the number of beach bulldozing permits annually requested. Coordination for each phase will be specific in regards to identifying borrow areas, and the applicant's will be responsible to ensure compliance with all mitigation and conservation measures for the entire project. For stormwater runoff concerns, the majority of the runoff drains toward Bogue Sound, away from the ocean, or within isolated depressions on the island. In regards to green space, over 90 percent of the oceanfront on Bogue Banks Island has been developed, with Fort Macon State Park occupying most of the undeveloped area. Avoidance of hardbottom impacts is addressed in the "EA" and EFH assessment.

2. In an April 5, 2001 letter, the US Department of the Interior Office of the Solicitor requested that a disclaimer be obtained from NC to demonstrate no affect on the delimitation of the coastline. Mr. Bobby Poole of the NC State Properties was contacted on June 11 and October 4, 2001 regarding this matter. In the October 4 discussion, Mr. Poole referenced his conversation with the NC Attorney General who stated that a disclaimer could not be legally obtained. The permit will be conditioned that the applicants obtain a NC disclaimer prior to conducting the work.

3. In a July 26, 2001 letter, the NMFS Protective Resource Division concluded informal consultation regarding listed endangered and threatened species, under their purview, within the project area. Their agency believes that any adverse effects have been adequately considered and minimized by the implementation of the terms and conditions established in the 1995 and amended 1997 Regional Biological Opinion, including the placement of observers on the dredge equipment.

4. Pursuant to the Endangered Species Act, formal consultation was initiated due to potential adverse impacts to listed species within the project area. Upon review of the July 2001 Biological Assessment, USFWS developed conservation measures that, outlined in a September

20, 2001 letter, could be implemented for the project and coordinated through informal consultation. In response, the applicants have provided written agreement to execute all identified conservation measures.

5. In a June 1, 2001 letter, USFWS provided comments pursuant to the Fish and Wildlife Coordination Act. The concerns expressed are the following: 1) 404(b)(1) guidelines, 40 CFR 230.10(c), and National Environmental Policy Act (NEPA) has not been satisfied, adding the need to prepare an EIS, 2) need to specify amount of fill volume and elaborate on turbidity and its affects, 3) inadequate sampling design in the monitoring plan, 4) incompatible material, specifically percent calcium bicarbonate, and the potential to harden the beach, 5) impacts to offshore benthos communities, 6) cumulative impacts, and 7) the permit should be modified to avoid, minimize, and mitigate anticipated adverse environmental impacts.

It was determined that a Federal EIS was not required due to the adequate documentation in the applicant's April 4, 2001 State EIS, that included considerable State agency and public input; the July 2001 Biological Assessment for Threatened and Endangered Species, the May 15, 2001 Essential Fish Habitat Assessment, and the supplemental information collected in the permit review process. Additionally, as discussed in the "EA", the implementation of a phased approach, refined borrow sites, shallow cuts in the borrow areas, altering the use of each borrow site to increase sand compatibility, pre- and post-monitoring plan for benthic and demersal organisms, monitoring threatened and endangered species during and post-construction, and routine compaction test are expected to minimize any unknown significant impacts that may occur on the quality of the human environment. Also, in a similar beach nourishment project in New Jersey, the pre-and post- monitoring results, conducted by the US Army Corps of Engineers (ACE) New York District and the Waterways Experiment Station of the USACE, in a 2001 Final Report demonstrated that only short-term affects, not significant, were incurred on the aquatic resources after the beach nourishment activity.

Fill volumes and turbidity have been specified and elaborated on in the "EA". The August 23, 2001 monitoring plan, measuring benthic and demersal impacts, was coordinated with the NMFS and the DMF, with input from Dr. Charles Peterson, and was determined to be adequate. This plan will include the borrow sites and the intertidal zone.

Based on these initial comments concerning sand compatibility, an additional 64 borings were conducted to further refine the borrow sites. Additionally, Mr. Ben Lackey of the Army Corps of Engineers (ACOE) Geotechnical Section and Mr. Phil Payonk of the ACOE Environmental Resources Section reviewed the compatibility results internally. Both Messrs. Lackey and Payonk provided comments concerning the compatibility of the proposed borrow areas. Their overall review showed the material to be compatible, with small differences that will lessen over time. Mr. Payonk provided comments concerning the higher percentage of carbonates and grain size in Borrow Site A, specifically. In conversations with Mr. Payonk, he stated that this difference is not documented to show any adverse affects on nesting turtles, benthic species, or other organisms inhabiting the project site. The project has been designed by the applicant to rotate the use of each borrow area at an approximate 2:1 ratio to reduce the deposit of Borrow Site A material in one long contiguous stretch of beach. For every four (4) loads from Borrow

Sites B1 and B2, there will be two (2) loads from Borrow Site A. This requirement to reduce the percentage of carbonate will result in additional cost to the applicant. In addition, the native beach has been described as an area that contains material with a broad distribution ban. With this broad distribution, it is expected that the material will sort out through natural processes and will be similar to the native beach. Compaction test will be conducted within designated transect to ensure cementation/hardening of the beach is not present. If the test are positive, tilling of the beach and readjusting the borrow areas for Phase II and III will take place. See "EA" addressing cumulative impacts, avoidance, minimization, and mitigation aspects of the project.

6. NMFS Habitat Conservation Division provided their concerns and comments in April 20, June 25, and September 26, 2001 letters. Their initial concerns referenced the presence of EFH within the project area, potential impacts to hardbottoms, the absence and need of monitoring plan (post and pre-construction), problems with suspended sediments (turbidity) and sand compatibility, insufficient NEPA review, and threatened and endangered species consultation under NMFS purview. In response to NMFS concerns, specifically with EFH, a May 15, 2001 EFH assessment was submitted to NMFS, and additional information was sent to their office, in an August 17, 2001 letter, addressing the above-mentioned concerns. Additionally, several meetings were conducted to resolve these issues and the August 23 monitoring plan has been approved.

Other Comments:

1. In an April 10, 2001 letter, a private citizen, Mr. Robert Murphy, expressed his concerns with the proposal. Disclosed in the letter, Mr. Murphy requested that a public hearing be held for public input on the final State EIS, the issue of public access be addressed, and that highly qualified personnel conduct all biological monitoring and paid for by the State to avoid a conflict of interest. In an October 9, 2001 telephone conversation with Mr. Mickey Sugg of my staff, these issues were adequately addressed.

2. The North Carolina Environmental Defense Fund stated, in a April 22, 2001 letter, their objections to the issuance of a permit for the following reasons: 1) the applicant should perform a new, comprehensive Environmental Impact Statement (EIS) for this project, 2) the need to develop a thorough, scientifically defensible cumulative impacts analyses for this and all ongoing and proposed beach engineering projects, and 3) the design and implementation of a statistically valid monitoring plan. It has been determined that a Federal EIS is not required as stated in paragraph (5) of Federal Comments. The applicant has addressed cumulative impacts in the October EA and has developed an approved monitoring plan.

3. In an April 12, 2001 letter, the North Carolina Coastal Federation requested the need for a Federal EIS, a public hearing, documentation examining EFH, additional information on sand compatibility, examination of cumulative impacts for all NC beach nourishment projects, and the inclusion of an adequate monitoring plan and alternative analysis. In addition, concerns were raised with allowing maintenance and potential renourishment in this project and in the applicant's requested November 1 to May 15 dredging window. For reasons stated in paragraph (2), it has been determined that a Federal EIS and public hearing is not required. EFH concerns

have been addressed, 64 additional borings have refined the borrow sites, and a monitoring plan has been approved by the DMF and the NMFS. Furthermore, the economics section of the alternative analysis has been reviewed and verified by an economist in the Planning Department of the Army Corps of Engineers as a thorough and adequate analysis. It has been confirmed that maintenance is not a part of the permit, and that the dredging window, verified by DMF, NMFS, and USFWS, will be November 16 to April 15.

4. Dr. Charles Peterson of the University of North Carolina at Chapel Hill Institute of Marine Sciences expressed his concerns, in an April 13, 2001 letter, regarding the inadequacy of the monitoring plan. Through various revisions of the plan, a final monitoring plan dated August 23, with Dr. Peterson's input, has been approved by the NCDMF and NMFS.

Alternatives:

The applicant has identified and thoroughly discussed three alternatives in its EA: 1) no action; 2) abandon property, retreat, and relocate; and 3) nourish the beach. The applicant also identified and discussed several variations of the beach nourishment alternative, including alternate borrow areas, methods of construction, fill profiles, and construction schedules.

The applicant concluded that neither the no action alternative nor the retreat/relocation alternative would not meet the project purpose of restoring the recreation beach and preserving property values and the tax base of Carteret County. The applicant also provided data on the costs to the applicant of both of these alternatives. I concur that neither the no action nor the retreat/ relocation alternative meets the applicant's purpose and need, and neither is practicable.

The only practicable alternative to ensure storm protection and to secure tax revenue within a 10-year period is to nourish the beach. Upon studying nourishment, several options were identified: lagoon sediments, inlet shoals (both inshore and offshore), nearshore bars, offshore deposits, recycled spoil sediments, accreting spits/beach deposits, attached bar deposits, inland deposits, freshwater pond deposits, fillets at jetties, and imported material. Of these choices, offshore deposits, inlet shoals (inshore and offshore), and recycled spoil sediments were more likely to provide the most compatible material to nourish the beach in the project area. Due to compatibility and other environmental concerns, the offshore deposits were the most practicable alternative as a nourishment source. See Section 2.0 of the "EA" for further details.

Evaluation:

I have reviewed and evaluated, in light of the overall public interest, the documents and factors concerning this permit application as well as the stated views of other interested agencies and the concerned public. In doing so, I have considered the possible consequences of this proposed work in accordance with regulations published in 33 CFR Part 320 to 330 and 40 CFR Part 230. The following paragraphs include my evaluation of comments received and how the project complies with the above-cited regulations.

a. Consideration of Comments: In accordance with policy guidance from the office, Chief of Engineers, Regulatory Guidance Letter 92-1, Federal Agencies Roles and Responsibilities, I have fully considered all agency comments. The proposed project will result in minimum adverse impacts to the waters of the Atlantic Ocean. It is my position that, with the inclusion of appropriate special conditions, all concerns of the responding agencies and public have been satisfied.

b. Evaluation of Compliance with 404(b)(1) Guidelines (Restrictions on discharge, 40 CFR 230.10): (An * is marked above the answer that would indicate noncompliance with the guidelines. No * marked signifies the question does not relate to compliance or noncompliance with the guidelines. An "X" simply marks the answer to the question posed.)

1. Alternatives test:

	Yes	No
	*	
a. Are there available, practicable alternatives having less adverse impact on the aquatic ecosystem and without other significant adverse environmental consequences that do not involve discharges into "waters of the United States" or at other locations within these waters?	___	X
		*
b. If the project is in a special aquatic site in a special aquatic site and is not water dependent, applicant clearly demonstrated that there are no practicable alternative sites available?	X	___

2. Special restriction. Will the discharge:

	Yes	No
	*	
a. violate state water quality standards?	___	X
	*	
b. violate toxic effluent standards (under Section 307 of the Act)?	___	X
	*	
c. jeopardize endangered or threatened species or their critical habitat?	___	X
	*	
d. violate standards set by the Department of Commerce to protect marine sanctuaries?	___	X

e. Evaluation of the EA indicates that the proposed discharge material meets testing exclusion criteria for the following reason(s):

* X Yes ___ No

(X) based on the above information, the material is not a carrier of contaminants.

( ) the levels of contaminants are substantially similar at the extraction and disposal sites and the discharge is not likely to result in degradation of the disposal site and pollutants will not be transported to less contaminated areas.

( ) acceptable constraints are available and will be implemented to reduce contamination to acceptable levels within the disposal site and prevent contaminants from being transported beyond the boundaries of the disposal site.

3. Other restrictions. Will the discharge contribute to significant degradation of "waters of the United States" through adverse impacts to:

a. human health or welfare, through pollution of municipal water supplies, fish, shellfish, wildlife and special aquatic sites?

* ___ Yes X No

b. life stages of aquatic life and other wildlife?

* ___ Yes X No

c. diversity, productivity and stability of the aquatic life and other wildlife or wildlife habitat or loss of the capacity of wetland to assimilate nutrients, purify water or reduce wave energy?

* ___ Yes X No

d. recreational, aesthetic and economic values? | * ___ X Yes No

4. Actions to minimize potential adverse impacts (mitigation). Will all appropriate and practicable steps (40 CFR 230.70-77) be taken to minimize the potential adverse impacts of the discharge on the aquatic ecosystem? | * ___ X Yes No

Summary:

I have reviewed the application, plans, and the environmental assessment furnished by the applicant. I am aware that the project would involve activities within Section 10 and 404 waters of the United States. As previously discussed, I do not consider any of these impacts significant.

After coordination with the appropriate State and Federal agencies and reviewing the application and plans and the public interest record, I find that the proposed work is not controversial, will not have a significant effect on the quality of the human environment, and complies with all requirements of National Environmental Policy Act and the 404(b)(1) Guidelines of the Clean Water Act.

I find that this application is not a major Federal action significantly affecting the human environment; and hence, the preparation of a detailed statement under Section 102(2)(c) of the National Environment Policy Act of 1969 is not required.

I have given full consideration to this application. After weighing favorable and unfavorable aspects, I find that the issuance of a permit to Carteret County, and the Towns of Pine Knoll Shores, Indian Beach, and Emerald Isle will not be contrary to the general public interest provided that it adheres to the conditions incorporated in the permit.

Approved by: Date 26 OCT 01

James W. DeLony
Colonel, U.S. Army
District Engineer
