foreseeable future actions in the Beaufort Sea and Chukchi Sea Planning Areas relative to the LMEs.

Ongoing Oil and Gas Exploration, Development, and Production Activities and Existing Infrastructure.

Onshore and in State Waters. Oil and gas exploration in the Arctic region of Alaska began in the late 1950s when federally-sponsored geological studies found that the region had significant oil reserve potential. The first State of Alaska lease sale on the North Slope took place in 1964, and by 1968, the Prudhoe Bay oil field (the largest oil field in North America) was in production. By 2001, oil development on the North Slope consisted of 19 producing fields and related infrastructure (roads, pipelines, power lines, production facilities, and transportation hubs). Because of the high cost of building infrastructure (due to the remoteness and harsh weather of the region), many Arctic fields remain undeveloped; for example, the EIA estimates that 35.4 Tcf of the discovered natural gas resources in the Arctic, two-thirds of which is in the Prudhoe Bay field, remain undeveloped due to lack of transportation infrastructure (NRC 2003; Budzik 2009).

Currently, there are 35 producing oil fields and satellites on the North Slope and nearshore areas of the Beaufort Sea. The oil fields are distributed among the various unit pools shown in Figure 4.6.1-8: Prudhoe Bay (12), Duck Island (3), Northstar (1), Badami (1), Kuparak (5), Milne Point (3), Colville River (8), Ooogaruk (1), and Nakiatchuq (1) (NTEL 2009). Industrial development centers on Prudhoe Bay; infrastructure includes artificial gravel islands, roadways, pipelines, production and processing facilities, gravel mines, and docks. Most oil and gas projects are onshore or are located offshore in State waters of the Beaufort Sea. Currently, there are no leases in the State waters of the Chukchi Sea, and no oil and gas production along its coast (MMS 2008b).

Two large diesel fuel spills occurred in the Beaufort Sea — one with a volume of 2,440 bbl, from a diesel tank on an eroded gravel island in the Canadian Beaufort Sea (September 1985); and another with a volume of 1,600 bbl, from a punctured barge delivering fuel to Kaktovik (August 1988) (MMS 2008b). Between 1995 and 2005, there were 4,481 spills of seawater, produced water, crude oil, diesel, and drilling muds on the Alaska North Slope subarea, with an estimated volume of 45,000 bbl (98% of which resulted from spills greater than 99 gal). Oil exploration and production facilities were responsible for more than 90% of the spills and about 90% of the volume. Over the past 20 years, however, most large spills were of diesel fuel and occurred in local villages (ADEC 2007a; MMS 2008b).

Ongoing oil and gas activities and existing infrastructure (both onshore and offshore) in the Arctic region contribute to cumulative effects on air and water quality, the acoustic environment, marine and coastal habitats, marine and coastal fauna (fish, marine and terrestrial mammals, and birds), sociocultural systems (local economies and subsistence), and cultural resources (if present). Important impact producing factors include subaerial noise and subsea noise and vibration, facility lighting, engine emissions and fuel spills (marine vessels and land-based vehicles and equipment), oil spills, hazardous spills and releases, oil and chemical releases (from wells and produced water), chronic seafloor disturbance (by anchors), bottom sediment disturbance (turbidity and contaminant resuspension), disturbance or injury of fish and wildlife, habitat displacement or degradation, deposition of fugitive dust, altered wildlife migration patterns, wildlife collisions with marine vessels and infrastructure, and resource consumption.

Canadian Arctic Activities. Northern Canada contains about a quarter of Canada's remaining discovered resources of conventional petroleum and a third to a half of the country's estimated potential (Northern Oil and Gas Directorate 2007). This resource is distributed throughout northern Canada as follows:

- Mackenzie Valley and onshore Yukon – Twenty-six significant discoveries and three producing fields: the Norman Wells oil field produces oil at rates of 30,000 bbl per day (6.294 bbl = 1 m^3) with initial recoverable reserves of 235 Mbbl; the Kotaneelee and Pointed Mountain fields close to the British Columbia-Alberta border had produced 417 billion ft^3 (35.3 ft^3 = 1 m^3) of gas by the end of 1997.

- Arctic Islands – Nineteen significant discoveries after fewer than 200 exploration wells; the Bent Horn field in the Arctic Islands, which produced high-quality light oil for many years on a seasonal basis, has only recently been abandoned.

- Mackenzie Delta/Beaufort Sea – Discovered resources of in excess of 1 Bbbl of oil and 9 Tcf of gas in 53 significant discoveries. Four Tcf of marketable gas have been discovered in three onshore discoveries, and offshore discoveries include over 200 Mbbl in the Amauligak field. On the Mackenzie Delta, the Ikhil gas discovery is being developed to supply natural gas to the town of Inuvik, where it will replace imported diesel oil for power generation and domestic use.

There is little information on oil and gas exploration and development activities currently being conducted by Canada in the Arctic. If such activities are in progress, it is assumed that the effects would be similar to those resulting from oil and gas exploration and development in the Alaska Arctic region.

Russian Arctic Activities. There is little information on oil and gas exploration and development activities currently being conducted by Russia adjacent to the U.S. Arctic. If such activities are in progress, it is assumed that the effects would be similar to those resulting from oil and gas exploration and development in the Alaska Arctic region.

Foreseeable Future Oil and Gas Exploration, Development and Production Activities and Infrastructure.

Onshore and in State Waters. Several exploration wells on State oil and gas leases in the Beaufort Sea have either been drilled recently or are reasonably foreseeable in 2012 (Petroleum News 2012a). These include:

- Repsol – One exploratory well (Kachemak-1) was drilled and experienced a loss of well control releasing about 42,000 gallons of drilling mud; no oil was spilled (ADEC 2012d). A permit for a second well, Q-4, was approved on March 29. The North Slope Borough and Nuiqsut has set a limit of no more than three drilling rigs operating at any given time;

- Brooks Range Petroleum Corp. – One well completed;

- Savant – Permit approved for one well, drilling would begin sometime in April;

- ConocoPhillips – One well completed;

- Pioneer – One well completed, another being drilled; and

- Great Bear – Seismic surveys underway (as of April 2), six to eight wells to be drilled beginning in mid-May.

In addition to these wells, Brooks Range Petroleum Corporation plans to drill seven horizontal production wells in the Mustang prospect by 2014. The prospect is located in the new Southern Miluveach Unit, on the southwestern boundary of the Kuparuk River Unit (Figure 4.6.1-8). Several other prospects held by Brooks Range Petroleum Corporation (near the Prudhoe Bay and Badami Units and Beechey Point) are considered economically feasible and will likely be developed in the near future (Petroleum News 2012b).

There are three other oil and gas developments in the Beaufort Sea coastal region that are reasonably foreseeable in the next 5 to 10 years, including the Alaska (Gas) Pipeline Project, the Point Thomson Project, and the Liberty Project (Figure 4.6.1-8). These projects would take place onshore or nearshore, in areas where industry infrastructure is already well established, but would also involve activities that could contribute to cumulative impacts in the marine environment, especially air and water quality, the acoustic environment, marine and coastal habitats, marine and coastal fauna (fish, marine mammals, and birds), sociocultural systems (local economies and subsistence), and cultural resources (if present).

Important impact-producing factors associated with new oil and gas projects in the Beaufort Sea coastal region include subaerial noise and subsea noise and vibration, engine emissions and fuel spills (marine vessels and land-based vehicles and equipment), oil spills, hazardous spills and releases, oil and chemical releases (in produced water), bottom sediment disturbance (turbidity and contaminant resuspension), disturbance or injury of fish and wildlife, habitat displacement or degradation, altered wildlife migration patterns, wildlife collisions with marine vessels and infrastructure, and resource consumption.

Alaska (Gas) Pipeline Project. The Alaska Pipeline Project (TransCanada) would connect the natural gas resources developed on the North Slope to markets both within and outside of Alaska. The project consists of a new gas treatment plant (GTP) near Prudhoe Bay; 93 km (58 mi) of 32-in.-diameter pipeline connecting the processing plant at the Point Thomson field to the GTP; and about 1,200 km (745 mi) of 48-in.-diameter mainline pipeline from the GTP to the Alaska-Yukon (Canada) border. TransCanada is currently in the process of conducting baseline studies and preparing reports in support of its Federal permit. The NOI to prepare an EIS for the pipeline project was issued by FERC on August 1, 2011, and public scoping took place in February 2012 (FERC 2012e). According to Office of the Federal Coordinator (Alaska Natural Gas Transportation Projects), further action on the pipeline to Alberta may be delayed while a second option, involving a pipeline to Valdez to facilitate large-scale LNG exports to Asia, is considered (OFC 2012). The pipeline project is estimated to take 10 years to permit and construct once its application is filed with FERC.

Point Thomson Project. The proposed Point Thomson Project (ExxonMobil) would delineate and evaluate hydrocarbon resources in the Point Thomson Unit (Figure 4.6.1-8), with the objective of initiating production of commercial hydrocarbon liquids by the winter season of 2015–2016. Hydrocarbon liquids would be delivered to the TAPS for shipment to market. Project activities include the construction of a central gravel pad for production and injection wells; support facilities, including offices, warehouses, maintenance buildings, temporary camps, drinking water and sanitary wastewater treatment systems, waste management facility, communication facilities, electric power generation and distribution facilities, and an emergency response boat ramp; two satellite gravel pads for production wells; ice roads; a gravel airstrip for year-round access to Point Thomson; a service pier; a sealift facility and barge mooring dolphins; a new gravel mine site; infield gravel roads; and infield gathering pipelines, one for each production well. Offshore portions of the reservoir would be reached using directional drilling. An export pipeline would also be constructed from the central pad to the existing Endicott common carrier pipeline connecting to TAPS Pump Station No. 1. Other infrastructure to be built includes water and power distribution systems, communications towers, and staging facilities (USACE 2011a).

Liberty Project. The proposed Liberty Project (British Petroleum) is an oil and gas development located about 8.9 km (5.5 mi) offshore on an expanded area of the Endicott Satellite Drilling Island (SDI) into the Beaufort Sea (Figure 4.6.1-8). The project involves expanding the Endicott SDI by about 8 ha (20 ac) to support drilling into the Liberty reservoir located on Federal offshore leases managed by BOEM and upgrading the Sagavanirktok River road bridge to accommodate the transportation of Liberty's drilling rig (both completed in 2009; Petroleum News 2009). The drilling program will include one to four production wells, and one or two water and gas injection wells. Oil produced from the project will be sent by existing pipeline infrastructure (Endicott production flowline system) from the Endicott SDI to the Endicott Main Production Island (MPI) for processing, then to the TAPS through the existing Endicott sales-oil pipeline. Produced gas will be used for fuel or re-injected into the reservoir for enhanced oil recovery. Equipment, supplies, and personnel will access the project site via the existing Endicott road system, which connects with roads at Prudhoe Bay and with the Dalton Highway. Onshore and offshore ice roads will be built to support project construction (and possibly drilling operations). No regularly scheduled helicopter access to the project site is expected (although there is sufficient area on the Endicott SDI for landing, if needed). A sealift by barge would necessitate travel through the Chukchi and Beaufort Seas; the barge would offload at an existing MPI dock. Extensive dredging is not anticipated (BP 2007).

Another onshore support activity associated with the Liberty project is the development of a new permitted gravel mine site. Water for the project is provided by the existing produced-water injection system and augmented with treated seawater (from the existing Endicott Seawater Treatment Plant), as needed (BP 2007).

The land use permit and easements for wellbores and injection wells into State subsurface were issued by the ADNR in January 2010 (ADNR 2010). The project was originally expected to start production in 2010, but has been delayed until 2013 or later (Petroleum News 2011a, b).

Federal Land and OCS Waters. There are three major areas of Federal land for which oil and gas activities are reasonably foreseeable in the next 5 to 15 years. These include the National Petroleum Preserve-Alaska (NPR-A), the Arctic National Wildlife Refuge (ANWR) Area 1002, and the Beaufort and Chukchi Seas OCS (discussed below).

<u>National Petroleum Reserve-Alaska.</u> The NPR-A is a 9.3-million-ha [23-million-ac] area of public land on the North Slope of Alaska managed by the BLM (Figures 4.6.1-7 and 4.6.1-8). The USGS estimates mean volumes of recoverable oil and natural gas in the NPR-A of 896 Mbbl and 53 Tcf, respectively. This estimate was lowered from the previous estimates on the basis of recent exploration drilling that showed an abrupt transition from oil to gas just 16 to 32 km (10 to 20 mi) west of the Alpine oil field and poor reservoir quality in key formations (Houseknect et al. 2010).

Integrated activity plans have been developed by BLM (2004, 2006a, and 2012a) that identify the lands within the NPR-A available for leasing, as well as those restricted from leasing, and specify stipulations and restrictions on surface activities in the lease areas of the NPR-A. There have been seven lease sales in the NPR-A (in 1999, 2002, 2004, 2006, 2008, 2010, and 2011) and as a result of these sales, the BLM currently administers 186 Federal oil and gas leases on the NPR-A (BLM 2012b). However, no production wells have been established in the NPR-A to date. A total of 29 exploration wells have been drilled within the reserve since 2000 (most focused to the west and southwest of Alpine), and additional exploratory drilling is likely in the coming decades (BLM 2012b). It is less certain at this time whether production facilities would be established within the NPR-A during the life of the Program.

<u>Arctic National Wildlife Refuge (1002 Area).</u> The ANWR is located on the northern coast of Alaska to the east of Prudhoe Bay (Figures 4.6.1-7 and 4.6.1-8). The area was designated by the Alaska National Interest Lands Conservation Act (ANILCA) in 1980. The USGS estimates that recoverable oil in the coastal plain area of ANWR (referred to as the 1002 Area) is between 5.7 and 16.0 Bbbl. Section 1002 of ANILCA deferred any decisions on oil and gas development until studies could be performed to better assess the extent and amount of petroleum resources, as well as potential impacts to the fish and wildlife resources in the region. These studies were completed and submitted to Congress in 1987. Currently, the 1002 Area is managed by the USFWS as a “minimal management” area and it will continue to be managed by the USFWS until Congress decides how petroleum resources in the 1002 Area will be developed. For this reason, it is uncertain whether leasing in ANWR will occur during the life of the Program (Budzik 2009; USFWS 2008).

The USFWS Comprehensive Conservation Plan (CCP) is a document that outlines and guides long-term management for a National Wildlife Refuge. The original CCP for Arctic Refuge was signed into effect in 1988. The USFWS is now midway through a 2-year process to revise the 1988 CCP and the accompanying EIS. The draft CCP contains six management alternatives but no preferred alternative. The USFWS will consider public comments before selecting a preferred alternative. The final CCP and EIS are anticipated in the summer of 2012 (see http://arctic.fws.gov/ccp.htm).

Beaufort and Chukchi Seas OCS. Exploratory drilling in Federal OCS lands began in 1981, a few years after construction of the TAPS was completed. After 33 years of leasing, however, there are no commercial oil or gas facilities on the OCS (see Figure 4.6.1-7 for active leases on the Federal OCS; Northstar accesses Federal reserves from a facility within State waters). Although exploratory drilling in the Beaufort Sea OCS has declined since 1990, there were several seismic programs in the region during the 1990s and early 2000s. Acquisitions of leases by Shell during OCS Lease Sale No. 195 (2005) and recent approval of its oil spill response plan by the BSEE indicate that drilling activity on the Beaufort Sea OCS is likely in the near term. Shell submitted its exploration plan to drill on three OCS lease blocks in the Camden Bay area of the Beaufort Sea in 2011. ConocoPhillips has also proposed drilling in the Chukchi Sea; however, at this date there in no approved plan (NRC 2003; NTEL 2009; BOEM 2012c).

Exploratory drilling in the Chukchi Sea OCS began in the late 1980s and continued into the 1990s; most of the seismic data acquisition was completed by the end of 1991 (although 2D and 3D surveys were conducted in 2006 and 2007). A second phase of activity began in early 2008 prior to OCS Lease Sale No. 193, where industry spent over 2.6 billion dollars acquiring leases. This sale is expected to initiate an exploration effort in the near term (NTEL 2009).

Exploration activities on the Beaufort and Chukchi Seas OCS could contribute to cumulative impacts in the marine environment, especially air and water quality, the acoustic environment, marine and coastal habitats, marine and coastal fauna (fish, marine mammals, and birds), and sociocultural systems (subsistence). Important impact-producing factors associated with these activities include subaerial noise and subsea noise and vibration, engine emissions and fuel spills (marine vessels), hazardous spills and releases, oil and chemical releases (from wells and produced water), disturbance or injury of fish and wildlife, and wildlife collisions with marine vessels.

Subsistence Activities. The majority of permanent residents of the Arctic and Bering Sea coasts are Alaska natives for whom subsistence activities are group activities that further core values of community, kinship, cooperation, and reciprocity (see Section 3.14.3.2). In general, subsistence foods consist of a wide range of fish and game products; these include fish, such as Broad white fish, Arctic cisco, and Arctic char/Dolly Varden; marine mammals, such as bowhead whale, bearded seal, ringed seal, and walrus; terrestrial mammals, such as caribou, wolves, and wolverines; and waterfowl, such as geese and eider. Table 3.14.3-14 provides a more comprehensive list of subsistence resources used by Alaska Native villages.

Each community has its own unique harvest pattern and preferences. Subsistence harvesting follows a seasonal pattern and is constrained by changes in climate and by the migration patterns of whales, fishes, and birds. Bowhead whales are harvested during both their spring and fall migrations. Subsistence activities generally occur along the coast, concentrated in areas directly offshore from villages. The village of Nuiqsut stages its fall bowhead whale hunt on Cross Island. Seaward harvesting occurs within 40 km (25 mi) of shore, but may extend as far as three times that distance, depending on the conditions of sea and ice. Marine vessels used in subsistence marine harvesting include light seal-skin *umiat* and aluminum skiffs (in open water for the fall harvest).

Subsistence resources on Federal lands and the navigable waters along the Arctic coast are managed by the Federal Subsistence Management Program under the FSB. The program is a multi-agency effort to support a subsistence way of life by rural Alaskans on Federal public land and waters while maintaining healthy populations of fish and wildlife (through research and monitoring). Priority for subsistence harvesting of Federal public lands and water are expressed in ANILCA. The MMPA encourages cooperative agreements between Alaska Native organizations and Federal agencies to conserve marine mammals and provide management of subsistence use.

Marine Vessel Traffic. The current level of vessel traffic is low, consisting mainly of vessels supporting the oil and gas industry (e.g., cargo vessels, tugs/barges, service vessels, spill response vessels, and hovercraft). Other vessels include those used by the military, by Arctic researchers (icebreakers), and by local communities for hunting and between-village transportation during the open water period. As open water season begins earlier and ends later, vessel traffic is likely to increase for shipping, research, and cruise-ship tourism in the coming decades (MMS 2008b).

There is substantial international vessel traffic in the Bering Strait (the narrow international strait that connects the northern Pacific Ocean to the Arctic Ocean) and Chukchi Sea (Figure 4.6.1-7); activity in this region increased from 245 marine vessel transits in 2008 (in the Bering Strait) to 325 transits in 2010. This trend is expected to continue with ongoing exploration and drilling activities on the U.S. OCS and the Northern Sea Route along the Russian portion of the Chukchi shelf (USCG 2011a).

Scientific Research. Scientific research programs are ongoing in the offshore areas of the Beaufort and Chukchi Seas. These include studies of marine mammals, fish, birds, habitats, ecosystems, and physical oceanography conducted by Federal agencies such as BOEM, NOAA (NMFS), and the NSF. Activities related to scientific research of physical systems involve the use of marine vessels, and include seismic surveys, ocean floor drilling/sampling, well installation, and geophysical logging. Activities related to scientific research of biological systems requires some human presence and interaction with wildlife, such as sampling, tagging, or tracking species of interest.

Research-related activities in the Beaufort and Chukchi Seas are likely to increase over the next 40 to 50 years (in response to concerns over the environmental effects of oil and gas development and climate change in the Arctic region). While such activities are necessary and beneficial, they may also contribute to adverse cumulative effects on water quality, the acoustic environment, coastal and marine habitats, and coastal and marine fauna (fish, marine mammals, and birds). Important impact-producing factors include subsea noise and vibration, disturbance or injury of fish and wildlife, and bottom sediment disturbance (turbidity and contaminant resuspension).

Wastewater Discharge to Arctic Waters. Point-source discharges to the Beaufort and Chukchi Seas include those from facilities related to the oil and gas industry, hard-rock and placer mining, military operations, and seawater treatment (ADEC 2010; USEPA 2010c). Most of these activities would remain at present levels for the foreseeable future and are not expected to affect the overall water quality in these regions. Discharges are regulated through the USEPA NPDES permit program. Section 403 of the CWA established the Ocean Discharge Criteria, which provide additional requirements for these types of discharges. The Alaska Department of Environmental Conservation issues all NPDES permits in Alaska except for those related to oil and gas, munitions, cooling water, pesticides, and offshore seafood processors, and those on tribal lands. Current NPDES permits in Alaska are available on the USEPA Region 10 Web site (see http://yosemite.epa.gov/r10/water.nsf/NPDES+Permits/CurrentAK822).

Non-point sources of pollution include stormwater and snowmelt that run over land or through the ground, entraining pollutants and depositing them into Arctic waters. The most common forms of pollution in Alaska's urban runoff include fecal coliform, sedimentation, and petroleum. Snow disposal into the marine environment also introduces oil, grease, antifreeze, chemicals, trash, animal wastes, salt, and sediments (sand, gravel, suspended and dissolved solids) (ADEC 2007b). Non-point source management programs under Section 319 of the CWA regulate these pollutant sources. The USEPA and NOAA also co-administer State Coastal Non-Point Pollution Control Programs under Section 6217 of the Coastal Zone Act Reauthorization Amendments of 1990.

Both point and non-point source discharges to Arctic waters are expected to continue and could increase over the next 40 to 50 years (based on projected increases in economic development in the Beaufort and Chukchi Seas coastal regions). Pollutant discharges contribute to cumulative effects on water quality, marine and coastal habitats, marine and coastal fauna (fish, marine mammals, and birds), commercial and recreational fisheries, and sociocultural systems (local communities and subsistence). Important impact-producing factors associated with discharges include contaminant releases via permitted conveyances and surface runoff.

Persistent Contaminants and Marine Debris. Persistent contaminants are natural and manmade substances introduced to the environment that are resistant to degradation naturally; these include various heavy metals (e.g., mercury, cadmium, lead, and chromium), as well as herbicides, pesticides, PCBs, and dioxin. Because they do not degrade naturally, these substances are capable of long-range transport and may bioaccumulate in the tissues of ecological and human receptors. Sources of persistent contaminants include permitted discharges and surface runoff (with suspended sediments) from agricultural, industrial, or urban areas; and atmospheric deposition. The presence of persistent contaminants in the waters and sediments in the Arctic region contributes to cumulative effects on water and sediment quality, marine and coastal habitats, marine and coastal fauna (fish, marine mammals, and birds), commercial and recreational fisheries, and sociocultural systems (subsistence). Important impact-producing factors include exposure of marine fauna to toxic pollutants (resulting in mortality or reproduction problems) and habitat displacement and/or degradation. Such factors lead to unstable or contaminated fish stocks (or other species) that in turn affect species higher in the food web (via toxicity or bioaccumulation).

NOAA defines marine debris as "any persistent, manufactured, or processed solid material that is directly or indirectly, intentionally or unintentionally, disposed of or abandoned into the marine environment" (NOAA 2009). Marine debris in Arctic waters could include ocean-based materials such as fishing gear, oil and gas items (plastic drill pipe thread protectors, hard hats, gloves, and 55-gal storage drums), and lost vessel cargo. Materials from land-based sources can also find their way into Arctic waters via blowing winds, waves washing ashore, littering, dumping in rivers and streams, and industrial losses. Weather also plays a role as storm water flows along streets and the ground carrying litter into storm drains; high winds and heavy rains are also capable of dispersing solid objects into marine waters (NOAA 2012d). The presence of marine debris in the waters and sediments of the Beaufort and Chukchi Seas contributes to cumulative effects on the same resources as described for persistent contaminants. Important impact-producing factors include collisions of marine vessels with debris and entanglement in or ingestion of debris by marine wildlife.

Military Operations. As an effect of changing climate in the Arctic (the opening of Arctic waters in the coming decades) and in response to security concerns (boundary disputes and competition for resources), the military plans to increase its presence in the Arctic region to monitor the air, land, maritime, space, and cyber domains for potential threats to the United States. This effort would include coordination with various domestic (e.g., USCG) and international partners (e.g., Russia and Canada). Military activities in the region would mainly involve the use of aircraft, submarines, icebreakers, or ice-strengthened surface vessels. The military does not anticipate a need for a deep-draft port between now and 2020. It is uncertain whether (or when) basing infrastructure would be needed; the military plans to reassess these needs periodically. Its strategy is finding balance between investing in Arctic capabilities in a timely fashion without making premature investments that draw resources away from more pressing needs (O'Rourke 2012).

Currently, the U.S. Air Force maintains four long range radar sites along the coasts of the Beaufort and Chukchi Seas: Kotzebue, Cape Lisburne, Point Barrow, and Barter Island (Figures 4.6.1-7 and 4.6.1-8). Four others have been deactivated: Point Lay (in 1994), and Wainwright, Bullen Point, and Flaxman Island (in 2007) (National Air Defense Radar Museum 2012).

In the coming decades, the military will likely increase its presence in the Arctic region via aircraft and marine vessels, including submarines and icebreakers. Increased air and marine vessel traffic contributes to cumulative effects on air and water quality, the acoustic environment, marine and coastal habitats, marine and coastal fauna (fish, marine mammals, and birds), and sociocultural systems (subsistence). Important impact-producing factors associated with increased traffic in the Beaufort and Chukchi Seas include subaerial and subsea noise, engine emissions and fuel spills (marine vessels), discharges of bilge water and waste, oil spills (vessel casualty), and wildlife collisions with marine vessels.

Mining (Coal and Minerals).

***Red Dog Mine**.* The Red Dog Mine, operated by Teck Cominco Alaska, (Teck Cominco is now known as Teck Alaska, a subsidiary of Teck Resources) is one of the largest lead and zinc mines in the world and the only base-metal lode mine currently in production in northwest Alaska (Figure 4.6.1-7). The open-pit mine (with processing mill, tailings impoundment, and support facilities) is located in the DeLong Mountains about 130 km (82 mi) north of Kotzebue and 74 km (46 mi) inland from the Chukchi seacoast; it produced more than a million tons of zinc and lead concentrates annually, but is estimated to be mined out by 2012. Teck Cominco Alaska is proposing to mine an adjacent deposit (Aqqaluk Deposit) and continue its operations until 2031 (USEPA 2010e; TCAK 2009 2012).

Processed ore (concentrate) is transported from the Red Dog Mine by an 84-km (52-mi) road to the DeLong Mountain Terminal, a port facility located on the Chukchi Sea (Figure 4.6.1-7). The terminal consists of a housing unit, six diesel storage tanks, two concentrate storage buildings, a laydown area, and a concentrate conveyor/ship loading system. Although concentrate is shipped from the mine to the terminal year-round, shipping of concentrate by barge (to deep sea cargo ships) occurs only during months when the waters are ice free (generally from July through October). The port site also includes a small domestic wastewater treatment system that discharges to the Chukchi Sea under a NPDES permit (USEPA 2006).

The Red Dog Mine would likely contribute to cumulative effects on air and water quality, marine and coastal habitats, marine and coastal fauna (fish, marine and terrestrial mammals, and birds), and sociocultural systems (local economies and subsistence). Important impact-producing factors associated with mining include noise, permitted releases to air and water, particulate and dust releases to air, engine emissions and fuel spills (marine vessels, and land-based vehicles and equipment), pollutant releases (via surface runoff), deposition of fugitive dust, and wildlife collisions with marine vessels.

Coal Development in Northern Alaska. Most of the coal resources in Alaska occur north of the Brooks Range, in the Northern Alaska-Slope coal province. The USGS estimates coal reserves in this region to be 3,870 billion short tons (1,910 billion short tons of bituminous and 1,960 billion short tons of sub-bituminous); however, the remoteness of the region and high cost of logistics and transport currently make large-scale coal development in northern Alaska uneconomical. Depending on infrastructure availability (e.g., if a gas pipeline were to be built), however, coalbed methane could be a target of future development (Flores et al. 2004).

The ADNR's Division of Mining, Land, and Water is currently considering a coal prospecting permit for the proposed Nanushak coal project, a small project located along the northern foothills of the Brooks Range near Anaktuvuk Pass. Currently, there are no large-scale coal mining proposals in the region (ADNR 2012c).

Other Mining Activities. Mining of placer gold in beach deposits and bench gravels along the Seward Peninsula (Chukchi Sea) continued through the 1950s (Koschmann and Bergendahl 1968). Past mining of this nature could have contaminated nearby water and sediments with metals such as mercury (if used in collecting gold). Most of the current placer operations are taking place near Nome, in the South Seward Peninsula, and would not affect the waters of the Beaufort or Chukchi Seas (BLM 2005).

There are no abandoned mine lands in the Arctic region (ADNR 2011a).

Dredging and Marine Disposal. Mechanical and hydraulic dredges have been used to excavate materials to construct artificial islands (drilling platforms), helipads, and coastal harbors/shipping corridors in the Beaufort Sea. All past dredging activities have been conducted to support the oil and gas industry — in the 1950s and 1960s, it was for shipping and transportation; in the 1970s and 1980s, it was mainly for the construction of islands (30 islands were built during this time). Most dredging occurred during the open water season in water depths less than 50 m (150 ft). Harbors, channels, and mooring basins were dredged in MacKinley Bay, Tuft Point, and Tuktoyaktuk (IMG Golder Corp. 2004). Several State and Federal regulations and permitting processes govern dredging operations in Arctic waters. The likelihood of future dredging projects is not certain, but is considered to be low.

The main benefit of dredging in Arctic waters is the improvement of navigational depths for marine vessels. Dredging and disposal may also contribute to adverse cumulative effects on water quality, the acoustic environment, coastal and marine habitats, coastal and marine fauna (fish and marine mammals), and cultural resources (if present). Important impact-producing factors of dredging and disposal are noise and turbidity/contaminant resuspension caused by bottom sediment disturbance.

Recreation and Tourism. Most nonresident recreational activity in the North Slope Borough consists of tour groups visiting Barrow or Deadhorse (see Section 3.13.1.3). Travel to these areas is primarily by air, although bus tours occasionally arrive via the Dalton Highway between Deadhorse and Fairbanks. Hikers and river rafters also visit the Arctic National Wildlife Refuge and other areas, using scheduled (to Kaktovik) or chartered (for remote locations) airplanes for access. An increasing number of cruise ships enter the Chukchi and Beaufort Seas, and a growing number of hikers and rafters visit coastal areas of the Chukchi Sea; lodging is currently available in Kaktovik. Gates of the Arctic National Park receives limited visitation, accessed through Anuktuvuk Pass or by chartered airplane. Hunters also visit the area using aircraft for access, and some hunters may enter the area using the Dalton Highway. Tourism and recreation in the Arctic region will likely increase in the coming decades as more enterprises take advantage of the longer summer (ice-free) seasons.

While recreation and tourism may have beneficial effects on local economies, they also contribute to adverse cumulative effects on water quality, marine and coastal habitats, marine and coastal fauna (fish, marine mammals, and birds), and sociocultural systems (subsistence). Important impact-producing factors include noise, disturbance or injury of fish and wildlife, and habitat displacement and/or degradation.

Climate Change. Because a growing body of evidence shows that climate change is occurring (Section 3.3), it is included as a current and foreseeable natural trend in the cumulative impacts analysis for some resources in the Arctic region. Analyses that take into account impact-producing factors related to climate change meet one or both of the following criteria:

- The resource is already experiencing impacts from climate change, so the effects are observable and not speculative.

- The resource will be directly affected by warming temperatures.

In the Arctic region, impacts of climate change include warming ocean temperatures, reductions in sea ice, permafrost thawing, and coastal erosion, which all affect terrestrial, coastal, and marine ecosystems (see Section 3.3.2). In addition to ecosystem effects, the loss of sea ice contributes to an ice-albedo feedback process that affects regional atmospheric circulation patterns and global heat budgets. Changes to the Arctic climate have been documented in several studies; these include an increase in atmospheric temperature (by 2 to 4°F since 1960), an increase in precipitation (by a rate of about 1% per decade), a decrease in the extent of sea ice (by a rate of about 3% per decade for March and 12% per decade for September since the 1970s); and a decrease in multi-year sea ice (by a rate of about 9 to 12% per decade since the 1980s).

Not all impacts from climatic and hydrologic changes that are the indirect result of temperature changes have been analyzed because they may be too uncertain to predict. For example, it is reasonable to expect changes in precipitation regimes as a result of climate change. Furthermore, it is also likely that precipitation changes would, in turn, affect the coastal salinity balance between freshwater flow and tidal influence in some areas, and that these changes would affect fisheries and fish populations in some way. Both the magnitude and direction of each factor in this sequence of occurrences, however, are uncertain. While we acknowledge that continuing climate change could result in changing regional ecological and socioeconomic patterns and distributions, at this stage of our understanding of underlying processes, the rates and directions of many of these changes are too speculative to include in the cumulative analyses that follow.

Legislative Actions. Major statutes governing the management and protection of resources within the Beaufort Sea and Chukchi Sea Planning Areas are listed in Appendix C. Regulations and permitting programs based on these statutes (e.g., the NPDES permitting program based on Section 402 of the Clean Water Act) are overseen by the USEPA and other regulating authorities. The statutes and regulations (including international agreements between the United States, Canada, and Russia) are discussed in the previous sections and in the resource impacts sections, as they apply.

4.6.2 Marine and Coastal Physical Resources

4.6.2.1 Gulf of Mexico Region

4.6.2.1.1 Water Quality. Section 4.4.3.1 discusses potential water quality impacts in coastal (bays and estuaries), marine (State offshore and Federal OCS), and deepwater environments in the GOM resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on water quality result from the incremental impacts of the Program (described in Section 4.4.3.1) when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS program activities. Table 4.6.1-2 presents the exploration and development scenario for the GOM cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in the GOM are summarized in Table 4.6.1-5 and discussed below, as applicable.

Ongoing and future routine OCS program activities, including those of the Program, involve vessel traffic, well drilling, pipelines (trenching, landfalls, and construction), chemical releases (drilling, operation discharges, and sanitary wastes), platforms (anchoring, mooring, and removal, except in deep waters), and onshore construction (coastal waters only). All of these activities have the potential to adversely affect water quality in the GOM over the next 40 to 50 years. Accidental oil spills are also counted among OCS program-related activities; assumptions for oil spills under the cumulative case scenario are provided in Table 4.6.1-4.

OCS program-related service vessel traffic in the GOM (to new facilities) could be as high as 1,900 trips per week over the next 40 to 50 years; service vessel traffic associated with the Program (a maximum of 600 trips per week) represents about 32% of this traffic.

Other types of marine vessel traffic occur in the GOM, one of the world's most concentrated shipping areas (USACE 2010). Non-OCS program traffic includes that related to crude oil and natural gas imports, commercial container shipments, tugs and barges, military and USCG operations, cruise ships, commercial fishing, and small watercraft. In 2010, the Port of New Orleans alone handled about 7,500 vessel calls (mainly tanker and dry bulk carrier), about 140 vessel calls per week (USDOT 2011b). Impacts on water quality from marine traffic arise from regular discharges of bilge water and waste, leaching of antifouling paints, and incidental spills (MMS 2001d), although operational discharges and spillage from marine vessels have declined substantially in the past few decades (NRC 2003b). Oil releases associated with vessel casualty are rare, but have been documented in the GOM.

The number of development and production wells and platforms constructed over the duration of the Program (at most 2,600 and 450, respectively) would be proportional to the amount of oil produced; these numbers represent about 22% of the total number of production wells and platforms (respectively) anticipated to be built in the GOM over the next 40 to 50 years as part of ongoing and future OCS programs. The length of new pipeline (at most

12,070 km [7,500 mi]) added as part of the Program represents about 17% of that anticipated as part of ongoing and future OCS programs.

The area of disturbed sea bottom from construction of platforms and pipelines over the duration of the Program (as much as 14,000 ha [34,600 ac] total) represents about 17% of that associated with ongoing and future OCS programs over the next 40 to 50 years. Bottom disturbance degrades water quality by increasing water turbidity in the vicinity of the operations and adding contaminants to the water column. It also changes sediment composition as suspended sediments (and contaminants, if present) are entrained in currents and deposited in new locations.

An inventory conducted by NOAA found that there were about 766 major and 8,147 minor land-based point sources of pollution releasing to watersheds and coastal drainage areas of the GOM; these included discharges from industrial facilities (6,909), wastewater treatment plants (1,925), and power plants (79) — most of which were located in the watersheds of the Atchafalaya/Vermilion Bays and Galveston Bays at the time of the inventory (NOAA 1995). The kinds of contaminants released include nitrogen (from organic chemicals, petroleum refining, industrial plants, and pesticide sources), phosphorus, metals (zinc, arsenic, cadmium, lead, and mercury), oil and grease, suspended solids (turbidity), biocides, and heat (from power plant cooling water discharges). Non-point sources release pollutants to the GOM via rivers and on-land drainages and are primarily from urban and agricultural runoff (containing animal waste and residual fertilizer, in particular nitrogen and phosphorous compounds), but also originate from seepage from landfills and industrial facilities and various kinds of on-land spills. These sources (together with similar sources from Mexico) combine to degrade water quality in the GOM, especially in coastal waters. Coastal water quality is also adversely affected by the loss of wetlands (Section 3.7.1).

Other types of actions taking place within GOM waters also contribute to the degradation of water quality in the GOM. These include marine mining operations, sediment dredging and disposal operations (suspended sediments and contaminants), LNG terminal operations (biocide-laden, cooled water), and activities related to the oil and gas industry, which operates hundreds of platforms in State and Federal waters and discharges large volumes of drilling wastes, produced water, and other industrial waste streams into GOM waters. Hydrocarbon releases through natural oil seeps along the continental slope and accidental oil spills are additional sources of water and sediment contamination.

There are 23 designated ocean dredged material disposal sites in the GOM, including 16 off the coast of Texas and Louisiana and in the Mississippi River GOM outlet and six off the coasts of Mississippi, Alabama, and Florida. Dredging operations are routinely conducted for channel construction and maintenance, pipeline emplacement, access to support facilities, creation of harbor and docking areas, and siting for onshore facilities. Offshore disposal, authorized under Title I of the *Marine Protection, Research and Sanctuaries Act of 1972*, as amended (33 USC 1401), and the *Federal Water Pollution Control Act*, as amended (33 USC 1251), consists primarily of dredged sediments but may also include fish wastes and decommissioned vessels. The site management and monitoring plans for many of these sites are available on the USEPA’s website (http://www.epa.gov). The USACE maintains an online database that tracks the projects (including quantities of materials, dredging and transport methods, and dumping frequency, size, and location) that dispose of materials at designated offshore disposal sites (http://el.erdc.usace.army.mil/odd). The direct impacts of dredging on water quality (increased turbidity and decreased dissolved oxygen at the dredge site) are fairly short lived; however, long-term landscape-scale changes can have significant adverse impacts on aquatic organisms and their habitats (Nightingale and Simenstad 2001) (Sections 4.6.3 and 4.6.4).

Currently, there is only one offshore LNG terminal in the GOM (Gulf Gateway Deepwater Port off the coast of Louisiana). However, natural gas demand growth in the United States has accelerated since the 1980s, and LNG imports are expected to increase significantly to meet this demand. As a result, 25 LNG terminal proposals have been approved to serve the U.S. market (Parfomak and Vann 2009). At least seven new licenses have been issued for additional facilities in the GOM, and it is anticipated that more LNG facilities will be built over the coming decades (USDOT 2012b) (Section 4.6.1.5). The impacts of LNG transport and LNG receiving terminals are associated with explosions and fires and with the cryogenic and cooling effects of either an accidental release of LNG or the release of cooled water during the vaporization process.

The majority of oil released to the GOM comes from chronic releases, mainly from naturally occurring seeps and runoff from land-based sources (NRC 2003b). Oil seeps are estimated to contribute up to 62% of the oil input in U.S. marine waters overall; runoff from land-based sources, about 21% (NRC 2003b). As many as 350 crude oil and tar seeps have been identified in the GOM. Seepage rates for the northern part of the GOM (along the continental slope) have been estimated at about 73,000 tons (526,000 bbl) per year,[39] comparable to that estimated for spills from OCS programs over the next 40 to 50 years (based on a worst-case scenario of about 559,600 bbl per year, excluding catastrophic events; Table 4.6.1-4). Spills associated with the Program (based on a worst-case scenario of about 114,500 bbl per year, excluding catastrophic events (Table 4.4.2-1), represent a small fraction, about 11%, of the combined annual oil inputs from oil seeps and oil spills (from pipelines, platforms, and tankers/barges and incidental spills) from OCS programs over the next 40 to 50 years. Natural gas seeps are also common, but little is known about their seepage rates (Kvenvolden and Cooper 2003).

The second largest contribution to oil releases in U.S. marine waters overall is related to oil consumption (about 32%): land-based runoff and river discharge (21%), recreational marine and non-tank vessels (2.6%), tank vessel operational discharges (<1%), atmospheric deposition (8.1%), and jettisoned aircraft fuel (<1%). Other important sources of oil releases include those associated with non-OCS program oil extraction/transportation activities (about 4.7% in total): platforms, produced water, atmospheric deposition, pipeline and tank vessel spills, operational discharges (cargo washings), and coastal facility spills (NRC 2003b).

[39] Total estimates for the GOM, taking into account oil seeping from the Campeche Basin offshore of Mexico in the southern part of the Gulf, run as high as 140,000 tons (1 Mbbl) per year (Kvenvolden and Cooper 2003).

Another issue of importance to the water quality in the GOM concerns the hypoxic zone in the GOM coast shelf waters (offshore of Louisiana and Texas to the west of the Mississippi Delta) (see Figure 4.6.1-5). The hypoxic zone is an area near the sea bottom that contains less than 2 ppm of dissolved oxygen, causing a condition of hypoxia that is inhospitable to fish and causes stress or death to benthic organisms (USGS 2011c). The hypoxic zone is attributed to water column stratification (driven by weather and river flow) and the decomposition of organic matter in bottom waters, as well as organic matter and nutrients (that fuel phytoplankton growth) carried by waters of the MARB. In July 2011, the hypoxic zone measured 17,520 km^2 (6,765 mi^2), which is smaller than originally predicted by the USEPA based on recent trends (USEPA 2011f). River discharge from the MARB watershed is projected to increase by as much as 20% in the coming decades. This phenomenon, in addition to natural upwelling of nutrient-rich deep ocean water into shallow areas (which may be an effect of climate change), could increase the extent of the hypoxic zone in the northern GOM over the next 40 to 50 years (USGCRP 2009). Activities associated with the Program are not expected to have a large effect on the hypoxic zone, because inflows of contaminants causing hypoxia are mainly from MARB waters discharging to the GOM.

Catastrophic oil spills are rare events, but their releases have a high potential to degrade water quality in both coastal and deep waters. Since the 1970s, there have been two CDEs in the GOM: the Ixtoc I event in the Cantarell oil field (Mexico), in 1979; and the DWH event, in 2010. The DWH event released an estimated 4.9 Mbbl between April 22 and July 15, 2010 (see Section 3.4.1.4.1 for a more detailed discussion on the effects of the DWH event). In response to the spill, 7,000 m^3 (1.84 million gal) of chemical dispersants were also released (Section 3.4.1.3). The short- and long-term impacts of the spill on water quality in the GOM are still being assessed, but as of January 2011, 134 km (83 mi) of shoreline were classified as heavily or moderately oiled (NOAA 2012b). SCAT observations in March 2012 indicated that oiling was still present in some areas along barrier islands and coastal areas in Louisiana, Mississippi, Alabama, and Florida (ERMA 2012a, b).

Studies conducted two months after the start of the DWH event (at depths of 1,500 m [4,921 ft]) found a continuous plume of dispersed oil at a depth of approximately 1,100 m (3,609 ft) that extended for 35 km (22 mi) from the DWH event site (Camilli et al. 2010). The plume consisted of droplets between 10 and 60 μm in size and contained monoaromatic hydrocarbons (benzene, toluene, ethyl benzene, and xylene) at concentrations greater than 50 μg per liter and persisted for months at this depth with no substantial biodegradation. High concentrations of aromatic hydrocarbons were detected in the upper 100 m (328 ft). PAHs were found at concentrations as high as 189 μg per liter extending as far as 13 km (8 mi) from the subsurface DWH event site, at depths between 1,000 and 1,400 m (3,281 and 4,593 ft) and extending as far as 13 km (8 mi) from the subsurface DWH site (Diercks et al. 2010).

Joye et al. (2011) estimated that the DWH event released 450 million kg (500,000 tons) of hydrocarbon gases at depth. In May through June 2010, high concentrations of dissolved hydrocarbon gases (methane, ethane, propane, butane, and pentane) were detected in a water layer between 1,000 and 1,300 m (3,281 and 4,265 ft) (Joye et al. 2011).

The fate of the estimated 771,000 gal of chemical dispersants injected at the DWH wellhead near the seafloor (at depths of about 1,500 m [4,921 ft]) was studied by Kujawinski et al. (2011). The study concluded that chemical dispersants at this depth underwent slow rates of biodegradation and recommended further studies to assess the impact of dispersant-oil mixtures on pelagic biota.

Global climate change will also affect water quality in the GOM in the coming decades, especially in terms of surface temperature, salinity, vertical stratification, and pH (USGCRP 2009). Increases in sea surface temperature in the GOM are thought to be correlated to increased hurricane intensity, similar to the way the “Loop Current” played a part in intensifying Hurricanes Ivan, Katrina, and Rita. Increased surface temperatures also increase thermal expansion of marine waters, thus adding to sea level rise. Changes in temperature and salinity affect density parameters, which in turn affect vertical mixing and stratification of the water column, processes that are especially important in estuaries (in terms of oxygen concentrations and nutrient availability). Estuaries with low-amplitude tides, such as those in the northeastern GOM, are highly susceptible to stratification and hypoxia. As sea surface temperatures increase, the ocean’s ability to absorb CO_2 is also decreased (because CO_2 is less soluble in warmer waters). Currently, healthy coastal wetlands (e.g., seagrasses, salt marsh, and mangroves) are important natural CO_2 “sinks.” As coastal wetlands are lost through coastal development and sea level rise, their function as CO_2 sinks is diminished.

The GOM region has already experienced increasing atmospheric temperatures since the 1960s. From 1900 to 1991, sea surface temperatures increased in coastal areas and decreased in offshore areas. Sea level rise along the northern coast is as high as 0.01 m/yr (0.03 ft/yr) and has contributed to the loss of coastal wetland and mangroves and increased the rates of shoreline erosion. Future sea level rise is expected to cause saltwater intrusion into coastal aquifers, potentially making some unsuitable as potable water supplies (Section 3.3.1).

Significant changes (increases or decreases) in precipitation and river discharges to the GOM would affect salinity and water circulation — which in turn affects water quality. Water quality impacts associated with increased river discharges result from increases in nutrients (nitrogen and phosphorous) and contaminants to estuaries, increases in harmful algal blooms, and an increase in stratification. Such changes could also affect dissolved oxygen content and the extent of the GOM hypoxic zone. Decreased discharge would diminish the flushing of estuaries and increase concentrations of pathogens.

Conclusion. Water quality in GOM coastal and marine waters would be affected by various activities associated with OCS programs over the next 40 to 50 years. These include service vessel traffic, well drilling, pipelines (trenching, landfalls, and construction), chemical releases (drilling, operation discharges, and sanitary wastes), platforms (anchoring, mooring, and removal, except in deep waters), construction of shore-based infrastructure (coastal waters only), and accidental oil spills. Coastal waters in the GOM are also affected by numerous other factors, including river inflows, urbanization, agricultural practices, municipal waste discharges, and coastal industry. Non-OCS activities likely to contribute to cumulative impacts include marine vessel traffic, wastewater discharge to coastal and marine waters, dredging and marine disposal, oil and gas production in State waters, oil and gas infrastructure, marine mineral mining, existing oil and gas-related infrastructure in State waters, military operations, and renewable energy development. Natural seepage of oil along the continental slope is also significant.

The cumulative impacts of ongoing and reasonably foreseeable future activities on water quality in the GOM are unavoidable and may, in cases like salinity and pH, be irreversible, since such trends are natural and are occurring on a global scale. However, because many other impacts could be mitigated (i.e., minimized) by the various regulatory controls already in place to protect the marine waters of the GOM, the overall cumulative impacts are considered to be moderate. The incremental contribution of the Program to cumulative impacts on water quality in the GOM would be small to medium relative to the cumulative case and relative to other ongoing and reasonably foreseeable future actions in the GOM (see Section 4.4.3.1).

The USEPA, in collaboration with other Federal and coastal State agencies, has assessed the coastal conditions of each region of the United States, including the GOM coast, by evaluating five indicators of condition, one of which was water quality, based on such parameters as dissolved oxygen, chlorophyll *a*, nitrogen, phosphorus, and water clarity.[40] The most recent assessment found the overall condition of the coastal waters of the GOM coast region to be fair to poor, with an overall condition rating score of 2.2 (on a 5.0-point scale) and an individual indicator score of 3.0 for water quality. Parameters such as dissolved oxygen and water clarity vary in relation to climatic factors (e.g., annual rainfall) (USEPA 2008a).[41] In addition, the hypoxic zone has been a perennial feature in the northern GOM since the 1950s.

The number of expected accidental oil spills in GOM waters associated with the Program would represent only a small increase over the number of expected spills from ongoing and future OCS programs and non-OCS program activities, comparable in volume to releases from naturally occurring oil seeps (discounting catastrophic spills). The incremental increase in adverse water quality impacts from these spills would depend on the weather and sea conditions at the spill location, the type of waves and tidal energy at the spill locations, the type of oil spilled (very light to very heavy), the depth of the spill event (deep water, shallow water, or surface water), and the volume and rate of spillage; therefore, the incremental contribution of expected oil spills to cumulative water quality impacts could range from small to large. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from moderate to major if it were to occur. Spill response and cleanup activities (e.g., *in situ* burning and use of chemical dispersants) could contribute to water quality impacts regardless of the size of spill. A more detailed discussion of the effects of oil spills on water quality in the GOM is presented in Section 4.4.3.1.2.

---

[40] Other indicators used to assess coast conditions include sediment quality (toxicity, contaminants, and total organic carbon), benthic community condition, coastal habitat loss, and fish tissue contaminants. The assessment found sediment quality in the Gulf coast region also to be poor (with sediments containing pesticides, metals, PCBs, and PAHs) (USEPA 2008b).

[41] The water quality score does not include the impact of the hypoxic zone in offshore GOM coast waters or the recent DWH event (USEPA 2008a).

4.6.2.1.2 Air Quality. Section 4.4.4.1 discusses potential air quality impacts in onshore and offshore areas of the GOM resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on air quality result from the incremental impacts of the Program (described in Section 4.4.4.1) when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS program activities. Table 4.6.1-2 presents the exploration and development scenario for the GOM cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in the GOM are summarized in Table 4.6.1-5 and discussed below, as applicable.

Ongoing and future routine OCS program activities, including those of the Program, involve production platforms, exploration wells, platform construction and removal, service vessels (pipelaying, support, and survey), helicopters, and tanker and barge transport. All these activities have the potential to adversely affect air quality in the GOM over the next 40 to 50 years. Accidental oil spills are also counted among OCS program-related activities; assumptions for expected oil spills under the cumulative case scenario are provided in Table 4.6.1-4. Other emission sources on the OCS that are not associated with oil and gas development activities include commercial marine vessels, commercial and recreational fishing, tanker lightering, military vessels, and natural sources such as oil or gas seeps. Onshore emission sources include power generation, industrial processing, manufacturing, refineries, commercial and home heating, on-road vehicles, and non-road engines (e.g., aircraft, locomotives, and construction equipment).

Criteria Pollutants. Over the past 20 years, the USEPA has promulgated a series of measures to reduce regional and nationwide emissions from fuel combustion sources (e.g., diesel marine engines), and the beneficial effects of these measures are evident in the data collected in 2006 (the most recent year for which data are reported).[42] NO_x emissions, mainly from transportation and fuel combustion sources, decreased nationwide by about 29% between 1990 and 2006. Most of the reductions in NO_x emissions occurred between 1998 and 2006 and are attributed to implementation of the Acid Rain Program and the NO_x State Implementation Plan (SIP) Call. SO_2 emissions, mainly from fuel combustion, industrial processes, and transportation sources, also decreased nationwide by about 38% between 1990 and 2006. During this same period, emissions from $PM_{2.5}$, PM_{10}, and CO decreased by 14, 30, and 38%, respectively (USEPA 2008b). At the State level, data collected between 1990 and 2002 indicate overall emissions have also declined in the five GOM coast States (Alabama, Florida, Louisiana, Mississippi, and Texas) in total: NO_x, down by 31%; SO_2, down by 15%; PM_{10}, down by 34%;

[42] This does not include new USEPA regulations that will apply international emission standards for ships operating off North American coasts, beginning in August 2012. The U.S. and Canada have designated waters off North American coasts collectively as an area in which stringent emission standards are needed (USEPA 2010f). In August 2012, the USEPA will require that ships operating within 200 nautical miles of the majority of U.S. and Canadian coastline, including the GOM (an area designated as the North American Emission Control Area), use lower sulfur fuels. The fuel standards are expected to reduce emissions of SO_x and fine particulate matter ($PM_{2.5}$) by as much as 85% from current levels. Engine-based controls (such as the use of high efficiency engines) would also reduce NO_x emissions.

and VOCs, down by 8%. Increases were observed only in Florida (NO_x up by 15% and VOCs up by 20%) and Alabama (VOCs up by 2%) during this period (USEPA 2011h).

Table 4.6.2-1 lists the estimated total emissions associated with ongoing and future OCS oil and gas activities in the GOM, including the 2012-2017 Program, over the next 40 years. These emissions were estimated by BOEM using emission factors from the *2008 Gulfwide Emission Inventory Study* (Wilson et al. 2010). In terms of absolute amounts, the largest emissions would be NO_x, followed by CO, with lesser amounts of VOC, SO_x, PM_{10}, and $PM_{2.5}$, in order of decreasing emissions. Under both the high and low scenarios, well drilling would be the largest source of NO_x; support vessels would be the largest source of SO_x. Well drilling and support vessels would be the largest sources of PM (equally); new production platforms would be the largest source of VOCs and CO. Emissions from Program activities in the GOM generally represent about 17 to 22% of the cumulative case emissions.

The USEPA's Acid Rain Program (established under Title IV of the 1990 CAA amendments) sets a permanent cap on the total amount of SO_2 that can be released from the electric power sector, with the final 2010 cap set at 8.95 million tons (about half of the emissions from the electric power industry in 1980). NO_x emissions from coal-fired boilers were also limited under the program (to about 8.1 million tons). Between 1980 and 2008, SO_2 emissions were reduced by about 52% compared to 1990 levels. In 2008, SO_2 emissions had already fallen below the emissions cap set for 2010 and monitoring data indicated the national composite average of SO_2 mean ambient concentrations declined by 71% between 1980 and 2008. NO_x emissions from the electric power sector in 2008 were also greatly reduced (by as much as 63% relative to projected levels in 2000 without the program). The USEPA also reports significant improvements in acid deposition indicators (wet sulfate and nitrogen deposition) (USEPA 2011i).

The Cross-State Air Pollution Rule was finalized in 2011 (replacing the USEPA's 2005 Clean Air Interstate Rule) and will take effect in 2012. The rule requires 27 States in the eastern half of the United States (including all of the GOM coast States) to reduce power plant emissions contributing to ozone and/or fine particulate pollution in other States by mandating significant reductions in SO_2 and NO_x emissions from power plants. The USEPA estimates that these actions will reduce SO_2 and NO_x emissions by 73% and 54%, respectively, from 2005 levels (USEPA 2011j).

MMS (currently BOEM) performed a cumulative air quality modeling analysis of platform emissions in a portion of the GOM in 1992 (MMS 1997b). The modeling incorporated a 40% increase in emissions above the 1992 levels to account for growth in oil and gas development. Predicted concentrations were well within the NAAQS and the Prevention of Significant Deterioration (PSD) Class II maximum allowable increases. An inventory study in the Breton National Wilderness Area (BNWA), a Class I area under the USEPA's PSD regulations, was conducted by MMS to estimate the contribution of OCS and non-OCS program emissions to concentrations of NO_x and SO_2 in the BNWA[43] (Billings and Wilson 2004). A

[43] Under the CAA, water quality degradation is limited in Class I areas by establishing stringent "increment" limits for NO_x and SO_2. These increments are the maximum increases in ambient pollutant concentrations allowed over baseline concentrations (Billings and Wilson 2004).

TABLE 4.6.2-1 Estimated Total Air Emissions for the Offshore Exploration and Development Scenario for the OCS GOM Cumulative Case

	Pollutant (10^3 tons for 40 yr)[a]					
Activity	NO_x	SO_x	PM_{10}	$PM_{2.5}$	CO	VOC
Well Drilling (D&P)	2,341.95–3,177.43	1.97–2.2	36.3–49.34	35.87–48.75	429.58–592.49	46.15–63.11
Well Drilling (E&D)	1,807.5–2,560.34	1.55–2.2	28.03–39.78	27.69–39.29	336.14–477.62	35.83–50.87
Helicopters	9.79–14.02	2.42–3.46	1.91–2.73	1.91–2.73	119.85–171.65	23.67–33.9
Oil Tanker/Barge Idling	0–29.67	0–3.85	0–0.57	0–0.57	0–3.15	0–28.91
Pipe-laying Vessels	250.54–574.33	42.54–97.53	9.45–21.67	9.45–21.67	52.00–119.2	9.45–21.67
Platform Construction	43.7–65.34	6.24–9.34	1.03–1.54	1.03–1.54	5.67–8.49	1.03–1.54
Platform Production	660.22–945.58	9.04–12.94	6.06–8.67	5.94–8.51	726.44–1,040.42	591.00–846.44
Platform Removal	43.7–65.34	6.24–9.34	1.03–1.54	1.03–1.54	5.67–8.49	1.03–1.54

Total (Cumulative OCS)	6,367.98–9,165.72	232.81–374.56	104.73–155.82	103.85–154.57	1,790.4–2,586.27	729.95–1,079.16
Total (Program)[b]	1,031.11–1,983.79	40.49–81.11	16.78–32.97	16.64–32.71	304.63–575.9	132.25–250.22

[a] The range of values reflects the low and high end of new exploration and development activity.

[b] Values from Table 4.4.4-1.

recent modeling-based cumulative increment analysis for SO_2 and NO_2, conducted by MMS, considered the cumulative effect of all onshore and offshore emission sources in the area with respect to the baseline year (Wheeler et al. 2008). The model results are summarized as follows:

- The increase in the 3-hr SO_2 concentration within the BNWA since 1977 (the baseline year) ranges from 0.42 to 1.70 µg/m^3; the maximum increment of 25.0 µg/m^3 has not been exceeded within the BNWA but a small portion of the increment may have been consumed. The largest change within a 50-km (31-mi) radius of the BNWA is 2.6 µg/m^3 and occurs to the south and east of Breton Island.

- The increase in the 24-hr SO_2 concentration within the BNWA since 1977 ranges from 0.11 to 1.18 µg/m^3; the maximum increment of 5.0 µg/m^3 has not been exceeded within the BNWA but a portion of the increment may have been consumed. The maximum 24-hr average SO_2 has increased over most of the GOM since 1977; it has increased or decreased over land, depending on location. For example, it has decreased as much as 7.7 µg/m^3 near Mobile, Alabama. In areas east of the Chandeleur Islands and southeast of the Breton Islands, it has increased between 1.0 and 1.64 µg/m^3.

- The annual SO_2 concentration within the BNWA has decreased by 1.07 to 1.89 µg/m^3 since 1977. The decrease in annual SO_2 is less than 0.5 µg/m^3 over much of the GOM and is greatest (more than 1.5 µg/m^3) near the GOM coast and inland over south Mississippi, Alabama, and eastern Louisiana. Isolated increases at grid points in Louisiana and the GOM are likely due to local additions of SO_2 point sources since 1977.

- The maximum increase in annual NO_2 concentration within the BNWA since 1988 (the baseline year) is 0.10 µg/m^3, well below the maximum allowable increment of 2.5 µg/m^3. Only a very small portion of the increment has been consumed. Since 1988, annual NO_2 concentrations have decreased over land where controls have been implemented, but have increased over the GOM due to the addition of offshore NO_x emission sources. The boundary between decreased onshore concentrations and increased offshore concentrations follows the southern Louisiana coastline then turns northeastward away from the Louisiana coast and over the GOM where it crosses the BNWA and runs through the northern part of the Chandeleur Island chain. Part of the BNWA has experienced an increase in NO_2 concentrations since 1988. Larger increases are observed in areas within 75 km (47 mi) of the BNWA boundaries.

BOEM continues to consult with the USFWS, which manages the BNWA, on any plans within 100 km (62 mi) of the BNWA.

Ozone Formation. In the Nation's ozone (O_3) nonattainment areas, emissions of NO_x and VOCs are being reduced through the SIP process in order for those areas to achieve compliance with the national O_3 standard. Prior to the revocation of the 1-hr O_3 standard in 2004, the Houston-Galveston-Brazoria (Texas) and Baton Rouge (Louisiana) areas were classified as severe nonattainment; the Beaumont-Port Arthur (Texas) nonattainment classification was serious. While the 1-hr O_3 standard no longer applies, the same emission controls will remain in effect while each State develops its plan to reach compliance with the new 8-hr standard. In October 2008, the USEPA reclassified the Houston-Galveston-Brazoria O_3 nonattainment area from a moderate 8-hr O_3 attainment area to a severe 8-hr O_3 nonattainment area and required the State to submit a revised SIP addressing the severe O_3 requirements of the CAA (73 FR 56983). In September 2010, the USEPA published a notice that the Baton Rouge moderate 8-hr O_3 attainment area had attained the 1997 8-hr O_3 NAAQS (75 FR 54778); the Beaumont-Port Arthur area was also designated an attainment area for the 1997 8-hr O_3 NAAQS in 2010 (75 FR 64675). There are no O_3 nonattainment areas in Alabama, Florida, or Mississippi.

Ozone levels in the southeast Texas have been in a steady downward trend since 1995. The maximum observed fourth highest 8-hr O_3 concentration in the Houston-Galveston area decreased from about 0.140 parts per million (ppm) in 1995 to around 0.100 ppm in 2005. Ozone levels in the Baton Rouge area remained steady over the same period, but the number of exceedances of the O_3 standard decreased. This data indicates that emission-reduction measures have been effective in reducing O_3 levels.

Modeling studies were performed using the preliminary emissions inventory prepared by Wilson et al. (2010) to examine the O_3 impacts with respect to the 8-hr O_3 standard of 80 parts per billion (ppb). One modeling study focused on the coastal areas of Louisiana extending eastward to Florida (Douglas et al. 2009). This study showed that the impacts of OCS emissions on onshore O_3 levels were very small, with the maximum contribution at locations where the standard of 1 ppb or less was exceeded. Another study, conducted by Yarwood et al. (2004), evaluated O_3 levels in southeast Texas. The results of this study indicated a maximum contribution to areas exceeding the standard of 0.2 ppb or less. The projected emissions for the cumulative case would be about the same as the emissions used in these modeling studies. The contributions to O_3 levels would therefore be similar. As emissions within the nonattainment areas are expected to decrease further in the future, the cumulative impacts from the OCS oil and gas program on O_3 levels would likely be reduced.

Visibility Impairment. Gaseous and fine particulate matter in the atmosphere can potentially degrade atmospheric visibility. Existing visibility in the eastern United States, including the GOM coast States, is impaired due to fine particulate matter containing primarily sulfates and carbonaceous material. High humidity is an important factor in visibility impairment in the GOM coastal areas. The absorption of water by the particulate matter makes them grow to a size that enhances their ability to scatter light and reduce visibility. The estimated natural mean visibility in the eastern United States is 97 to 129 km (60 to 80 mi) (Malm 1999).

Based on data presented by Malm (2000), the observed mean visual range in coastal Louisiana, Mississippi, and Alabama is about 38 to 48 km (24 to 30 mi). In the Texas coastal areas, the average visibility is about 48 to 64 km (30 to 40 mi). In the GOM coast States, about

60 to 70% of the human-induced visibility degradation (impairment) is attributed to sulfate particles, while about 20% is from organic or elemental carbon particles. About 8% of the visibility degradation is attributed to nitrate particles (Malm 2000; USEPA 2001).

Visibility degradation in large urban areas, such as Houston, can be especially pronounced during air pollution episodes. In some severe cases, it may hinder navigation by boats and aircraft. Degraded visibility also adds to the perception by the observer of bad air quality even when monitors do not record unhealthful pollutant levels.

A study of visibility from platforms off Louisiana revealed that significant reductions in Louisiana coastal and offshore visibility are almost entirely due to transient occurrences of fog (Hsu and Blanchard 2005). Episodes of haze are short-lived and affect visibility much less. Offshore haze often appears to result from plume drift generated from coastal sources. The application of visibility screening models to individual OCS facilities has shown that the emissions from a single facility are not large enough to significantly impair visibility. It is not known to what extent aggregate OCS sources contribute to visibility reductions; however, the effects from OCS sources are likely to be very minor because offshore emissions are substantially smaller than the onshore emissions.

In July 1999, the USEPA published its Regional Haze Regulations Final Rule to address visibility impairment in the Nation's National Parks and Wilderness Areas (64 FR 35714). These regulations established goals for improving visibility in Class I areas through long-term strategies for reducing emissions of air pollutants that cause visibility impairment. The rule requires States to establish goals for each affected Class I area to improve visibility on the haziest days and to ensure no degradation occurs on the clearest days. Since visibility impairment involves considerable cross-boundary transport of air pollutants, States are encouraged to coordinate their efforts through regional planning organizations. Texas and Louisiana are part of the Central States Regional Air Planning Association. Mississippi, Alabama, and Florida are members of the Visibility Improvement State and Tribal Association of the Southeast. The USEPA provides funding to the regional planning organizations to address regional haze by developing regional strategies to reduce emissions of particulate matter and other pollutants that lead to haze (USEPA 2011k).

The Regional Haze Regulations along with the rules on ozone and acid rain should result in a lowering of regional emissions and improvement in visibility. Projected emissions from all cumulative OCS program activities are not expected to be substantially different from year 2000 emissions. The contribution of OCS program-related emissions to visibility impairment is expected to be very minor.

Greenhouse Gases. Table 4.6.2-2 lists the total calculated emissions of CO_2, CH_4, and N_2O from OCS activities related to the GOM portion of the 2012-2017 Program and compares them to the 2012-2017 Program overall (accounting for OCS program activities in GOM, Cook Inlet, and the Arctic region); the total U.S. emissions from all sources in 2009 are also provided for reference. Activities in the GOM account for most of the GHG emissions associated with the 2012-2017 Program, comprising between 95% and 98% of all Program-related GHG emissions. For reference, the estimated annual emissions of CO_2 and CH_4 from OCS activities in the GOM

TABLE 4.6.2-2 Estimated Greenhouse Gas Emissions for the 2012-2017 Program in the GOM Relative to the OCS Program Overall over the Next 40 Years

Pollutant	2012-2017 OCS Program (all) (Tg CO_2e)[a, b]	2012-2017 GOM Program (Tg CO_2e)	Total U.S. Emissions from All Sources (2009) (Tg CO_2e)	Percent of Total U.S. Emissions (2009) from GOM Program[c]
CO_2	336.25–512.6	341.54–487.94	5,505.2	0.15–0.22
CH_4	3.98–120.22	3.17–115.88	686.3	0.01–0.42
N_2O	2.85–4.23	2.83–4.14	295.6	0.02–0.04
$CO_2 + CH_4 + N_2O$	348.37–637.05	342.25–607.97	6,487.1	0.13–0.23
All GHG	348.37–637.05	342.25–607.97	6,633.2	0.13–0.23
Total	348.37–637.05	342.25–607.97	38,726.0	

[a] One Tg is equal to 10^{12} g, or 10^6 metric tons. The CO_2e for a gas is derived by multiplying the mass of the gas by the associated GWP, which accounts for the relative effectiveness of a gas to contribute to global warming with respect to the same amount of CO_2. In these calculations, CH_4 is given a GWP of 21, while NO_2 is given a GWP of 310.

[b] Values represent the total emissions for the 2012-2017 Program in the GOM, Cook Inlet, and Arctic regions.

[c] Values are calculated by dividing the estimated annual emissions of the GOM program (equal to the value in the third column divided by 40) by the total U.S. emission from all sources in 2009 (fourth column).

Source: USEPA 2011l.

were less than 0.5% of CO_2 and CH_4 emissions in the United States from all sources in 2009; the estimated annual N_2O emissions from OCS activities in the GOM comprise less than 0.05% of N_2O emissions in the United States from all sources in 2009. Although these are small contributions, it should be noted that some GHGs (e.g., CO_2) can persist in the atmosphere for a century, well beyond the life of the Program.

GHG emissions are one of the causes of climate change; however, assessing their impact requires consideration on a global scale. For this reason, it is not possible to estimate the impact of GHG emission from particular sources, such as the OCS activities associated with the Program. On a global scale, the contribution from the Program to total GHG emissions is small. On a national scale, the contribution of the Program could be significant, although greater contributions of GHG to the U.S. total come from energy consumption (generated mainly by the combustion of coal and natural gas). Total U.S. GHG emissions increased by 11% between 1990 and 2010 (at an average annual rate of 0.5%); GHG emissions from the Program would contribute to this trend in future years.

Oil Spills. Accidental oil spills are sources of gaseous emissions. No more than 40 large spills (greater than 1,000 bbl) and 2,280 small spills (1,000 bbl or less) are expected for the GOM cumulative case as a result of the OCS program (Table 4.6.1-4). Oil spills cause localized increases in VOC concentrations (proportional to the size of the spill) due to evaporation. Most of these emissions would occur within a few hours of the spill and decrease (by dispersion) drastically after that period (MMS 2003a). A more detailed discussion of the effects of oil spills on air quality in the GOM is presented in Section 4.4.4.1.

Unexpected catastrophic discharge events at well locations may result in fires; *in situ* burning is also a preferred technique for cleanup and disposal of oil spills (documented in soil spill contingency plans). Smoke generated from such fires would be expected to reach shore quickly (within a day), but would be limited in geographic extent (MMS 2003a). A discussion of the effects of fires on air quality in the GOM is presented in Section 4.4.4.1.

Conclusion. The effects of various U.S. EPA regulations and standards are expected to result in a steady, downward trend in future air emissions. This trend should be realized in spite of continued industrial and population growth along the GOM coast. Previous O_3 nonattainment areas in the GOM coast region (Beaumont-Port Arthur, Texas, and Baton Rouge, Louisiana) were reclassified as attainment areas in 2010. States such as Texas are required to implement SIPs to reduce emissions in their O_3 nonattainment areas. The overall cumulative impacts on air quality in the GOM over the next 40 to 50 years are expected to be minor to moderate, and the incremental contribution of the routine Program activities to air quality impacts would be small (see Section 4.4.4.1).

The Program would contribute slightly to onshore levels of NO_2, SO_2, and PM_{10}, but concentrations are well within the national standards and PSD increments. The effects from future OCS program activities are expected to remain about the same as in previous years. Portions of the GOM coast region have O_3 levels that exceed the Federal standard, but the contribution from all OCS program activities to ozone levels is very small (about 1%; see Section 4.4.4.1.1). Ozone levels are on a declining trend due to air pollution control measures that have been implemented by the States. This trend is expected to continue as a result of local as well as nationwide control efforts. The contribution of the Program to onshore O_3 would therefore remain very small. The GOM coast region has significant visibility impairment from anthropogenic emission sources. However, visibility is expected to improve somewhat as a result of regional and national programs to reduce emissions. The contribution from OCS program activities to visibility impairment, therefore, is expected to remain small. The number of expected accidental oil spills in GOM waters associated with the Program would represent only a small increase over the number of expected spills from ongoing and future OCS programs and non-OCS program activities. The incremental increase in adverse air quality impacts from these spills (and *in situ* burning of spilled crude or diesel) would be localized and temporary (due to the spreading of oil and action by winds, waves, and currents that disperse volatile compounds to extremely low levels over a relatively large area); therefore, the incremental contribution of expected oil spills to cumulative air quality impacts could range from small to medium. Air quality impacts associated with an unexpected, low-probability CDE (and *in situ* burning) would also be reduced by these factors, and could be moderate if it were to occur. Spill response and cleanup activities (e.g., *in situ* burning and use of chemical dispersants) could contribute to air quality impacts regardless of the size of spill. A more detailed discussion of the effects of oil spills on air quality in the GOM is presented in Section 4.4.4.1.2.

4.6.2.1.3 Acoustic Environment. Section 4.4.5.1 discusses impacts on the acoustic environment in the GOM resulting from the Program. Section 4.4.7 evaluates the direct and indirect impacts of noise on marine fauna (fish, marine mammals, sea turtles, and birds), and Section 4.6.4 addresses the cumulative impacts of noise on marine fauna. Cumulative impacts on the acoustic environment result from the incremental impacts of the Program when added to impacts from existing and reasonably foreseeable future OCS program activities (that are not part of the Program) and other non-OCS program activities. Table 4.6.1-2 presents the exploration and development scenario for the GOM cumulative case (encompassing the Program and other OCS program activities). Ongoing and reasonably foreseeable non-OCS program activities contributing to adverse cumulative impacts on the acoustic environment in the GOM include marine subsurface and surface vessel traffic, aircraft traffic (helicopters and fixed-wing aircraft), dredging, construction of onshore and offshore facilities (e.g., production platforms and drilling rigs in State waters), LNG facility operations, renewable energy projects (foreseeable), marine geophysical (seismic) surveys, active sonars, underwater explosions, ocean science studies, and mining operations. This section addresses the quality of the acoustic environment only; the cumulative impacts of noise on GOM marine fauna are discussed in Section 4.6.4.1.

Ambient (background) noise has numerous natural and man-made sources that vary with respect to season, location, depth of occurrence, time of day, and noise characteristics (e.g., frequency and duration).[44] Natural sources of ambient noise include wind and waves, surfs (produced by waves breaking onshore), precipitation (rain and hail), lightning, volcanic and tectonic noise, and biological noise (from fishes, shrimp, and marine mammals). Vessels are the greatest man-made contributors to overall marine noise in the GOM. Underwater explosions in open water are the strongest point sources of man-made sound. Baseline acoustic conditions in the GOM are discussed in more detail in Section 3.6.1.

Ongoing and future routine OCS program activities, including those of the Program, that generate noise include operating airgun arrays (during marine seismic surveys), drilling, pipeline trenching, and onshore and offshore construction and decommissioning of platforms and drilling rigs. New marine vessel and aircraft traffic (including those associated with emergency-response and cleanup activities in the event of a spill), accidental releases (e.g., loss of well control events), and marine vessel collisions also contribute to noise. A preliminary study of the noise impacts of OCS-related geophysical surveys found that marine seismic surveys have the greatest impact on marine mammals, sea turtles, fish, and commercial and recreational fisheries (MMS 2004a). Noise generated from OCS and non-OCS program activities would be transmitted through both air and water, and may be transient or more extended (occurring over the long term). Table 3.6.1-1 provides a listing of the source levels and frequencies associated with various anthropogenic activities in the GOM.

Conclusion. The quality of the acoustic environment in the GOM would continue to be adversely affected by routine operations of ongoing and future OCS program and non-OCS program activities. The magnitude of cumulative impacts in the GOM is time- and

---

[44] Higher frequencies are attenuated with distance from the source more rapidly than lower frequencies. Traffic noise generated in deep water contributes to background noise levels at greater distances than traffic noise generated in shallow water.

location-specific and could range from minor to major, depending on the ambient acoustic conditions and the nature and combination of all OCS and non-OCS program activities taking place in the GOM over the next 40 to 50 years. The incremental contributions due to noise generated by routine Program activities could range from small to medium, depending on the timing of the disturbance and the location and characteristics of noise sources present (e.g., their frequency and duration). The cumulative impacts of noise on marine fauna (fish, marine mammals, sea turtles, and birds) are discussed in Section 4.6.4.

The number of expected accidental oil spills in GOM waters associated with the Program would represent only a small increase over the number of expected spills from ongoing and future OCS programs and non-OCS program activities. The incremental increase in adverse acoustic environment impacts from these spills (mainly due to noise sources associated with response and cleanup activities) would be localized and temporary; therefore, the incremental contribution of expected oil spills due to noise would be small. Impacts associated with an unexpected, low-probability CDE could be minor to moderate if it were to occur. Most of the impacts to the acoustic environment are due to noise sources (e.g., mechanical equipment, skimmers, support vessel traffic, and aircraft traffic) associated with spill response and cleanup activities. A more detailed discussion of the effects of oil spills on the acoustic environment in the GOM is presented in Section 4.4.5.1.

4.6.2.2 Alaska Region – Cook Inlet

4.6.2.2.1 Water Quality. Section 4.4.3.2 discusses potential water quality impacts in coastal (bays and estuaries), marine (State offshore and Federal OCS), and deepwater environments in Cook Inlet resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on water quality result from the incremental impacts of the Program (described in Section 4.4.3.2) when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS program activities. Table 4.6.1-3 presents the exploration and development scenario for the Cook Inlet cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in Cook Inlet are summarized in Table 4.6.1-6 and discussed below, as applicable.

OCS program activities (i.e., those of the Program; there are no existing OCS program activities) involve service vessel traffic, chemical releases (permitted discharges), and disturbance of bottom sediments. Accidental oil spills are also counted among OCS program-related activities; assumptions for oil spills under the cumulative case scenario are provided in Table 4.6.1-4. All these activities have the potential to adversely affect water quality in Cook Inlet.

OCS program-related service vessel traffic in Cook Inlet could be as high as one to three trips per week over the next 40 to 50 years, all of which are associated with the Program. Extensive non-OCS program marine traffic also occurs in Cook Inlet. Non-OCS program traffic includes that related to crude oil and finished product transport, LNG and ammonia carriers (at the Nikiski industrial complex), tugs and barges, ferries, commercial fishing vessels, military and USCG vessels, a coal carrier, dredge vessels, cruise ships, and small watercraft. Fuel barge traffic is minimal since much of the refined oil for regional consumption is transported to Anchorage by a pipeline from the Tesoro refinery in Nikiski. An estimated 480 large vessels (other than fuel barges on domestic trade) called at Cook Inlet ports in 2010. About 67% of these were made by container vessels, roll-on/roll-off cargo ships, or ferries; 20% were gas or liquid tank ships calling at Nikiski. The remaining traffic consisted of bulk carriers, general cargo ships, tugs, and fishing and passenger vessels. Impacts on water quality from vessel traffic in Cook Inlet result mainly from oil and gasoline spills when vessels run aground, collide, catch fire, or sink (Eley 2012).

The number of platform production wells constructed over the period of the Program (at most, 110) would be proportional to the amount of oil produced and reflects the total number of new platform production wells anticipated to be built in Cook Inlet over the next 40 to 50 years as part of the OCS program (no subsea production wells are planned). The length of new pipeline (at most 241 km [150 mi] offshore and 169 km [105 mi] onshore) added as part of the Program represents all of that anticipated over the next 40 to 50 years as part of the OCS program.

The area of sea bottom disturbed from construction of platforms and pipelines over the period of the Program (as much as 215 ha [530 ac] total) also represents that associated with the OCS program over the next 40 to 50 years. Bottom disturbance degrades water quality by increasing water turbidity (i.e., suspended sediment concentration) in the vicinity of the operations and adding contaminants to the water column. It also changes sediment composition as suspended sediments (and contaminants, if present) are entrained in currents and deposited in new locations.

As summarized in Section 3.4.2, the principal point sources of pollution in Cook Inlet include municipal discharges, as well as discharges from seafood processors and the petroleum industry. Point-source pollution is rapidly diluted by the energetic tidal currents in Cook Inlet, and the USEPA *National Coastal Condition Report III* has rated the coastal waters of south central Alaska, including Cook Inlet, as good (although water clarity in upper Cook Inlet was rated poor because of very high loadings of glacial river sediments) (USEPA 2008a). Non-point sources release a range of contaminants via rivers and on-land drainages and are primarily from urban runoff (related to land development); forest practices (e.g., timber harvest operations); harbors and marinas; roads, highways, and bridges; hydromodification (related to dams, channel modification, and stream bank erosion); mining; and agriculture (ADEC 2007). Point-source discharges are anticipated to remain at present levels for the foreseeable future; non-point-source discharges should improve as a result of Alaska's water pollution control strategy (as outlined in ADEC 2007). Low concentrations of hydrocarbons are found throughout the waters of Cook Inlet and are attributed to natural sources — natural oil seeps, river discharges carrying carbon compounds of biogenic origin, and the deposition of fuel and natural organic matter (e.g., from fires) (MMS 2003a).

Activities taking place within Cook Inlet waters also contribute to the degradation of water quality. These include oil spills associated with marine vessel traffic, sediment dredging and disposal in local harbors (suspended sediments and contaminants), and activities related to the oil and gas industry, which operates platforms in State waters and discharges drilling wastes, produced water, and other industrial waste streams into Cook Inlet waters (MMS 2003a).

Most of the oil released to Cook Inlet is from commercial and recreational vessels (MMS 2003a). Small spills (less than 1,000 bbl) from commercial and recreational vessels or from OCS program activities (e.g., accidental releases) are not expected to affect the overall quality of Cook Inlet water (because they would be localized and short in duration); however, large spills (greater than 1,000 bbl) could temporarily degrade the overall quality of its water (MMS 2003a). Oil spills in ice-covered waters during winter months are generally contained within a much smaller area (compared with spills in open waters) because oil weathering (i.e., spreading, evaporation, and migration) is much slower and some oil may solidify. While such factors have proven to be favorable for most response strategies, the presence of ice can also complicate response efforts. Spills on ice are fairly easy to detect and map, unless there is fresh snowfall at the time of the spill; however, oil spilled within and under the ice can be hidden from view. Broken ice also makes spilled oil difficult to detect and map, and it can reduce the effectiveness of conventional recovery systems (MMS 2009b; DF Dickens Associates, Ltd. 2004).

Climate change predictions are based on models that simulate all relevant physical processes under a variety of projected greenhouse gas emission scenarios (Section 3.3). Because the complexity of modeling global and region climate systems is so great, uncertainty in climate projections can never be eliminated. The IPCC projections relating generally to water and water quality over the next two decades include:

- Sea level will rise by 0.18 to 0.59 m (0.6 to 2 ft) by the end of the twenty-first century;
- Sea ice, glaciers, and ice sheets in polar regions will continue melting;
- Ocean pH will decrease by 0.14 to 0.35 over the twenty-first century;
- Precipitation will increase at high latitudes (>90% likely); and
- Annual river discharges (runoff) will increase by 10 to 40% at high latitudes and decrease by 10 to 30% in the dry regions at mid-latitudes.

Alaska has experienced extensive regional warming since the 1960s, with a rise in annual temperature of about 3°C (5°F) since the 1960s. The general effects of warming include the extensive melting of glaciers, thawing of permafrost, and increased precipitation (Section 3.3). Modeling studies of warming in Cook Inlet project very large warming trends, ranging from 4°C to 10°C (7°F to 18°F) by the year 2100; precipitation is projected to increase by 20 to 25% (Kyle and Brabets 2001).

Conclusion. Water quality in Cook Inlet would be affected by various activities associated with the Program over the next 40 to 50 years. These include marine vessel traffic, chemical releases (sanitary wastes), disturbance of bottom sediments, and accidental oil spills (from marine vessel casualty and the oil and gas industry). Water quality is also affected by many other factors, including river inflows, urbanization, forest practices, mining, municipal waste discharges, and agriculture. Non-OCS program activities likely to contribute to cumulative impacts include marine vessel traffic, wastewater discharge to the inlet, dredging and marine disposal, and oil and gas related activities, as well as infrastructure in State-owned marine waters. Natural seepage of oil along the west part of the inlet also may be significant. The cumulative impacts on Cook Inlet water quality from all OCS and non-OCS activities in Cook Inlet over the next 40 to 50 years are expected to be minor to moderate, and the incremental contribution of the routine Program activities to water quality impacts would be small to medium. These impacts may lessen with time since oil and gas production in the Cook Inlet is currently on the decline (see Section 4.4.3.2).

The USEPA, in collaboration with other Federal and coastal State agencies, has assessed the coastal conditions of each region of the United States, including Cook Inlet, by evaluating five indicators of condition, one of which was water quality, based on such parameters as dissolved oxygen, chlorophyll *a*, nitrogen, phosphorus, and water clarity. The most recent assessment found the overall condition of the coastal waters of south central Alaska, including Cook Inlet, good (although water clarity in upper Cook Inlet was rated poor). Point source discharges are anticipated to remain at present levels for the foreseeable future; non-point source discharges should improve as a result of Alaska's water pollution control strategy. Low concentrations of hydrocarbons are found throughout the waters of Cook Inlet and are attributed to natural sources.

The number of expected accidental oil spills in Cook Inlet waters associated with the Program would represent only a small increase over the number of expected spills from ongoing non-OCS program activities (mainly oil and gas production in State waters). The incremental increase in adverse water quality impacts from these spills would depend on the weather and sea conditions at the spill location (e.g., whether ice is present), the type of waves and tidal energy at the spill locations, the type of oil spilled (very light to very heavy), the depth of the spill event (deep water, shallow water, or surface water), and the volume and rate of spillage; therefore, the incremental contribution of expected oil spills to cumulative water quality impacts could range from small to large. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from moderate to major if it were to occur. Spill response and cleanup activities (e.g., *in situ* burning and use of chemical dispersants) could contribute to water quality impacts regardless of the size of spill. A more detailed discussion of the effects of oil spills on water quality in Cook Inlet is presented in Section 4.4.3.2.2.

4.6.2.2.2 Air Quality. Section 4.4.4.2 discusses potential air quality impacts in onshore and offshore areas of Cook Inlet resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on air quality result from the incremental impacts of the Program (described in Section 4.4.4.2) when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS program activities. Table 4.6.1-3 presents the exploration and development scenario for Cook Inlet cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in Cook Inlet are summarized in Table 4.6.1-6 and discussed below, as applicable.

OCS program activities, i.e., those of the Program (there are no existing OCS program activities), involve production platforms, exploration wells, platform construction and removal, marine vessels (pipelaying, support, and survey), helicopters, and tanker and barge transport. All these activities have the potential to adversely affect air quality in the Cook Inlet region via direct emissions or other releases to air (e.g., volatile components of fuel). Accidental oil spills are also counted among OCS program-related activities; assumptions for oil spills under the cumulative case scenario are provided in Table 4.6.1-4. Existing emission sources in the Cook Inlet Planning Area include oil production activities in State waters, onshore petroleum processing and refining, onshore oil and gas production, marine terminals, and commercial shipping.

Criteria Pollutants. Except for a few population centers such as Anchorage, Fairbanks, and Juneau, the existing air quality in Alaska is relatively pristine, with pollutant concentrations well within ambient standards (Section 3.5.2.2). The primary industrial emissions in the Cook Inlet region are associated with oil and gas production, power generation, small refineries, paper mills, and mining. Other sources include vessel traffic in Cook Inlet and emissions from on-land motor vehicles and refuse burning (MMS 2003a). While some growth of these activities is likely to take place in the future, overall emissions are expected to remain low. More stringent emission standards on motor vehicles and new USEPA standards on non-road engines and marine vessels would result in a downward trend in emissions.

Modeling studies of proposed OCS production facilities in the Cook Inlet show that concentrations of NO_2, SO_2, and PM_{10} are within the PSD Class II and Class I maximum allowable increments and the NAAQS. Pollutant concentrations within the Tuxedni NWA, the only Class I area adjacent to the Cook Inlet Planning Area, exceed the Class I significance levels. As a consequence, any proposed facilities that would exceed the Class I significance levels, would need a comprehensive PSD increment consumption analysis done before permitting (MMS 2003a).

New USEPA regulations will apply international emission standards for ships off North American coasts. The U.S. and Canada have designated waters off North American coasts as an area in which stringent emission standards will become enforceable in August 2012 (USEPA 2010f). The area, called the North American Emission Control Area (NA ECA), will require the use of lower sulfur fuels in ships operating within 200 nautical miles of the majority of U.S. and Canadian coastline, including Cook Inlet. The fuel standards are expected to reduce emissions of SO_x and fine particulate matter ($PM_{2.5}$) by as much as 85% from current levels. Engine-based controls (such as high efficiency engines) would also reduce NO_x emissions.

Ozone Formation and Visibility Impairment. The baseline conditions and impacts from OCS activities on ozone and visibility are discussed in Sections 3.5.2.2 and 4.4.4.2, respectively. Because conditions in Alaska are seldom favorable for significant O_3 formation, the contribution of leasing activity associated with the Program to O_3 levels in the Cook Inlet region is expected to be small. OCS emission sources affecting visibility are also small; however, preliminary visibility screening for the Tuxedni NWA suggests sources within about 50 km (30 mi) may result in a plume visible from the site (MMS 2003a).

Greenhouse Gases. GHG emissions are one of the causes of climate change; however, assessing their impact requires consideration on a global scale. For this reason, it is not possible to estimate the impact of GHG emission from particular sources, such as the OCS activities associated with the Program. On a global scale, the contribution from the Program to total GHG emissions is small. On a national scale, the annual contribution of the Program is also small (generally less than 0.5%, much less significant than from activities in the GOM).

Oil Spills. Accidental oil spills are sources of gaseous emissions. No more than one large spill (1,000 bbl or greater) and 18 small spills (less than 1,000 bbl) are projected for the Cook Inlet Planning Area cumulative case as a result of the OCS program (Table 4.6.1-4). Most accidental spills in the Cook Inlet region are of non-crude products caused by onshore train derailments, pipeline failures, and leaks (crude oil comprises about 4% of all product spills) (ADEC 2007b). Since 1976, there have been nine major crude oil spills in the inlet, ranging in volume from 10,000 to 396,000 gal (with the largest of these coming from construction barges, offshore platforms, and jet fuel releases); the last oil spill (9,000 gallons; 214 barrels) occurred in 1997 as a result of a loss of well control incident at the Steelhead Platform (State of Alaska 2011). Oil spills cause localized increases in VOC concentrations (proportional to the size of the spill) due to evaporation. Most of these emissions would be expected to occur within a few hours of the spill and decrease (by dispersion) drastically after that period (MMS 2003a). However, oil spills in ice-covered waters during winter months would be contained within a much smaller area (compared with spills in open waters) because oil weathering (i.e., spreading, evaporation, and migration) is much slower and some oil may solidify (MMS 2009b). A more detailed discussion of the effects of oil spills on air quality in Cook Inlet is presented in Section 4.4.4.2.

Catastrophic events at well locations may result in fires; *in situ* burning is also a preferred technique for cleanup and disposal of oil spills (documented in soil spill contingency plans). Smoke generated from such fires would be expected to reach shore quickly (within a day), but would be limited in geographic extent (MMS 2003a). A discussion of the effects of fires on air quality in Cook Inlet is presented in Section 4.4.4.2.

Conclusion. OCS program activities in combination with other oil and gas exploration, development, and production activities in the Cook Inlet Planning Area could affect air quality in the region over the next 40 to 50 years. Air pollutant concentrations associated with offshore and onshore emission sources are expected to remain well within applicable State and Federal standards over the life of the Program. Therefore, the overall cumulative impacts on air quality in Cook Inlet from all OCS and non-OCS activities over the next 40 to 50 years are expected to be minor to moderate, and the incremental contribution of the routine Program activities to air quality impacts would be small (see Section 4.4.4.2).

The number of expected accidental oil spills in Cook Inlet associated with the Program would represent only a small increase over the number of expected spills from ongoing non-OCS program activities (mainly oil and gas production in State waters). The incremental increase in adverse air quality impacts from these spills (and *in situ* burning of spilled crude or diesel) would be localized and temporary (due to the spreading of oil and action by winds, waves, and currents that disperse volatile compounds to extremely low levels over a relatively large area); therefore, the incremental contribution of expected oil spills to cumulative air quality impacts could range from small to medium. Air quality impacts associated with an unexpected, low-probability CDE (and *in situ* burning) would also be reduced by these factors, and could be moderate if it were to occur. Spill response and cleanup activities (e.g., *in situ* burning and use of chemical dispersants) could contribute to air quality impacts regardless of the size of spill. A more detailed discussion of the effects of oil spills on air quality in Cook Inlet is presented in Section 4.4.4.2.2.

4.6.2.2.3 Acoustic Environment. Section 4.4.5.2 discusses impacts on the acoustic environment in Cook Inlet resulting from the Program (OCS program activities from 2012 to 2017). Section 4.4.7 evaluates the direct and indirect impacts of noise on marine fauna (mammals, birds, and fish), and Section 4.6.4 addresses the cumulative impacts of noise on marine fauna. Cumulative impacts on the acoustic environment result from the incremental impacts of the Program when added to impacts from reasonably foreseeable future OCS program activities (that are not part of the Program) and other non-OCS program activities.[45] Table 4.6.1-3 presents the exploration and development scenario for the Cook Inlet cumulative case (encompassing the Program and other OCS program activities). Ongoing and reasonably foreseeable non-OCS program activities contributing to adverse cumulative impacts on the acoustic environment in the Cook Inlet include aircraft overflights, vessel activities and traffic, construction and decommissioning of onshore and offshore facilities (e.g., related to ongoing oil and gas exploration and development in State waters), and other activities (e.g., seismic surveys) conducted as part of the existing oil and gas industry in the inlet. This section addresses the quality of the acoustic environment only; the cumulative impacts of noise on Cook Inlet marine fauna are discussed in Section 4.6.4.2.

Ambient (background) noise has numerous natural and man-made sources that vary with respect to season, location, depth of occurrence, time of day, and noise characteristics (e.g., frequency and duration).[46] Natural sources of ambient noise include wind and wave action, strong tidal fluctuations, currents, ice, precipitation (rain and hail), lightening, volcanic and tectonic noise, and biological noise (from marine mammals and coastal birds). Vessels (e.g., tankers, supply ships, tugboats, barges, and fishing boats) are the greatest man-made contributors to overall marine noise in Cook Inlet. Baseline acoustic conditions in Cook Inlet are discussed in more detail in Section 3.6.2.

---

[45] Currently, there are no existing OCS program activities in Cook Inlet.

[46] Higher frequencies are attenuated with distance from the source more rapidly than lower frequencies. Traffic noise generated in deep water contributes to background noise levels at greater distances than traffic noise generated in shallow water.

Future routine OCS program activities, including those of the Program, that generate noise include operating airgun arrays (during marine seismic surveys), drilling, pipeline trenching, and onshore and offshore construction of platforms and drilling rigs. Vessel and aircraft traffic (including that associated with emergency response and cleanup activities in the event of a spill), accidental releases (e.g., loss of well control events), and vessel collisions also contribute to noise. A preliminary study of the noise impacts of OCS-related geophysical surveys found that marine seismic surveys have the greatest impact on marine mammals, sea turtles, fish, and commercial and recreational fisheries (MMS 2004a). Noise generated from OCS and non-OCS program activities would be transmitted through both air and water, and may be transient or more extended (occurring over the long term).

Conclusion. The quality of the acoustic environment in Cook Inlet would continue to be adversely affected by ongoing and future non-OCS program activities and by future OCS program activities (currently there are no existing OCS activities). The magnitude of cumulative impacts due to noise in Cook Inlet water from all OCS and non-OCS activities taking place in the inlet over the next 40 to 50 years is time- and location-specific and could range from minor to major, depending on the ambient acoustic conditions and the nature of activities taking place. The incremental contributions due to noise generated by routine Program activities could range from small to medium, depending on the timing of the disturbance and the location and characteristics of noise sources present (e.g., their frequency and duration). The cumulative impacts of noise on marine fauna (fish, marine mammals, sea turtles, and birds) are discussed in Section 4.6.4.

The number of expected accidental oil spills in Cook Inlet waters associated with the Program would represent only a small increase over the number of expected spills from ongoing non-OCS program activities. The incremental increase in adverse acoustic environment impacts from these spills (mainly due to noise sources associated with response and cleanup activities) would be localized and temporary; therefore, the incremental contribution of expected oil spills due to noise could range from small to medium. Impacts associated with an unexpected, low-probability CDE could be minor to moderate if it were to occur. Most of the impacts to the acoustic environment are due to noise sources (e.g., mechanical equipment, skimmers, support vessel traffic, and aircraft traffic) associated with spill response and cleanup activities. A more detailed discussion of the effects of oil spills on the acoustic environment in Cook Inlet is presented in Section 4.4.5.2.

4.6.2.3 Alaska Region – Arctic

4.6.2.3.1 Water Quality. Section 4.4.3.3 discusses potential water quality impacts in coastal (bays and estuaries), marine (State offshore and Federal OCS), and deepwater environments in the Arctic region resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on water quality result from the incremental impacts of the Program (described in Section 4.4.3.3) when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS program activities.[47] Table 4.6.1-3 presents the exploration and development scenario for the Arctic region cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in the Arctic are summarized in Table 4.6.1-7 and discussed below, as applicable.

Ongoing and future routine OCS program activities (i.e., those of the Program and existing OCS program activities) involve service vessel traffic, waste disposal, chemical releases (permitted discharges), and disturbance of bottom sediments. All these activities have the potential to adversely affect water quality in the Beaufort and Chukchi Seas. Accidental oil spills are also counted among OCS program-related activities; assumptions for oil spills under the cumulative case scenario are provided in Table 4.6.1-4.

OCS program-related service vessel traffic in the Beaufort and Chukchi Seas could be as high as 78 trips per week (up to 30 in the Beaufort Sea and 48 in the Chukchi Sea) over the next 40 to 50 years; vessel traffic associated with the Program represents about 35% of this traffic but would occur only during open-water and broken ice conditions (typically during August and September). Non-OCS program traffic in the Beaufort and Chukchi Seas is relatively low and includes that related to the oil and gas industry (e.g., cargo vessels, spill response vessels, and hovercraft), military operations, and Arctic research. Small marine vessels are used by local communities for hunting and between-village transportation during the open water period (MMS 2008b). Impacts on water quality from marine vessel traffic arise from regular discharges of bilge water and waste, leaching of anti-fouling paints, and incidental spills.

In the Beaufort Sea Planning Area, the number of platform and subsea production wells constructed over the period of the Program (at most 120 and 10, respectively) would be proportional to the amount of oil produced; these numbers represent about 39 and 40% (respectively) of the total number of platform and subsea production wells to be built in the planning area over the next 40 to 50 years as part of the Program. The lengths of new onshore and offshore pipeline (at most 129 km [80 mi] and 250 km [155 mi], respectively) added as part of the Program represent about 28 and 37%, respectively, of that anticipated as part of the OCS program over the next 40 to 50 years.

In the Chukchi Sea Planning Area, the number of platform and subsea production wells constructed over the period of the Program (at most 280 and 82, respectively) would be proportional to the amount of oil produced; these numbers represent about 32 and 35%%, respectively, of the total number of new platform and subsea production wells anticipated to be built in the planning area over the next 40 to 50 years as part of the OCS program. The lengths of new onshore and offshore pipeline (at most 0 km [0 mi] and 402 km [250 mi], respectively) added as part of the Program represent about 0 and 19%, respectively, of that anticipated as part of the OCS program.

[47] Currently, there are no existing OCS program activities in the Beaufort Sea and Chukchi Sea Planning Areas, but it is assumed that exploration and development activities as a result of Sale 193 (Chukchi Sea) will have occurred before commencement of the exploration and development activities associated with the Program (Section 4.4.1.3).

The area of sea bottom disturbed from construction of platforms and pipelines over the period of the Program (as much as 581 ha [1,440 ac] in the planning areas combined) represents about 29% of that associated with the OCS program over the next 40 to 50 years. Bottom disturbance degrades water quality by increasing water turbidity in the vicinity of the operations and adding contaminants to the water column. It also changes sediment composition as suspended sediments (and contaminants, if present) are entrained in currents and deposited in new locations.

As summarized in Section 3.4.3.3, the water quality in the Beaufort and Chukchi Seas is relatively uncontaminated by anthropogenic pollutants (compared to other regions that typically receive pollutants from industrial, agricultural, and municipal discharges and related runoff). The principal point sources of pollution are facilities related to the oil and gas industry, hard-rock mining, military operations, and seawater treatment. Non-point sources release a range of contaminants via rivers and on-land drainages that could include contaminated runoff related to mining operations (e.g., gold mining on the Seward Peninsula). Most of these activities would remain at present levels for the foreseeable future and are not expected to affect the overall water quality in these regions.

Activities taking place within Arctic waters also contribute to the degradation of water quality. These include oil spills associated with vessel traffic, sediment dredging and disposal in local harbors (suspended sediments and contaminants), and activities related to the oil and gas industry, which operates platforms in State waters and discharges drilling wastes, produced water, and other industrial waste streams into the Beaufort Sea (MMS 2008b; ADEC 2007a).

Most of the oil released to Arctic waters is from leaks related to the oil industry (ADEC 2007a). Small spills (less than 1,000 bbl) from commercial and recreational vessels or from OCS program activities (e.g., accidental releases) are not expected to affect the overall quality of the Beaufort or Chukchi Seas because they are localized and short in duration; however, large spills (1,000 bbl or greater) could temporarily degrade the overall quality of their water (MMS 2003a). Oil spills in ice-covered waters are generally contained within a much smaller area (compared with open-water spills) because in the cold Arctic environment, oil weathering (i.e., spreading, evaporation, and migration) is much slower and some oil may solidify or become contained within sea ice. While such factors have proven to be favorable for most response strategies, the presence of ice can also complicate the response strategy. Spills on ice are fairly easy to detect and map, unless there is fresh snowfall at the time of the spill; however, oil spilled within and under the ice can be hidden from view. Broken ice also makes spilled oil difficult to detect and map, and it can reduce the effectiveness of conventional recovery systems (MMS 2009b; DF Dickens Associates, Ltd. 2004).

Climate change predictions are based on models that simulate all relevant physical processes under a variety of projected greenhouse gas emission scenarios (Section 3.3). Because the complexity of modeling global and region climate systems is so great, uncertainty in climate projections can never be eliminated. Changes to the Arctic climate include:

- Atmospheric temperature increases of 1 to 2°C (2–4°F) since the 1960s and continuing increases at a rate 1°C (2°F) per decade in winter and spring;

- Precipitation increases at a rate of about 1% per decade;

- Decreases in March sea ice extent at a rate of about 3% per decade and September sea ice at a rate of about 12% per decade (since the 1970s);

- Multi-year ice decreases at a rate of about 9% per decade (since the 1980s);

- Temperatures increases at the top of the permafrost layer by up to 3°C (5°F) since the 1980s; and

- Thawing of the permafrost base at a rate of up to 0.04 m/yr (0.13 ft/yr).

The retreat of sea ice is increasing impacts on coastal areas from storms. In areas where permafrost has thawed, coastlines are more vulnerable to erosion from wave action.

Conclusion. Water quality in the Beaufort and Chukchi Seas would be affected by the following activities associated with the Program: marine vessel traffic, waste disposal, chemical releases (permitted discharges), disturbance of bottom sediments, and accidental oil spills (from vessels and the oil and gas industry). Non-OCS program activities likely to contribute to cumulative impacts include marine vessel traffic, wastewater discharge, dredging and marine disposal, oil-related, and gas-related activities and infrastructure in State-owned marine waters, and other industrial activities (e.g., Red Dog Mine). Impacts related to marine vessel traffic in the Beaufort and Chukchi Seas (especially shipping and research vessels, icebreakers, and cruise ships) would likely increase in the coming decades as the open-water season begins earlier and ends later.

The cumulative impacts of ongoing and reasonably foreseeable future activities on water quality in the Arctic are unavoidable and may, in cases of melting sea ice, be irreversible, since such trends are natural and are occurring on a global scale. However, because many other impacts could be mitigated (i.e., minimized) by the various regulatory controls already in place to protect the marine waters of the Beaufort and Chukchi Seas, the overall cumulative impacts are considered to be moderate. The incremental contribution of the Program to cumulative impacts on water quality would be small to medium relative to the cumulative case and relative to other ongoing and reasonably foreseeable future actions in the Arctic (see Section 4.4.3.3).

The number of expected accidental oil spills in Arctic waters associated with the Program would represent only a small increase over the number of expected spills from future OCS programs and ongoing and future non-OCS program activities (mainly oil and gas development in State waters). The incremental increase in adverse water quality impacts from these spills would depend on the weather and sea conditions at the spill location (e.g., whether ice is present), the type of waves and tidal energy at the spill locations, the type of oil spilled (very light to very heavy), the depth of the spill event (deep water, shallow water, or surface water), and the volume and rate of spillage; therefore, the incremental contribution of expected oil spills to cumulative water quality impacts could range from small to large. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from moderate to major if it were to occur. Spill response and cleanup activities could contribute to water quality impacts regardless of the size of spill. A more detailed discussion of the effects of oil spills on water quality in Arctic waters is presented in Section 4.4.3.3.2.

4.6.2.3.2 Air Quality. Section 4.4.4.3 discusses potential air quality impacts in onshore and offshore areas of the Beaufort and Chukchi Seas resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on air quality result from the incremental impacts of the Program (described in Section 4.4.4.3) when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS program activities.[48] Table 4.6.1-3 presents the exploration and development scenario for the Arctic cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in the Arctic are summarized in Table 4.6.1-7 and discussed below, as applicable.

Ongoing and future routine OCS program activities, including those of the Program, involve production platforms, exploration wells, platform construction and removal, marine vessels (pipelaying, support, and survey), helicopters, and tanker and barge transport. All these activities have the potential to adversely affect air quality in the Beaufort and Chukchi Seas. Accidental oil spills are also counted among OCS program-related activities; assumptions for oil spills under the cumulative case scenario are provided in Table 4.6.1-4. Existing emission sources in the Beaufort Sea and Chukchi Sea Planning Areas include oil and gas exploration, development, and production activities in State waters (Beaufort Sea only); onshore petroleum processing and refining; marine terminals (e.g., DeLong Mountain Terminal on the Chukchi Sea); aircraft traffic; and vessel traffic.

Except for a few population centers such as Anchorage, Fairbanks, and Juneau, the existing air quality in Alaska is relatively pristine with pollutant concentrations well within ambient standards (Section 3.5.2.3). This is also the case in the Chukchi and Beaufort Seas and the North Slope area, with the exception of "Arctic haze," which is attributed to combustion sources in Russia (MMS 2010). The primary industrial emissions in the Beaufort and Chukchi Sea Planning Areas are associated with onshore oil development and production, offshore oil development and production (in State waters), power generation, mining (Red Dog Mine), and marine transportation. While some growth of these activities is likely to take place in the future, overall emissions are expected to remain low. More stringent emission standards on motor vehicles and new USEPA standards on non-road engines and marine vessels would result in a downward trend in emissions.

Criteria Pollutants. On the Alaska North Slope, the main sources of air emissions are associated with onshore oil production from the Prudhoe Bay, Kuparuk River, Colville River, Oooguruk, Milne Point, and Badami fields and oil production in State waters (Northstar and

48 Currently, there are no existing OCS program activities in the Beaufort Sea and Chukchi Sea Planning Areas, but it is assumed that exploration and development activities as a result of Sale 193 (Chukchi Sea) will have occurred before commencement of the exploration and development activities associated with the Program (Section 4.4.1.3).

Duck Island fields). As of 2009, about 16.2 Bbbl[49] of oil have been produced from North Slope reservoirs, including the Beaufort Sea (ADNR 2009c). Production from the region peaked at about 730 Mbbl in 1988 and has been in decline since then (EIA 2011c). The USDOE projects that the annual production of oil will continue to decline, from about 234 Mbbl in 2010 to 37 Mbbl in 2050 (EIA 2009n). There are a number of planned and potential future oil development projects, both onshore and in State and Federal waters in the Beaufort Sea Planning Area. There are very few other emission sources in the Chukchi Sea Planning Area.

Air monitoring at a number of sites in the Kuparuk and Prudhoe Bay fields has shown that concentrations of NO_2, SO_2, and PM_{10} are well within the NAAQS. Modeling studies for the Liberty project indicate that emissions from these areas have little effect on ambient concentrations in other locations (with maximum concentrations occurring within 100 to 200 m [330 to 660 ft] from the facility boundary and considerably lower concentrations at a distance of 1 km [0.62 mi]) (MMS 2010). For this reason, it is anticipated that emissions from new facilities would be small and localized with little interaction between facilities.

Table 4.6.2-3 lists the estimated total emissions associated with all future OCS oil and gas activities in the Beaufort and Chukchi Seas, including the 2012-2017 Program, over the next 50 years. These emissions were estimated by BOEM using emission factors from the *2008 Gulfwide Emission Inventory Study* (Wilson et al. 2010).[50] In terms of absolute amounts (using the high scenario), the largest emissions would be NO_x, followed by VOCs, CO, and SO_x, with lesser amounts of PM_{10} and $PM_{2.5}$, in order of decreasing emissions. Under both the high and low scenarios, support vessels would be the largest source of NO_x; the drilling of exploration and development wells would be the largest source of SO_x and PM; and platform production would be the largest source of CO and VOCs. Emissions from Program activities in the Arctic region generally represent about 37 to 39% of the Arctic cumulative case emissions.

Ozone Formation and Visibility Impairment. The baseline conditions and impacts from OCS activities on ozone and visibility are discussed in Sections 3.5.2.3 and 4.4.4.3, respectively. Because conditions in Alaska are seldom favorable for significant O_3 formation, the contribution of leasing activity associated with the Program to O_3 levels in the Beaufort and Chukchi Sea Planning Areas is expected to be small. OCS emission sources affecting visibility are also small.

Greenhouse Gases. Table 4.6.2-4 lists the total calculated emissions of CO_2, CH_4, and N_2O from OCS activities related to the Beaufort and Chukchi Seas (Arctic region) portion of the 2012-2017 Program and compares them to the 2012-2017 Program overall (accounting for OCS program activities in GOM, Cook Inlet, and the Arctic region) and to the total U.S. emissions from all sources in 2009. Activities in the Arctic region account for a small portion of the GHG emissions associated with the 2012-2017 Program, comprising between 1.8 and 4.6% of all program-related GHG emissions. For reference, the estimated annual emissions of CO_2, CH_4,

49 Historic figures include both oil and natural gas liquids produced at Prudhoe Bay and surrounding fields.

50 In the absence of Arctic-specific data, the emission factors from the Wilson et al. (2010) study are considered the best approximation for estimating total emissions related to exploration and development in the Arctic region. Another source, Shell Offshore Inc. (2010), was used to estimate emissions related to icebreakers.

TABLE 4.6.2-3 Estimated Total Air Emissions for the Offshore Exploration and Development Scenario for the OCS Program Arctic Region Cumulative Case

	Pollutant (10^3 tons for 50 yr)[a]					
Activity	NO_x	SO_x	PM_{10}	$PM_{2.5}$	CO	VOC
Well drilling (D&P)	6.57–27.7	1.34–5.66	0.45–1.89	0.45–1.89	0.03–0.15	0.17–4.93

TABLE 4.6.2-4 Estimated Greenhouse Gas Emissions for the 2012-2017 Program in the Arctic Region Relative to the 2012-2017 OCS Program Overall over the Next 40 Years

Pollutant	2012-2017 Program (all) (Tg CO_2e) [a, b]	2012-2017 Arctic Program (Tg CO_2e)	Total U.S. Emission from All Sources (2009)	Percent of Total U.S. Emissions from Arctic Program [c]
CO_2	341.54–512.6	5.29–24.66	5,505.2	0.003–0.010
CH_4	3.98–120.22	0.81–4.33	686.3	0.004–0.014
N_2O	2.85–4.23	0.02–0.09	295.6	0.00–0.001
$CO_2 + CH_4 + N_2O$	348.57–637.05	6.12–29.08	6,487.1	0.003–0.010
All GHG	348.57–637.05	6.12–29.08	6,633.2	0.003–0.010
Total	348.57–637.05	6.12–29.08	38,726.0	

[a] One Tg is equal to 10^{12} g, or 10^6 metric tons. The CO_2e for a gas is derived by multiplying the mass of the gas by the associated GWP, which accounts for the relative effectiveness of a gas to contribute to global warming with respect to the same amount of CO_2. In these calculations, CH_4 is given a GWP of 21, while NO_2 is given a GWP of 310.

[b] Values represent the total emissions for the 2012-2017 Program in the GOM, Cook Inlet, and Arctic regions.

[c] Values are calculated by dividing the estimated annual emissions of the Arctic Program (equal to the value in the third column divided by 40) by the total U.S. emission from all sources in 2009 (fourth column).

Source: USEPA 2011l.

and N_2O from OCS activities in the Arctic region were less than 0.05% of CO_2, CH_4, and N_2O emissions in the United States from all sources in 2009. Although these are small contributions, it should be noted that some GHGs (e.g., CO_2) can persist in the atmosphere for a century, well beyond the life of the Program.

GHG emissions are one of the causes of climate change; however, assessing their impact requires consideration on a global scale. For this reason, it is not possible to estimate the impact of GHG emissions from particular sources, such as the OCS activities associated with the Program. On a global scale, the contribution from the Program to total GHG emissions is small. On a national scale, the contribution of the Program is also small (much less significant than from activities in the GOM).

Oil Spills. Accidental oil spills are a source of gaseous emissions. No more than six large spills (1,000 bbl or greater) and 450 small spills (less than 50 bbl) are projected for the Beaufort and Chukchi Sea Planning Areas cumulative case as a result of the OCS program (Table 4.6.1-4). Most of the accidental spills in the North Slope region are of non-crude products during fuel transfer operations at remote villages (ADEC 2007a). While there is no discernible trend in the annual number of spills or total volume released, there is a seasonal pattern to spill events, with increases occurring during winter months (likely coinciding with increased exploration activities). Since 1976, there have been no major crude oil spills in Arctic waters (State of Alaska 2011). Oil spills cause localized increases in VOC concentrations (proportional to the size of the spill) due to evaporation. Most of these emissions would be expected to occur within a few hours of the spill and decrease (by dissipation) drastically after that period (MMS 2010). However, oil spills in ice-covered waters during winter months would be contained within a much smaller area (compared with spills in open waters) because oil weathering (i.e., spreading, evaporation, and migration) is much slower and some oil may solidify (MMS 2009b). A more detailed discussion of the effects of oil spills on air quality in the Arctic region is presented in Section 4.4.4.3.

Catastrophic events at well locations may result in fires; *in situ* burning is also a preferred technique for cleanup and disposal of oil spills (documented in oil spill contingency plans). Smoke generated from such fires would be expected to reach shore quickly (within a day), but would be limited in geographic extent (MMS 2003a). A discussion of the effects of fires on air quality in the Arctic region is presented in Section 4.4.4.3.

Conclusion. OCS program activities in combination with other oil and gas exploration, development, and production activities in the Beaufort and Chukchi Sea Planning Areas could affect air quality in the region. Air pollutant concentrations associated with offshore and onshore emission sources are expected to remain well within applicable State and Federal standards over the life of the Program. Therefore, the overall cumulative impacts on air quality in the Beaufort and Chukchi Sea Planning Areas are expected to be minor to moderate, and the incremental contribution of routine Program activities to air quality impacts would be small (see Section 4.4.4.3).

The number of expected accidental oil spills in Arctic waters associated with the Program would represent only a small increase over the number of expected spills from ongoing non-OCS program activities (mainly oil and gas production in State waters). The incremental increase in adverse air quality impacts from these spills (and *in situ* burning of spilled crude or diesel) would be localized and temporary (due to the spreading of oil and action by winds, waves, and currents that disperse volatile compounds to extremely low levels over a relatively large area); therefore, the incremental contribution of expected oil spills to cumulative air quality impacts could range from small to medium. Air quality impacts associated with an unexpected, low-probability CDE (and *in situ* burning) would also be reduced by these factors, and could be moderate if it were to occur. Spill response and cleanup activities (e.g., *in situ* burning and use of chemical dispersants) could contribute to air quality impacts regardless of the size of spill. A more detailed discussion of the effects of oil spills on air quality in the Arctic region is presented in Section 4.4.4.2.3.

4.6.2.3.3 Acoustic Environment. Section 4.4.5.3 discusses impacts on the acoustic environment in the Arctic region resulting from the Program. Section 4.4.7 evaluates the direct and indirect impacts of noise on marine fauna (fish, marine mammals, and birds), and Section 4.6.4 addresses the cumulative impacts of noise on marine fauna. Cumulative impacts on the acoustic environment result from the incremental impacts of the Program when added to impacts from reasonably foreseeable future OCS program activities (that are not part of the

Program) and other non-OCS program activities.[51] Table 4.6.1-3 presents the exploration and development scenario for the Beaufort Sea and Chukchi Sea Planning Areas cumulative case (encompassing the Program and other OCS program activities). Ongoing and reasonably foreseeable non-OCS program activities contributing to adverse cumulative impacts on the acoustic environment in the Arctic region include aircraft traffic, marine vessel traffic, construction of onshore and offshore facilities (e.g., related to ongoing oil and gas exploration and development in State waters), and other activities (e.g., seismic surveys) conducted as part of the existing oil and gas industry in the Beaufort and Chukchi Seas. This section addresses the quality of the acoustic environment only; the cumulative impacts of noise on marine fauna in the Beaufort and Chukchi Seas are discussed in Section 4.6.4.3.

Ambient (background) noise has numerous natural and man-made sources that vary with respect to season, location, depth of occurrence, time of day, and noise characteristics (e.g., frequency and duration).[52] Natural sources of ambient noise include wind and wave action, currents, ice, precipitation (rain and hail), lightening, and biological noise (from marine mammals and coastal birds). Marine vessels (e.g., tankers, supply ships, tugboats, barges, and fishing boats) are the greatest man-made contributors to overall marine noise in the Arctic region. Baseline acoustic conditions in the region are discussed in more detail in Section 3.6.3.

Future routine OCS program activities, including those of the Program, that generate noise include operating airgun arrays (during marine seismic surveys), drilling, pipeline trenching, and onshore and offshore construction and decommissioning of platforms (including artificial islands and causeways), and drilling rigs. Vessel and aircraft traffic (including that associated with emergency response and cleanup activities in the event of a spill), accidental releases (e.g., loss of well control events), and vessel collisions also contribute to noise. A preliminary study of the noise impacts of OCS related geophysical surveys found that marine seismic surveys have the greatest impact on marine mammals, sea turtles, fish, and commercial and recreational fisheries (MMS 2004a). Noise generated from OCS and non-OCS program activities would be transmitted through both air and water, and may be transient or more extended (occurring over the long term).

Conclusion. The quality of the acoustic environment in the Beaufort and Chukchi Seas would continue to be adversely affected by ongoing and future non-OCS program activities and by future OCS program activities (currently there are no existing OCS activities, although seismic studies and exploratory drilling have been conducted in the past). The magnitude of cumulative impacts due to noise in the Beaufort and Chukchi Seas from all OCS and non-OCS activities taking place in the Arctic region over the next 40 to 50 years is time- and location-specific and could range from minor to major, depending on the ambient acoustic conditions and the nature of activities taking place. The incremental contribution due to noise generated by

---

51 Currently, there are no existing OCS program activities in the Beaufort Sea and Chukchi Sea Planning Areas, but it is assumed that exploration and development activities as a result of Sale 193 (Chukchi Sea) will have occurred before the Program (Section 4.4.1.3).

52 Higher frequencies are attenuated with distance from the source more rapidly than lower frequencies. Traffic noise generated in deep water contributes to background noise levels at greater distances than traffic noise generated in shallow water.

routine Program activities could range from small to medium, depending on the timing of the disturbance and the location and characteristics of noise sources present (e.g., their frequency and duration). The cumulative impacts of noise on marine fauna (fish, marine mammals, and birds) are discussed in Section 4.6.4.

The number of expected accidental oil spills in Arctic waters associated with the Program would represent only a small increase over the number of expected spills from ongoing non-OCS program activities. The incremental increase in adverse acoustic environment impacts from these spills (mainly due to noise sources associated with response and cleanup activities) would be localized and temporary; therefore, the incremental contribution of expected oil spills due to noise could range from small to medium. Impacts associated with an unexpected, low-probability CDE could be minor to moderate if it were to occur. Most of the impacts to the acoustic environment are due to noise sources (e.g., mechanical equipment, skimmers, support vessel traffic, and aircraft traffic) associated with spill response and cleanup activities. A more detailed discussion of the effects of oil spills on the acoustic environment in the Arctic region is presented in Section 4.4.5.3.

4.6.2.4 Summary for the Gulf of Mexico Region

4.6.2.4.1 Water Quality. There are many factors affecting the water quality in the GOM currently. In general, these include marine vessel traffic, wastewater discharge, dredging and marine disposal, oil and gas production (in State waters and on the OCS), military operations, LNG terminal operations, LOOP operations, and natural oil seepage along the continental slope. Coastal waters are also affected by numerous other factors, including river inflows, urbanization, agricultural practices, municipal waste discharges, and coastal industry. Climate change is also expected to affect water quality in the coming decades, especially in terms of surface temperature, salinity, vertical stratification, and pH. Another issue of importance to water quality in the GOM concerns an area known as the hypoxic zone, a zone of oxygen depletion (due to high nutrient loads) which is located at the bottom of the continental shelf of Louisiana and Texas. Cumulative impacts on water quality are attributed to a combination of all these factors and, overall, are considered to be moderate. The incremental contribution of the Program to cumulative impacts on water quality in the GOM would be small to medium.

Routine operations under the Program could result in localized and short-term minor to moderate impacts as a result of structure placement and construction (pipelines and platforms), operational discharges (produced water, bilge water, and drill cuttings), bottom disturbance, and waste discharges. Compliance with NPDES permits and USCG regulations would reduce the magnitude of most of these impacts. The effects of expected accidental oil spills (most of which are less than 1,000 bbl) would depend upon weather and sea conditions at the spill site, the type of oil spilled, the depth of the spill event, and the volume and rate of spillage; therefore, the incremental contribution of expected oil spills to cumulative water quality impacts could range from small to large. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from moderate to major if it were to occur. Spill response and cleanup activities could also contribute to water quality impacts. While small spills (less than 1,000 bbl) would result in short-term, localized impacts, the impacts associated with larger spills (1,000 bbl or greater) or a CDE could persist for an extended period (especially in wetlands and low-energy environments).

4.6.2.4.2 Air Quality. In general, the ambient air quality in coastal counties along the GOM is relatively good. Coastal counties are in attainment for all criteria pollutants except 8-hr ozone (in some areas of Texas and Louisiana). Visibility in the coastal region is about 48 to 64 km (30 to 40 mi). Most of the human-caused visibility degradation is attributed to sulfate particles, but also to organic or elemental carbon particles and nitrate particles. The effects of various USEPA regulations and standards are expected to result in a steady, downward trend in future air emissions in the coming decades. Cumulative impacts on air quality in the GOM region are attributed to both offshore and onshore activities. Offshore activities in the GOM are mainly associated with the oil and gas industry, but also include various marine vessel traffic (shipping, fishing, cruise ships), tanker lightering, and military operations. Onshore emission sources include power generation, industrial processing, manufacturing, refineries, commercial and home heating, on-road vehicles, and non-road engines (e.g., aircraft, locomotives, and construction equipment). Overall, cumulative impacts on air quality in the GOM over the next 40 to 50 years are expected to be minor to moderate.

The incremental contribution of routine operations under the Program would be small, because they would not cause exceedance of the NAAQS in public access areas or affect visibility. Small accidental oil spills (less than 1,000 bbl) would have localized and temporary effects and are considered minor from an air quality standpoint. The effects of expected accidental oil spills (most of which are less than 1,000 bbl) would be localized and temporary due to dispersion; therefore, the incremental contribution of expected oil spills to cumulative air impacts could range from small to medium. Air quality impacts associated with an unexpected, low-probability would also be reduced by these factors, and would be moderate if it were to occur. Spill response and cleanup activities could also contribute to air quality impacts.

4.6.2.4.3 Acoustic Environment. Sources of ambient noise in the GOM include wind and wave activity, precipitation (rain and hail), lightning, biological noise, and distant marine vessel traffic. The main sources of anthropogenic noise are numerous in the GOM and include marine vessel traffic, dredging, construction, oil and gas activities (such as seismic surveys), marine mineral mining, sonar, explosions, and ocean science studies. The quality of the acoustic environment in the GOM would continue to be adversely affected by ongoing and future OCS and non-OCS activities. The magnitude of cumulative impacts in the GOM is time- and location-specific and could range from minor to major, depending on the ambient acoustic conditions and the nature and combination of noise sources from all OCS and non-OCS activities.

Routine operations under the Program would result in minor impacts to ambient noise levels mainly associated with seismic surveys, drilling and production, infrastructure placement and removal, and marine vessel traffic. Depending on the source, changes in ambient noise levels could be short-term and localized (e.g., from vessel traffic), long-term and localized (e.g., from production), or short-term and less localized (e.g., seismic surveys), and some may extend well beyond the survey boundary. The contribution of the Program to cumulative impacts could be small to medium, depending on the timing of the disturbance and the location and characteristics of noise sources present (e.g., their frequency and duration). The incremental increase in adverse acoustic environmental impacts from expected accidental oil spills in GOM waters (most of which are less than 1,000 bbl) would be localized and temporary; therefore, the incremental contribution of expected oil spills to cumulative noise-related impacts would be small. Impacts associated with an unexpected, low-probability CDE could range from minor to moderate if it were to occur. Most of the impacts to the acoustic environment would be due to noise sources associated with response and cleanup activities.

4.6.2.5 Summary for Alaska – Cook Inlet

4.6.2.5.1 Water Quality. Factors affecting the water quality in Cook Inlet include marine vessel traffic, wastewater discharge, dredging and marine disposal, oil and gas production (currently only in State waters), and military operations. Water quality is also affected by numerous other factors, including river inflows, urbanization, forest practices, mining, municipal waste discharges, and agriculture. Natural seepage of oil along the west part of the inlet may also be significant. Cumulative impacts on water quality are attributed to a combination of all these factors and, overall, are considered to be minor to moderate. These impacts may lessen with time since oil and gas production in Cook Inlet is currently in decline. The incremental contribution of the Program to cumulative impacts on water quality in Cook Inlet would be small to medium.

Routine operations under the Program could result in localized and short-term minor to moderate impacts as a result of structure placement and construction (pipelines and platforms), operational discharges (produced water, bilge water, and drill cuttings), bottom disturbance, and waste discharges. Compliance with NPDES permits and USCG regulations would reduce the magnitude of most impacts. The effects of expected accidental oil spills (most of which are less than 1,000 bbl) would depend upon weather and sea conditions at the spill site, the type of oil spilled, the depth of the spill event, and the volume and rate of spillage; therefore, the incremental contribution of expected oil spills to cumulative water quality impacts could range from small to large. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from moderate to major if it were to occur. Spill response and cleanup activities could also contribute to water quality impacts. While small spills (less than 1,000 bbl) would result in short-term, localized impacts, impacts associated with larger spills (1,000 bbl or greater) or a CDE could persist for an extended period (especially in wetlands and low-energy environments).

4.6.2.5.2 Air Quality. Except for a few population centers such as Anchorage, the existing air quality in Alaska is relatively pristine with pollutant levels that are well within the ambient standards. Cumulative impacts on air quality in Cook Inlet are attributed to both offshore and onshore activities. Offshore activities in the region are mainly associated with the oil and gas industry, but also include various marine vessel traffic (shipping, fishing, cruise ships). Onshore emission sources include power generation, industrial plants, mining, commercial and home heating, on-road vehicles, and non-road engines (e.g., aircraft, locomotives, and construction equipment). Overall, cumulative impacts on air quality in Cook Inlet over the next 40 to 50 years are expected to be minor to moderate.

The incremental contribution of routine operations under the Program would be small, because they would not cause exceedance of the NAAQS in public access areas or affect visibility. Small accidental oil spills (less than 1,000 bbl) would have localized and temporary effects and are considered minor from an air quality standpoint. The effects of expected accidental oil spills would be localized and temporary due to dispersion; therefore, the incremental contribution of expected oil spills to cumulative air impacts could range from small to medium. Air quality impacts associated with an unexpected, low-probability CDE would also be reduced by these factors, and could be moderate if it were to occur. Spill response and cleanup activities could also contribute to air quality impacts.

4.6.2.5.3 Acoustic Environment. Ice, strong tidal fluctuations, and currents all play an important role in the ambient noise levels in Cook Inlet. The main sources of anthropogenic noise are aircraft overflights, marine vessel traffic, oil and gas activities (including seismic surveys and production operations), and other operations such as dredging and pile driving (for new docks). The quality of the acoustic environment in Cook Inlet would continue to be adversely affected by ongoing and future non-OCS program activities and by future OCS program activities (currently there are no existing OCS activities, although seismic studies and exploratory drilling have been conducted in the past). The magnitude of cumulative impacts in the inlet is time- and location-specific and could range from minor to major, depending on the ambient acoustic conditions and the nature and combination of noise sources from all OCS and non-OCS activities.

Routine operations under the Program would result in minor impacts to ambient noise levels mainly associated with seismic surveys, drilling and production, infrastructure placement and removal, and marine vessel traffic. Depending on the source, changes in ambient noise levels could be short-term and localized (e.g., from vessel traffic), long-term and localized (e.g., from production), or short-term and less localized (e.g., seismic surveys), and some may extend well beyond the survey boundary. The contribution of the Program to cumulative impacts could range from small to medium, depending on the timing of the disturbance and the location and characteristics of noise sources present (e.g., their frequency and duration). The incremental increase in adverse acoustic environmental impacts from expected accidental oil spills in Cook Inlet waters (mainly due to noise sources associated with response and cleanup) would be localized and temporary; therefore, the incremental contribution of expected oil spills to cumulative noise-related impacts would be small. Impacts associated with an unexpected, low-probability CDE could range from minor to moderate if it were to occur. Most of the impacts to the acoustic environment would be due to noise sources associated with response and cleanup activities.

4.6.2.6 Summary for Alaska – Arctic

4.6.2.6.1 Water Quality. Factors affecting the water quality in the Beaufort and Chukchi Seas include marine vessel traffic, wastewater discharge, oil and gas production (currently only in State waters), and military operations. Water quality is also affected by numerous other factors, including river inflows, mining, and municipal waste discharges. Cumulative impacts on water quality are attributed to a combination of all these factors and, overall, are considered to be moderate. Impacts related to marine vessel traffic in the Beaufort and Chukchi Seas (especially shipping and research vessels, icebreakers, and cruise ships) would likely increase in the coming decades as the open-water season begins earlier and ends later (an effect of climate change). The incremental contribution of the Program to cumulative impacts on water quality in Arctic waters would be small to medium.

Routine operations under the Program could result in localized and short-term minor to moderate impacts as a result of structure placement and construction (pipelines and platforms), operational discharges (produced water, bilge water, and drill cuttings), bottom disturbance, and waste discharges. Compliance with NPDES permits and USCG regulations would reduce the magnitude of most of these impacts. The effects of expected accidental oil spills (most of which are less than 1,000 bbl) would depend upon weather and sea conditions at the spill site, the type of oil spilled, the depth of the spill event, and the volume and rate of spillage; therefore, the incremental contribution of expected oil spills to cumulative water quality impacts could range from small to large. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from moderate to major if it were to occur. Spill response and cleanup activities could also contribute to water quality impacts. While small spills (less than 1,000 bbl) would result in short-term, localized impacts, impacts associated with larger spills (1,000 bbl or greater) or a CDE could persist for an extended period (especially in wetlands and low-energy environments).

4.6.2.6.2 Air Quality. The Arctic region has a low population. Barrow is the largest city in the North Slope Borough, with a population (in 2010) of just 4,600. The primary industrial emissions in the region are associated with the oil and gas industry, power generation, small refineries, paper mills, and mining. Currently, North Slope Borough is designated as an unclassified/attainment area for all criteria pollutants. The region does experience air pollution problems (e.g., Arctic haze), however, due to long-range transport of air pollutants from industrial parts of northern Eurasia and North America. Overall, cumulative impacts on air quality in the Arctic region over the next 40 to 50 years are expected to be minor to moderate. The incremental contribution of the Program would be small.

The incremental contribution of routine operations under the Program would be small, because they would not significantly increase onshore airborne pollutants or affect visibility. Small accidental oil spills (less than 1,000 bbl) would have localized and temporary effects and are considered minor from an air quality standpoint. The effects of expected accidental oil spills (most of which are less than 1,000 bbl) would be localized and temporary due to dispersion; therefore, the incremental contribution of expected oil spills to cumulative air impacts could range from small to medium. Air quality impacts associated with an unexpected, low-probability CDE would also be reduced by these factors (depending on the season), and could be moderate if it were to occur. Spill response and cleanup activities could also contribute to air quality impacts.

4.6.2.6.3 Acoustic Environment. Arctic waters are a unique acoustic environment, mainly because of the presence of ice, which can contribute significantly to ambient sound levels (e.g., ice cracking generates noise; ice deformation generates low-frequency noise). Ambient levels of natural sound can vary dramatically between and within seasons. During open-water season, wind and waves (and biological sounds) are important sources of ambient sounds. The main sources of anthropogenic noise are aircraft overflights, marine vessel traffic, oil and gas activities (including seismic surveys and production operations), human settlements, and military activities. The quality of the acoustic environment in the Beaufort and Chukchi Seas would continue to be adversely affected by ongoing and future non-OCS program activities and by future OCS program activities (currently there are no existing OCS activities, although seismic studies and exploratory drilling have been conducted in the past). The magnitude of cumulative impacts in the Beaufort and Chukchi Seas is time- and location-specific and could range from minor to major, depending on the ambient acoustic conditions and the nature and combination of noise sources from all OCS and non-OCS activities.

Routine operations under the Program would result in minor impacts to ambient noise levels mainly associated with seismic surveys, drilling and production, infrastructure placement and removal, and marine vessel traffic. Depending on the source, changes in ambient noise levels could be short-term and localized (e.g., from vessel traffic), long-term and localized (e.g., from production), or short-term and less localized (e.g., seismic surveys), and some may extend well beyond the survey boundary. The contribution of the Program to cumulative impacts could range from small to medium, depending on the timing of the disturbance and the location and characteristics of noise sources present (e.g., their frequency and duration). The incremental increase in adverse acoustic environmental impacts from expected accidental oil spills in Arctic waters (most of which are less than 1,000 bbl) would be localized and temporary; therefore, the incremental contribution of expected oil spills to cumulative noise-related impacts would be small. Impacts associated with an unexpected, low-probability CDE could range from minor to moderate if it were to occur. Most of the impacts to the acoustic environment would be due to noise sources associated with response and cleanup activities.

4.6.3 Marine and Coastal Habitats

4.6.3.1 Gulf of Mexico Region

4.6.3.1.1 Coastal and Estuarine Habitats. Section 4.4.6.1.1 discusses direct and indirect impacts on coastal and estuarine habitats in the GOM resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on these resources result from the incremental impacts of the Program (described in Section 4.4.6.1.1) when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS activities. Table 4.6.1-2 presents the exploration and development scenario for the GOM cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future OCS programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in the GOM are summarized in Table 4.6.1-5 and discussed below, as applicable.

A number of activities associated with the Program could result in impacts on coastal and estuarine habitats in the GOM (Section 4.4.6.1.1). These activities include construction of pipelines and shoreline facilities, maintenance dredging of inlets and channels, and vessel traffic. Impacts associated with these activities could include (1) losses of beach and dune habitat and indirect effects that contribute to reductions in beach habitat in areas of ongoing shoreline degradation; and (2) elimination of wetland habitat and indirect effects that contribute to reductions in wetland habitat. Similar activities would occur from previous and future sales during the life of the Program (see Table 4.6.1-2). Excluding the estimated number of offshore pipelines installed, which is not relevant to this analysis, the activities associated with the Program will be about 15–30% of the total amount of OCS program activity that will occur during the life of the Program.

Barrier Beaches and Dunes. Impacts on barrier beaches and dunes primarily result from factors that reduce sediment input to downdrift areas or that directly contribute to increased erosion of beaches and dunes. Construction projects may reduce the sediment contribution to the GOM barrier landforms from inflowing rivers, or they may restrict the movement of sediments to downdrift areas and natural replenishment of barrier beaches. Other activities may disturb barrier dune vegetation, thereby promoting dune erosion, or directly disturb beach and dune substrates, resulting in increased erosion of beaches and dunes. Increases in wave action can also contribute to beach erosion.

Ongoing non-OCS activities that could affect barrier beaches and dunes include those related to State oil and gas development, commercial shipping (and other marine vessel traffic), coastal development, and recreation (Table 4.6.1-5). These activities can be reasonably expected to continue into the future. A number of activities reduce the sediment supply to barrier beaches and dunes. Past activities that have contributed to sediment deprivation and submergence of coastal lands have contributed to erosion and land losses, particularly along the Louisiana coast, and are expected to continue into the foreseeable future. Channelization and diversion of Mississippi River flows, as well as the construction of Mississippi River dams and reservoirs, and subsequent reductions in sediment supply to deltaic areas to the west have resulted in the continued extensive erosion of coastal habitats. Past construction of dams on other rivers discharging to the western GOM has also resulted in a reduction in sediments delivered to the coast, which, along with natural causes of sediment supply reductions, have resulted in ongoing land loss along the Texas coast. The emplacement of groins, jetties, and seawalls for beach stabilization in much of the GOM contributes to the reduction of sediment inputs and the acceleration of coastal erosion in downdrift areas. Maintenance dredging of barrier inlets and bar channels, in combination with channel jetties, has resulted in impacts on adjacent barrier beaches down-current due to sediment deprivation, especially on the sediment-starved coastal areas of Louisiana. Maintenance dredging is an ongoing practice and is expected to continue to be an impact-producing factor into the future; this includes, for example, efforts to accommodate larger cargo vessels. The past construction of canals for pipelines and navigation has resulted in losses of coastal barrier habitat. Although new navigation canals from the GOM to inland areas are unlikely to be needed and current pipeline construction methods result in little, if any, impacts on barrier landforms, existing pipeline canals are expected to continue to be sediment sinks and to promote the reduction of adjacent barrier island dunes and beaches. However, the replenishment of barrier beaches with sand obtained from OCS sources and the beneficial use of dredged material are expected to continue to aid in the restoration of barrier islands.

The presence of pipelines, even after decommissioning, in some areas of the GOM may potentially result in the reduction or elimination of suitable sediment sources used for beach renourishment and restoration projects, due to the necessity of pipeline avoidance. Loss of sediment sources could potentially restrict restoration activities in some areas. In addition, at restoration sites, pipeline safety buffers can reduce areas available for restoration, and pipeline surveys divert funds otherwise available. However, as noted above, fewer than 12 new pipeline landfalls would be constructed under the Program. Pipeline disturbance widths are generally small with modern placement methods, and the rights-of-way would be less than 200 m (656 ft) in width. Operators are interested in protecting pipelines from coastal erosion, so a synergy could be developed with coastal restoration projects. Because of demand for OCS material for coastal restoration, BOEM is trying to cluster pipelines and to keep pipelines away from known marine mineral resources (BOEM 2012a; USDOI 2009). The impacts on barrier beaches and dunes from sediment removal activities associated with maintenance dredging under the Program would represent a very small contribution to the past, ongoing, and expected future degradation of barrier beaches and dunes from non-OCS activities.

Although coastal barrier islands in most of the Central Planning Area generally receive minimal recreational use, most barrier beaches in Texas, Alabama, and Florida are accessible and extensively used for recreation. Pedestrian and vehicular traffic on beaches and dunes can destabilize substrates, either by reducing vegetation density — and thus increasing erosion by wind, waves, and traffic — or by directly disturbing or displacing substrates. In addition, considerable private and commercial development has occurred on many barrier islands in the GOM, resulting in losses of beach and dune habitat. The impacts on barrier beaches and dunes from substrate-disturbance activities associated with pipeline construction under the Program are expected to be greatly minimized by non-intrusive construction techniques and would not be expected to appreciably add to the cumulative effects of other substrate-disturbing activities.

Activities that increase wave action along barrier beaches and dunes can contribute to their erosion. The construction of seawalls, groins, and jetties in Texas and Louisiana has contributed to coastal erosion in part by increasing or redirecting the erosional energy of waves. Vessel traffic related to shipping and transportation can result in wake erosion of channels between barrier islands. A large number of vessels use the navigation channels near the GOM coast. A portion of the impacts related to vessel traffic would be associated with the Program; however, activities conducted under the Program would contribute a relatively small number of vessel trips to the total.

Barrier beaches and dunes could be affected by accidental spills of oil or petroleum products resulting from ongoing and future activities in the GOM (Section 4.6.1.1). Although the majority of these spills would be small (less than 50 bbl), catastrophic releases can impact extensive areas of shoreline. Oil released into coastal waters as a result of the DWH event, April–July 2010, affected more than 1,046 km (650 mi) of the GOM coastal habitat, from the Mississippi River delta to the Florida panhandle, with the Louisiana, Mississippi, Alabama, and Florida coasts all affected (OSAT-2 2011; National Commission 2011). The greatest impacts were in Louisiana. More than 209 km (130 mi) of coastal habitat were moderately to heavily oiled, with only 32 km (20 mi) occurring outside of Louisiana (National Commission 2011). Little or no oil affected Texas coastal habitats. Heavy to moderate oiling occurred along a substantial number of Louisiana beaches, with the heaviest oiling on the Mississippi Delta, in Barataria Bay, and on the Chandeleur Islands (OSAT-2 2011). The majority of Mississippi barrier islands had light oiling to trace oil, although heavy to moderate oiling occurred in some areas. Some heavy to moderate oiling also occurred on beaches in Alabama and Florida, with the heaviest stretch of oiling extending from Dauphin Island, Alabama, to near Gulf Breeze, Florida (OSAT-2 2011). Light to trace oiling occurred from Gulf Breeze to Panama City, Florida. Deposition of oil occurred in the supratidal zone (above the high tide mark), deposited and buried during storm events; intertidal zone; and subtidal zone, there remaining as submerged oil mats (OSAT-2 2011). On Grand Isle, Louisiana, and Bon Secour, Alabama, oil was found up to 105 cm (41 in.) below the surface (OSAT-2 2011). Low-molecular-weight and volatile compounds were mostly depleted from oil that reached shorelines, due to weathering at sea (OSAT-2 2011). Although much of the oil remaining after cleanup is highly weathered, several constituents have the potential to cause toxicological effects (OSAT-2 2011).

Non-OCS activities, such as the domestic transportation of oil, foreign crude oil imports, and State oil and gas development may also result in accidental spills that could potentially affect coastal barrier beaches and dunes. The amount of oil contacting barrier islands from a spill would depend on a number of factors such as the location and size of the spill, waves and water currents, and containment actions. Naturally occurring seeps may also be a source of crude oil introduced into GOM waters (NRC 2003b; Kvenvolden and Cooper 2003). The magnitude of resulting impacts and the persistence of oil would depend on factors such as the amount of oil deposited, remediation efforts, substrate grain size, and localized erosion and deposition patterns. In areas of barrier beach erosion, such as Louisiana, remediation would likely include the minimization of sand removal or replacement of removed sand. The impacts of potential oil spills associated with the Program would be expected to add a small contribution to the impacts of other sources of oil.

Indirect effects on coastal barrier beaches and dunes could result from global climate change. Factors associated with global climate change include changes in temperature and rainfall, alteration in stream flow and river discharge, sea level rise, changes in hurricane frequency and strength, sediment yield, mass movement frequencies and coastal erosion, and subsidence (Yanez-Arancibia and Day 2004). Potential thermal expansion of ocean water and melting of glaciers and ice caps could result in a global rise in mean sea level (Section 4.6.1.6). Recent rates of sea level rise have been approximately 3 mm/yr (0.12 in./yr), but this rate may increase to 4 mm/yr (0.16 in./yr) by 2100 (Blum and Roberts 2009). Sea-level rise could result in increased inundation of barrier beaches and increases in losses of beach habitat. Effects of sea level rise include damage from inundation, floods and storms; and erosion (Nicholls et al. 2007). Effects of increased storm intensity include increases in extreme water levels and wave heights; increases in episodic erosion, storm damage, risk of flooding, and defense failure (Nicholls et al. 2007). Patterns of erosion and accretion can also be altered along coastlines (Nicholls et al. 2007). The small tidal range of the GOM coast increases the vulnerability of coastal habitats to the effects of climate change.

Hurricanes and other severe storm events can affect coastal barrier beaches and dunes. Increased wave action and intensity on barrier habitats may result in increased erosion and changes in beach and dune topography or losses of habitat. Hurricanes and tropical storms are inherent components of the GOM ecosystem that have long influenced coastal habitats and are expected to continue to be sources of impacts. Anthropogenic impacts on barrier beaches and dunes may be greatly exacerbated by severe storm events such as hurricanes. In 2005, Hurricanes Katrina and Rita caused extensive erosion of barrier landforms in the central and western GOM. Extreme storms such as these can result in relatively permanent change to these habitats, particularly in areas that are already experiencing erosion and retreat as a result of sediment deprivation, sea level rise, and coastal development.

Wetlands. Factors that affect coastal wetlands include the direct elimination of wetland habitat by excavation or filling, the reduction of sediment inputs, the erosion of wetland substrates, and the degradation of wetland communities by reduced water quality or hydrologic changes. Construction projects may fill wetlands for facility siting or excavate wetlands for the construction of canals or pipelines. Other projects may reduce the sediment delivered to coastal wetlands from inflowing rivers. A number of activities may degrade wetlands or promote wetland losses indirectly by causing changes to wetland hydrology or introducing contaminants. Routine OCS operations could have direct impacts on wetlands as a result of direct losses of habitat from construction activities, pipeline landfalls and channel dredging, and indirect impacts as a result of altered hydrology caused by channel dredging.

Ongoing non-OCS activities that could affect coastal wetlands include those related to State oil and gas development, commercial shipping (and other marine vessel traffic), coastal development, dredging operations, discharge of municipal wastes and other effluents, domestic transportation of oil and gas, and foreign crude oil imports (Table 4.6.1-5). These activities can be reasonably expected to continue into the future. A number of these activities result in the localized destruction of wetlands. The construction of pipelines and navigation channels would result in direct losses of wetlands that are crossed, due to excavation. In addition, the creation of spoil banks along canals would bury wetland habitat. Large areas of coastal wetlands are also lost by drainage and filling, due to urban development and agricultural use (Gosselink et al. 1979; Bahr and Wascom 1984). Although activities that affect wetlands are regulated by State and Federal agencies, construction of industrial facilities, commercial sites, and residential developments would be expected to result in continued wetland losses. Pipeline installation and vessel traffic outside of established traffic routes could have short-term impacts on seagrass communities, which are primarily located in the eastern GOM. The direct impacts on coastal wetlands from pipeline, navigation canal, or facility construction under the Program would represent a small contribution to the past, ongoing, and expected future losses of wetlands from non-OCS activities.

Indirect impacts on wetlands from non-OCS activities are expected to continue to contribute to wetland degradation and conversion of wetlands to open water. A major factor that has contributed to the ongoing loss of coastal wetlands, particularly in the Mississippi River Delta region of Louisiana, is the reduction in sediments provided to coastal marshes. Reductions in sediment supply, in combination with natural subsidence, have contributed significantly to the conversion of coastal marsh to open water. The construction of dams and levees and channelization along the Mississippi River restrict the sediment supply and overbank flow of floodwaters, limiting the release of sediments and fresh water to coastal marshes (LCWCRTF 1998, 2003; USACE 2004).

Coastal wetlands are also lost due to the effects of large storm events, and the continuing erosion of barrier islands reduces their capacity to act as buffers for coastal wetlands (LCWCRTF 2001). Construction of canals for pipelines and navigation would result in future continuing progressive losses from canal widening and failure of mitigation structures, which would contribute to the conversion of wetlands to open water. Canal construction and maintenance dredging of navigation canals result in hydrologic changes, primarily high levels of tidal and storm flushing and draining potential of interior wetland areas. Such alterations of water movement can result in erosion of marsh substrates and increase inundation levels, and can result in substantial impacts on the hydrologic basin. Construction and maintenance of canals through coastal wetlands can increase the impacts of coastal storms, such as hurricanes, in the conversion of wetlands to open water. Saltwater intrusion results from canal construction and reduced freshwater inputs due to river channelization, and causes considerable deterioration of coastal wetlands. Wetland losses due to subsidence have also been attributed to extraction of oil in some portions of the Mississippi River Delta, or the withdrawal of groundwater along the Texas coast. Changes in wetland hydrology, as well as increases in turbidity and sedimentation, as a result of construction projects, can affect wetlands.

Degradation of wetlands can result from water quality impacts due to stormwater discharges and discharges of waste water from vessels, municipal treatment plants, and industrial facilities. Water quality may also be affected by waste storage and disposal sites. The direct and indirect impacts on coastal wetlands under the Program would represent a small contribution to the past, ongoing, and expected future impacts on wetlands from non-OCS activities.

Accidental spills of oil or petroleum products from OCS activities (Section 4.4.6.1) could impact coastal wetlands. The majority of these spills would be small (less than 50 bbl). Should spills occur in shallow water from marine vessel accidents and pipelines, they could contact and affect coastal wetlands. Most spills that occur in deep water would be unlikely to contact and impact wetlands. Catastrophic releases in deep water, however, can impact extensive areas of shoreline. Oil released into coastal waters as a result of the DWH event, April–July 2010, affected more than 1,046 km (650 mi) of the GOM coastal habitat, from the Mississippi River delta to the Florida panhandle, with the Louisiana, Mississippi, Alabama, and Florida coasts all affected (OSAT-2 2011; National Commission 2011). Non-OCS activities, such as State oil and gas development, the domestic transportation of oil, and foreign crude oil imports, may also result in accidental spills that could potentially impact coastal wetlands. Naturally occurring seeps may also be a source of crude oil that could potentially affect coastal wetlands. The amount of oil contacting wetlands, the magnitude of resulting impacts, and the length of time for recovery would depend on a number of factors such as the location and size of the spill, containment actions, waves and water currents, type of oil, types of remediation efforts, amount of oil deposition, duration of exposure, season, substrate type, and extent of oil penetration. Impacts from oil spills would be expected to range from short-term effects on vegetation growth to permanent loss of wetlands and conversion to open water. The impacts of potential oil spills associated with the Program are expected to constitute a small addition to the impacts of all other sources of oil in the GOM.

Global climate change could result in indirect effects on coastal wetlands. Factors associated with global climate change include changes in temperature and rainfall, alteration in stream flow and river discharge, wetland loss, salinity, sea level rise, changes in hurricane frequency and strength, sediment yield, mass movement frequencies and coastal erosion, and subsidence (Yanez-Arancibia and Day 2004). Effects of sea level rise include damage from inundation, floods and storms; erosion; saltwater intrusion; rising water tables/impeded drainage; and wetland loss and change (Nicholls et al. 2007). Effects of increased storm intensity include increases in extreme water levels and wave heights; increases in episodic erosion, storm damage, risk of flooding, and defense failure (Nicholls et al. 2007). Patterns of erosion and accretion can also be altered along coastlines (Nicholls et al. 2007). The small tidal range of the GOM coast increases the vulnerability of coastal habitats to the effects of climate change. A study of coastal vulnerability along the entire U.S. GOM coast found that 42% of the shoreline mapped was classified as being at very high risk of coastal change due to factors associated with future sea level rise (Thieler and Hammar-Klose 2000). A revised coastal vulnerability index study of the coast from Galveston, Texas, to Panama City, Florida, indicated that 61% of that mapped coastline was classified as being at very high vulnerability, with coastal Louisiana being the most vulnerable area of this coastline (Pendleton et al. 2010). Potential thermal expansion of ocean water and melting of glaciers and ice caps could result in a global rise in mean sea level (Section 4.6.1.6). Sea level rise would result in greater inundation of coastal wetlands and likely result in an acceleration of coastal wetland losses, particularly in Louisiana, as wetlands are converted to open water. In addition, large changes in river flows into the GOM could affect salinity and water circulation in estuaries, which, in turn, could impact estuarine wetland communities.

Hurricanes and other severe storm events impact coastal wetlands through increased wave action and intensity, resulting in increased erosion of wetland substrates and conversion of coastal wetlands to open water. Hurricanes and tropical storms are inherent components of the GOM ecosystem that have long influenced coastal habitats and are expected to be continuing sources of impacts. However, impacts on wetlands as a result of human activities, such as those that create marsh openings that enhance tidal and storm-driven water movements, may be amplified by severe storm events such as hurricanes. In 2005, Hurricanes Katrina and Rita caused extensive impacts on wetlands in the Central and Western GOM. For example, up to 259 km^2 (100 mi^2) of coastal wetlands in Louisiana may have been converted to open water as a result of the storms, and up to 60,700 ha (150,000 ac) of coastal wetlands and bottomland forests were damaged in national wildlife refuges along the GOM coast (USFWS 2006). It is possible that extreme storms such as these could result in relatively permanent change to these habitats, particularly in areas that are already experiencing erosion and conversion of wetlands to open water as a result of sediment deprivation, sea-level rise, channelization, and coastal development.

Seagrass Beds. As identified in Section 4.4.6.1, the principal OCS activities under the Program that could potentially affect seagrass beds include placement of structures (e.g., pipelines) and vessel traffic within the vicinity of the beds. In addition, coastal development associated with OCS oil and gas activities could contribute to cumulative impacts on submerged seagrass beds. Most of the seagrass beds in the GOM are in the Eastern Planning Area, where no OCS activities are proposed during the Program.

Ongoing and future non-OCS activities that may contribute to cumulative effects on seagrass habitats include anchoring, fishing/trawling, offshore shipping (and other marine vessel traffic), diving, and continued onshore development (Table 4.6.1-5). The extensive seagrass beds located in the eastern GOM may be susceptible to impacts from non-OCS activities such as dredging and onshore development that contribute to increased sedimentation, turbidity, nutrient input, and various types of point and non-point source contamination.

As noted in Section 4.4.6.1, oil spills reaching coastal areas could affect submerged seagrass beds. The majority of these spills would be small (less than 50 bbl). Should spills occur in shallow water from vessel accidents and pipelines, they could contact and affect seagrass beds. Most spills that occur in deep water would be very unlikely to contact and impact seagrasses; however, catastrophic releases can impact extensive areas of shoreline. As identified in Table 4.6.1-4, it is assumed that up to 40 large oil spills (1,000 bbl or greater), up to 330 small-sized spills 50 to 999 bbl, and up to 1,950 small oil spills of less than 50 bbl could occur as a result of ongoing and future OCS activities. A catastrophic spill event would have an assumed spill size of 4 Bbbl. As discussed previously, non-OCS activities and oil seeps could also contribute substantially to releases of oil in the GOM. Oil spills in shallow water in the GOM from OCS and non-OCS activities could have significant effects on submerged seagrass beds. The magnitude and severity of potential effects on seagrass beds from oil spills would be a function of the location, timing, duration, and size of the spill; the proximity of the spill to seagrass beds; and the timing and nature of spill containment and cleanup activities. Releases that occur in the shallow portions of the eastern GOM have the potential to be of greatest significance, due to the more extensive growth of seagrasses along that coastline. It is unlikely that OCS spills would contact the extensive seagrass areas offshore Florida and along its coast because of the great distance between these resources and locations in the Central and Western Planning Areas where leasing will occur.

Conclusion. Ongoing OCS and non-OCS program activities in combination with naturally occurring events have resulted in considerable losses of coastal and estuarine habitats in the GOM; cumulative impacts on these resources, therefore, are considered to be moderate to major. Routine operations under the Program would result in minor localized impacts, primarily due to facility construction, pipeline landfalls, channel dredging, and vessel traffic; therefore, the incremental contribution of routine Program activities to cumulative impacts is expected to be small to medium (see Section 4.4.6.1.1).

The cumulative impacts of past, present, and future oil spills and natural seeps on submerged seagrass beds would be moderate to major. The incremental impacts of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program on these resources would be negligible to large, depending on the location, timing, duration, and size of the spill; the proximity of the spill to seagrass beds; and the timing and nature of spill containment and cleanup activities (see Section 4.4.6.1.1). The majority of these spills would be small (less than 50 bbl) and most of them would not likely contact and affect coastal and estuarine habitats. Large oil spills (1,000 bbl or greater) or an unexpected, low-probability CDE that occur in or reach shallower nearshore areas have the greatest potential to affect extensive areas of shoreline and coastal and estuarine habitats. Although these are rare events, the impacts of such releases on coastal and estuarine habitats could range from moderate to major if they were to occur.

4.6.3.1.2 Marine Benthic and Pelagic Habitats. Sections 4.4.6.2.1 and 4.4.6.3.1 discuss direct and indirect impacts, respectively, on marine benthic and pelagic habitats in the GOM resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on these resources result from the incremental impacts of the Program (described in Sections 4.4.6.2.1 and 4.4.6.3.1) when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS activities. Table 4.6.1-2 presents the exploration and development scenario for the GOM cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future OCS programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in the GOM are summarized in Table 4.6.1-5 and discussed below, as applicable.

Cumulative impacts on marine benthic and pelagic habitats could result from a number of activities associated with ongoing and future OCS and non-OCS activities in the GOM, including those of the Program. Activities with the potential to affect these resources include vessel traffic, seismic surveys, and construction (all noise-producing activities), well drilling, pipeline placement (trenching, landfalls, and construction), platform placement (anchoring, mooring, and removal, except in deep waters), and routine discharges (drilling, production, platform, and vessel). Accidental oil spills are also counted among OCS and non-OCS activities.

Up to 12,000 development and production wells and 2,000 oil platforms are anticipated to be built in the GOM under the cumulative scenario (Table 4.6.1-2). In addition, the construction of platforms and pipelines would disturb as much as 81,000 ha (200,200 ac) of bottom surface over the next 40 to 50 years (Table 4.6.1-2). Bottom disturbance resulting from the Program may degrade water quality by increasing water turbidity in the vicinity of the operations and adding contaminants to the water column. It also changes sediment composition as suspended sediments (and contaminants, if present) are entrained in currents and deposited in new locations. The increased amount of drilling anticipated under the Program will result in OCS discharges of drill muds, cuttings, and produced waters. Impacts of OCS routine operations (exploration, production and decommissioning activities) on marine benthic and pelagic habitat are discussed in detail in Sections 4.4.6.2.1 and 4.4.6.3.1. Overall, routine operations represent a negligible to moderate long-term disturbance, with the severity of the impacts generally decreasing dramatically with distance from the well site.

Ongoing and future non-OCS activities with the potential to affect marine benthic and pelagic habitats in the GOM include sediment dredging and disposal, sand mining, anchoring, fishing/trawling, and tankering of imported oil. Anchoring by non-OCS marine vessels could cause significant chronic disturbance the benthic habitat and biota and temporarily reduce water quality by generating turbidity in the water column. Anchoring could involve boats used for recreational and commercial fishing or scuba diving, and commercial ship traffic. The amount of damage that could result from anchoring activity would depend upon vessel size, the size of the anchor and chain, sea conditions at the time of anchoring, and the location or position of the anchor on the feature. Areas damaged by anchors may take more than 10 years to recover, depending upon the severity of the damage. Due to a lack of regulation of non-OCS activities on these features, there is a likelihood of damages increasing due to heavier usage of the resources in the future. Sand mining and dredging operations in conjunction with ship channel maintenance and construction, pipeline placement and burial, and support facility access occur throughout the GOM as part of non-OCS activities. Sediments dredged and sidecast or transported to approved dredged material disposal sites would alter bottom habitat and communities and remove, injure, or kill local biotic communities in addition to generating turbidity over the length of the water column. Similarly, bottom trawling degrades benthic habitats and temporarily increases the turbidity of the water (Jones 1992). Benthic habitat disturbances from OCS activities (e.g., pipeline trenching and placement and platform placement) would add to the existing impacts to benthic habitat from these non-OCS sediment-disturbing activities.

Other ongoing and future non-OCS activities with the potential to affect marine benthic and pelagic habitats include offshore marine transportation, and pollutant inputs from point and non-point sources. Vessel traffic is a source of chronic noise that could temporarily and episodically reduce local habitat quality by disturbing pelagic and shallow water benthic organisms. Multiple contaminant sources exist from nearshore point sources and contaminants can also be delivered to the continental shelf during storms and high river discharge. A primary example is the cultural eutrophication of the GOM, which has resulted in a large seasonal hypoxic zone off the coasts of Louisiana and Texas (see Figure 4.6.1-5) and restricts the use of benthic and bottom water habitat by marine biota over a wide area. In addition to non-point source pollution, LNG terminal operations (biocide-laden, cooled water), and activities related to the oil and gas industry, which operates hundreds of platforms in State and Federal waters, discharges large volumes of drilling wastes, produced water, and other industrial waste streams to GOM waters. Pollutant inputs into the GOM and their impact on water quality are discussed in Section 4.6.2.1. The impacts of these activities on marine pelagic habitat can be temporary or long term and could result in reduced habitat quality for marine biota.

In the benthic and pelagic habitats of the GOM, climate change may cause the temporal variability of key chemical and physical parameters — particularly hydrology, dissolved oxygen, salinity, and temperature — to change or increase, which could significantly alter the existing structure of the benthic and phytoplankton communities (Rabalais et al. 2010). For example, freshwater discharge into the GOM has been increasing and is expected to continue to increase as a result of the increased rainfall in the Mississippi River Basin (Dai et al. 2009). Such changes could result in severe long-term or short-term fluctuations in temperature and salinity that could reduce or eliminate sensitive species. Such changes are most likely to occur in the Mississippi Estuarine Ecoregion, where freshwater inputs are highest. In addition, greater rainfall may increase inputs of nutrients into the GOM, potentially resulting in more intense phytoplankton blooms that could promote benthic hypoxia (Rabalais et al. 2010). Hypoxic or anoxic conditions can reduce or eliminate the suitability of benthic habitat for marine organisms. The increased storm severity predicted to result from climate change may also increase disturbance to benthic habitats that are already stressed by trawling, anchoring, and dredging operations, as well as OCS-related pipeline trenching. See Sections 3.7.2.1 and 3.7.3.1 for a complete discussion of how climate change may affect marine benthic and pelagic habitat.

Marine benthic and pelagic habitat and biota could be affected by oil spills from both OCS and non-OCS activities, including the domestic transportation of oil, the import of foreign crude oil, and State development of oil. Storms, operator error, and mechanical failures may result in accidental oil releases from a variety of non-OCS related activities. Assumptions for oil spills for the GOM cumulative case are provided in Table 4.6.1-4; Table 4.4.2-2 presents assumptions for catastrophic spills. Large and potentially catastrophic spills could result from pipeline ruptures, tanker spills associated with an FPSO system, or loss of well control. In addition, crude oil enters the environment of the GOM from naturally occurring seeps. At least 63 seeps have been identified in the GOM (mostly off the coast of Louisiana) (MacDonald et al. 1996), and more than 350 naturally occurring and constant oil seeps that produce perennial slicks of oil at consistent locations may be present in the GOM (MacDonald et al. 2002, as cited in Kvenvolden and Cooper 2003). Seeps in the northern GOM have been estimated to discharge $0.4–1.1 \times 10^8$ L (252,000 to 692,000 bbl) per year of crude oil annually to overlying GOM waters (MacDonald et al. 2002).

For both OCS and non-OCS program-related oil spills, it is assumed that the magnitude and severity of the potential effects on benthic and pelagic habitat would be a function of the location, timing, duration, and size of the spill and the timing and nature of spill containment and cleanup activities. Detailed discussion of the impacts of OCS accidental hydrocarbon releases on marine benthic and pelagic habitat can be found in Sections 4.4.6.2.1 and 4.4.6.3.1.

Coral Reefs and Hard-Bottom Habitat. Sensitive coral reef and hard-bottom benthic habitats in the GOM may be more susceptible to OCS program-related impacts and take longer to recover if impacts were to occur. Consequently, these habitats receive special protection. Four coral reef and hard-bottom habitats are designated for the various protections: (1) banks offshore of Texas and Louisiana (including the FGBNMS), (2) the Pinnacle Trend off the Louisiana-Alabama coast, (3) seagrass and low-relief live-bottom areas primarily located in the Central and Eastern Planning Areas, and (4) potentially sensitive biological features of moderate to high relief that are not protected by (1) and (2). As identified in Section 4.4.6.2.1, NTL No. 2009-G39 has several protections in place to minimize and mitigate the adverse effects of oil and gas exploration and development on coral reefs and hard-bottom habitat.

Cumulative impacts on coral reef and hard-bottom habitat could result from a number of activities associated with ongoing and future activities in the GOM, including those of the Program. Activities with the potential to affect these resources include vessel traffic, seismic surveys, and construction (all noise-producing activities), as well as well drilling, pipeline placement (trenching, landfalls, and construction), chemical releases (drilling discharges, operation discharges, and sanitary wastes), and platforms placement (anchoring, mooring, and removal, except in deep waters). Impacts of OCS exploration, production and decommissioning activities on marine benthic and pelagic habitat are discussed in detail in Section 4.4.6.2.1. Overall, impacts on coral reef and live-bottom habitat from routine activities would be minimized by the protection stipulated by NTL 2009-G39. However, low-relief or small, isolated, unmapped live-bottom could be affected by direct mechanical damage and turbidity and sedimentation.

Ongoing and future non-OCS activities with the potential to affect these habitats include anchoring by non-OCS activity vessels, fishing/trawling, discharges by non-OCS offshore marine transportation, and tankering of imported oil. Anchoring could involve boats used for recreational and commercial fishing or scuba diving, and commercial ship traffic. The amount of damage that could result from anchoring activity would depend upon vessel size, the size of the anchor and chain, sea conditions at the time of anchoring, and the location or position of the anchor on the feature. Recovery of areas damaged by anchors may be long term, depending upon the severity of the damage. Due to a lack of regulation of non-OCS activities on these features, there is a likelihood of damages increasing due to heavier usage of the resources in the future.

Trawling activities are another source of damage to coral and hard-bottom habitat. Because anchoring and collection activities by scuba divers on the living reef areas of the Flower Garden Banks are prohibited, biota associated with the Flower Garden Banks are unlikely to be significantly affected by these activities. Similarly, use of spiny lobster and stone crab traps may also damage bottom substrate such as seagrasses and corals. Strings of traps deployed without buoys are sometimes retrieved by dragging 18-kg (40-lb) grapnels and chains across the bottom until the trap string is hooked, potentially damaging bottom habitats in the process.

Impacts could also occur due to discharges from other non-OCS activities, including tankers or other marine traffic passing in the vicinity of coral reef and hard-bottom habitat. Because water depths are typically greater than 20 m (66 ft) at the tops of most of the banks, dilution of discharges would greatly reduce concentrations of potentially toxic components before they could come in contact with these features; consequently, it is assumed that discharges from such activities would not be concentrated enough to reduce habitat quality.

Climate change has the potential to profoundly affect coral communities on coral and hard-bottom features in several ways including (Section 3.7.1.1.4):

- Increased frequency of bleaching as a stress response to warming water temperatures (Hoegh-Guldberg et al. 2007);

- Excessive algal growth on reefs and an increase in bacterial, fungal, and viral agents (Boesch et al. 2000; Twilley et al. 2001);

- Greater frequency of mechanical damage to corals from greater severity of tropical storms and hurricanes (Janetos et al. 2008);

- Decreases in the oceanic pH and carbonate concentration are expected to reduce the reef formation rate, weaken the existing reef structure, and alter the composition of coral communities (Janetos et al. 2008); and

- Climate change may allow the range expansion of non-native species.

Potential interactions between climate change and OCS activities could affect hard-bottom habitat. For example, ocean acidification and increases in water temperature may slow the recovery of corals exposed to drilling muds or oil from an accidental spill. Another potential interaction could occur between oil and gas platforms and climate change, in which new hard-bottom–associated species are able to expand northward due to warming and the availability of hard substrate in the form of active or decommissioned oil platforms. By acting as stepping stones across the GOM, oil platforms have been implicated in the introduction of a non-native coral species (*Tubastraea coccinea*) and fishes such as sergeant majors (*Abudefduf saxatilis*) and yellowtail snapper (*Ocyurus chrysurus*) into the FGB (Hickerson et al. 2008).

Oil spills from both OCS and non-OCS activities could affect coral reef and hard-bottom habitat and biota. Detailed discussion of the impacts of OCS accidental hydrocarbon releases on hard-bottom and coral reef habitat can be found in Section 4.4.6.2.1. It is assumed that accidental oil releases from most non-OCS activities would be at the surface or located sufficiently far from coral reef and hard-bottom habitat and biota that they would be unlikely to greatly affect these habitats. The magnitude and severity of potential effects on coral reef and hard-bottom habitat and biota from such exposure would be a function of the location, timing, duration, and size of the spill; the proximity of the spill to the features; and the timing and nature of spill containment and cleanup activities. Depending upon location, spills from non-OCS sources and releases from natural seeps could contribute to the overall exposure of communities associated with topographic features in the GOM OCS planning areas to oil, with corresponding lethal or sublethal effects.

High Density Deepwater Communities (HDDC). High density deepwater communities (HDDCs) include coldwater corals and chemosynthetic communities. Cumulative impact factors for HDDCs include both OCS and non-OCS cumulative activities. Potential impacts on HDDCs resulting from ongoing and future routine OCS program activities, including those of the Program, could result from noise, well drilling, pipeline placement (trenching, landfalls, and construction), chemical releases (drilling discharges, operation discharges, and sanitary wastes), and platform placement (anchoring, mooring, and removal, except in deep waters). Mitigation measures instituted to protect these HDDCs include Notice to Lessee (NTL) 2009-G40, which requires the avoidance of HDDCs or areas that have a high potential for supporting these community types, as interpreted from geophysical records. Impacts of OCS exploration, production, and decommissioning activities on HDDCs are discussed in detail in Section 4.4.6.2.1. Overall, impacts on HDDCs from exploration and site development activities are expected to be minor because of the provisions in NTL 2009-G40 that protect HDDCs from oil and gas development activities. However, small and unmapped HDDCs may be completely or partially destroyed by bottom-disturbing activities. In such cases, recovery would likely be long term, although permanent loss of the affected feature is also possible. For these HDDCs, impacts could be major.

Ongoing and future non-OCS activities that have the potential to adversely affect HDDCs include fishing/trawling, anchoring, and offshore marine transportation. Due to the water depths of these areas and the widely scattered nature of these habitats, such activities are unlikely to greatly affect HDDCs in the GOM. However, deepwater trawling could destroy HDDCs and recover could be long term or may not occur at all. Generally, commercially important deepwater fish species use *Lophelia* reefs as juveniles (SAFMC 1998).[53]

As climate change has the potential to affect warm water corals, it could affect coldwater *Lophelia* reefs (Section 3.7.2.1.7). The saturation depth of aragonite (the primary carbonate formed used by hard corals) appears to be a primary determinant of deepwater coral distribution, with reefs forming in areas of high aragonite solubility (Orr et al. 2005). The depth at which the water is saturated with aragonite is projected to become shallower over the coming century, and most coldwater corals may be in undersaturated waters by 2100 (Orr et al. 2005). Consequently, the spatial extent, density, and growth of deepwater corals may decrease, diminishing their associated ecosystem functions (Orr et al. 2005). There are potential interactions between climate change and OCS activities that could affect HDDC. For example, ocean acidification may slow the recovery of deepwater corals exposed to drilling muds or oil from an accidental spill.

Oil spills from both OCS and non-OCS activities could affect HDDCs. Detailed discussion of the impacts of OCS accidental hydrocarbon releases can be found in Section 4.4.6.2.1. The magnitude and severity of potential effects on biota associated with topographic features from such exposure would be a function of the location, timing, duration, and size of the spill, the proximity of the spill to the features, and the timing and nature of spill containment and cleanup activities. It is assumed that most accidental oil releases would be at the surface or located sufficiently far from HDDCs that they would be unlikely to greatly affect communities associated with the topographic features.

Conclusion. Impact-producing factors for marine benthic and pelagic habitats include those from both OCS and non-OCS activities. For OCS activities, planning and permitting procedures and stipulations that promote identification and avoidance of sensitive habitats would minimize the potential for direct impacts on sensitive seafloor areas during routine OCS activities. In the GOM, stipulations that are currently in place restrict OCS activities in the immediate vicinity of seafloor areas containing important topographic features, live bottom habitat, and HDDC, and there is relatively little likelihood that OCS activities would affect overall viability of ecological resources in such areas. Non-OCS activities with a potential to impact marine benthic and pelagic habitats in the GOM include oil and gas production in State waters, sediment dredging and disposal, sand mining, anchoring, fishing/trawling, and tankering of imported oil. Disturbances from these activities such as noise, marine vessel discharges, and bottom disturbance would occur in addition to similar impacts from OCS Program activities.

---

[53] There is evidence that oil and gas extraction reduces the natural release of hydrocarbons that support deep-sea chemosynthetic communities (Quigley et al. 1999). However, *Lophelia* corals do not depend on hydrocarbon seepage to meet their metabolic requirements (Becker et al. 2009), and presumably would not be affected by a reduction in natural hydrocarbon release to marine waters.

Overall, the cumulative impacts on marine habitat would be moderate to major, considering OCS routine operations and the significant impacts to marine habitat from past, present, and future human activities. The incremental contribution of routine Program activities to cumulative impacts on marine habitat would range from negligible to medium (see Section 4.4.6.2.1).

Accidental oil spills could result from both OCS and non-OCS activities. Overall, the cumulative impacts on marine habitats from oil spills would range from minor to moderate. The incremental impacts of expected oil spills, most of which would be small (less than 1,000 bbl), would range from negligible to small, depending on the location, timing, duration, and size of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities (Section 4.4.6.2.1). Spills in deeper water, whether from OCS or non-OCS sources, are unlikely to have overall community-level effects on seafloor habitats because of the relatively small proportion of seafloor area that would come in contact with released oil at concentrations great enough to elicit toxic effects. Impacts associated with an unexpected, low-probability CDE affecting shallow and intertidal habitats could range from minor to moderate, depending on the habitats affected. Although pelagic habitat is likely to recover following a CDE, the recovery time for intertidal and shallow subtidal benthic habitat directly affected by such oil spills could be long term.

4.6.3.1.3 Essential Fish Habitat. Section 4.4.6.4.1 discusses direct and indirect impacts on EFH in the GOM resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on these resources result from the incremental impacts of the Program (described in Section 4.4.6.4.1) when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS activities. Table 4.6.1-2 presents the exploration and development scenario for the GOM cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future OCS programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in the GOM are summarized in Table 4.6.1-5 and discussed below, as applicable.

Cumulative impacts on EFH could result from ongoing and future OCS and non-OCS activities that have the potential to directly kill managed fish species, disturb ocean bottom habitats, increase sediment suspension, degrade water quality, or affect the food supply for fishery resources. Activities include seismic surveys (noise), well drilling, pipeline placement (trenching, landfalls, and construction), platform placement (anchoring, mooring, and removal, except in deep waters) and routine discharges (drilling, production, platform, and vessel). Accidental oil spills are also counted among OCS and non-OCS activities.

Routine OCS activities could disturb bottom areas due to the installation of platforms and pipelines and the anchoring of vessels and structures. Up to 12,000 development and production wells and 2,000 oil platforms are anticipated to be built in the GOM under the cumulative scenario (Table 4.6.1-2). In addition, the construction of platforms and pipelines over the period of the Program would disturb as much as 81,000 ha (200,200 ac) of bottom surface over the next 40 to 50 years (Table 4.6.1-2). Under the cumulative scenario, it is anticipated that less than 40 new pipeline landfalls could occur in the GOM (Table 4.6.1-2) with up to 12 of these resulting from the Program. As discussed in Section 4.4.6.4, deposition of drilling muds and cuttings could potentially affect EFH by altering grain-size distributions and chemical characteristics of sediments such that benthic prey of some managed fish species would be affected in the immediate area surrounding drill sites. Produced water will also be released into the GOM during the production phase.

Platform removals using explosives will likely kill some fish and shellfish, including managed species for which EFH has been established, and would remove platform-associated fouling communities that serve as prey for managed species. Up to 280 platforms may be removed under the Program compared with up to 1,200 platforms removed using explosives as a result of cumulative OCS activities during the life of the Program. If large numbers of fish are killed as the result of removal of platforms using explosives, there could be effects on managed species and their prey in the immediate vicinity of the removed platforms. Once a platform is removed, the fouling community that serves as a food source for some managed and prey fish species in the vicinity would no longer be available, and the associated fishes would be forced to relocate to other foraging areas. However, given the relatively small area that would be affected by such removals, GOM-wide effects on managed species are not anticipated.

See Section 4.4.6.4.1 for a detailed discussion of the impacts of routine operations on EFH and managed species in the GOM. Overall, it is expected that the incremental impacts of exploration and site development activities on marine EFH would be medium, and impacts are not expected to permanently reduce the EFH available to managed species or result in population-level impacts to managed species. The most sensitive benthic habitats, such as those associated with hard bottoms and topographic features, are not expected to be affected by routine operations, and effects would be minimized or eliminated by existing lease stipulations.[54]

There are also State oil and gas activities that can affect EFH. Louisiana and Texas have experienced substantial oil and gas development within their coastal areas including exploratory drilling, production platform installation, and pipeline installation. Factors that could affect EFH from these activities would be similar to those described above for OCS activities. However, the effects from non-OCS oil and gas activities could possibly be more severe than the effects from routine OCS activities because the activities are closer to shore and in shallower environments. As a consequence, more benthic EFH may be damaged, and resulting changes in sedimentation and turbidity could affect a greater proportion of the water column.

Other non-OCS activities that influence EFH may include commercial fishing, commercial shipping (and other marine vessel traffic), land development, water quality degradation, dredge and fill and dredge disposal operation, and construction of channel stabilization structures such as jetties could affect EFH (GMFMC 1998). As discussed below, these non-OCS activities when combined with OCS activities could result in cumulative impacts

[54] There is evidence that oil and gas extraction reduces the natural release of hydrocarbons that support deep-sea chemosynthetic communities (Quigley et al. 1999). However, *Lophelia* corals do not depend on hydrocarbon seepage to meet their metabolic requirements (Becker et al. 2009), and presumably would not be affected by a reduction in natural hydrocarbon release to marine waters.

on EFH over time, especially if these impacts occur frequently or are of sufficient magnitude that habitat recovery times are prolonged.

Barges carrying cargo arrive and depart through ports and travel through the GOM Intracoastal Water Way, which serves as a major route for needed goods and supplies. Discharges of treated wastes or hazardous chemicals could negatively affect water quality (Section 4.6.2.1.1), a component of EFH, as well as aquatic vegetation. Pollutants generated from boat maintenance activities on land and water could also negatively impact water quality. Oil and grease are commonly found in bilge water, especially in vessels with inboard engines, and these products may be discharged during vessel pump out (USEPA 1993).

Sand mining and routine dredging operations for channel construction and maintenance, pipeline emplacement, and creation of harbor and docking areas can affect EFH in the GOM by suspending sediments and affecting water quality. As suspended sediments settle to the bottom, the benthic prey of some managed fish species could be smothered. In most cases, benthic organisms would recolonize such areas unless maintenance dredging operations are repeated frequently. Dumping sites for dredge spoils in the GOM, most of which are located within State waters, could also alter water quality and affect benthic organisms that serve as prey for some managed fish species. Pipeline and platform placement that would occur as part of OCS activities would also add to the existing disturbance of benthic habitat from sand mining and dredging activities.

Commercial and recreational fisheries in the GOM also impact EFH. For example, most of the wild shrimp caught are harvested using bottom trawls. The nets are held open with bottom sled devices made from wood or steel. In addition to capturing and killing some nontarget fish and invertebrate species, the sleds, or “doors,” drag along the bottom, potentially digging up sediments and hard substrate. Such activities could disrupt the benthic community and increase the turbidity of the water (Jones 1992). Similarly, use of spiny lobster and stone crab traps may also damage bottom substrate such as seagrasses and corals. Pipeline and platform emplacement add to the disturbance of benthic habitat by temporarily increasing turbidity in disturbed regions.

Other potential interactions between fishing and OCS activities result from the presence of platforms, around which reef-associated fish species tend to congregate. Recreational fishing targeting platform areas increase fishing pressure on overfished species such as snapper and grouper. Explosive removal of platforms also likely results in higher proportional mortality of reef-associated fish.

Other events, including hurricanes, turbidity plumes, and hypoxia, could also affect various managed fish or their habitat, although the GOM fish community as a whole should be adapted to such events. For example, a hurricane or a series of hurricanes could temporarily degrade the quality of large areas of wetlands that serve as nursery and feeding areas for a variety of managed fish and invertebrate species.

Climate change could affect EFH in several ways. Climate change may cause the temporal variability of key chemical and physical parameters — particularly hydrology, dissolved oxygen, salinity, and temperature — to change or increase, which could significantly alter the existing structure of the benthic and phytoplankton communities (Rabalais et al. 2010). For example, freshwater discharge into the GOM has been increasing and is expected to continue to increase as a result of the increased rainfall in the Mississippi River Basin (Dai et al. 2009). Such changes could result in severe long-term or short-term fluctuations in temperature and salinity that could reduce or eliminate sensitive species. Such changes are most likely to occur in the Mississippi Estuarine Ecoregion, where freshwater inputs are highest. In addition, greater rainfall may increase inputs of nutrients into the GOM, potentially resulting in more intense phytoplankton blooms that could promote benthic hypoxia (Rabalais et al. 2010). Hypoxic or anoxic conditions can reduce or eliminate the suitability of benthic EFH for marine organisms. The increased storm severity predicted to result from climate change may also increase disturbance to benthic habitats that are already stressed by trawling, anchoring, and dredging operations and OCS-related pipeline trenching. See Sections 3.7.2.1 and 3.7.3.1 for a complete discussion of how climate change may affect marine benthic and pelagic habitat.

Climate change has the potential to profoundly affect coral and hard bottom EFH in several ways, including the following (Section 3.7.1.1.4):

- Increased frequency of bleaching as a stress response to warming water temperatures (Hoegh-Guldberg et al. 2007);
- Excessive algal growth on reefs and an increase in bacterial, fungal, and viral agents (Boesch et al. 2000; Twilley et al. 2001);
- Greater frequency of mechanical damage to corals from greater severity of tropical storms and hurricanes (Janetos et al. 2008);
- Decreases in the oceanic pH and carbonate concentration are expected to reduce the reef formation rate, weaken the existing reef structure, and alter the composition of coral communities (Janetos et al. 2008); and
- Range expansion of non-native species into the northern GOM.

Another primary impact expected to result from climate change is the loss of wetland habitat, which is an important EFH for many larval and juvenile stages of managed species. Wetland loss could be caused by several factors including erosion, sea level rise, discharging nutrient-laden waters to the environment, reduced sediment load of the Mississippi River, and human-induced subsidence from groundwater withdrawals, among others. Cumulative effects on wetlands are discussed in Section 4.6.3.1.1.

As climate change has the potential to affect warm water corals, it could affect coldwater *Lophelia* reefs (Section 3.7.2.1.7). The saturation depth of aragonite (the primary carbonate formed used by hard corals) appears to be a primary determinant of deepwater coral distribution, with reefs forming in areas of high aragonite solubility (Orr et al. 2005). The depth at which the water is saturated with aragonite is projected to become shallower over the coming century, and most coldwater corals may be in undersaturated waters by 2100 (Orr et al. 2005). Consequently, the spatial extent, density, and growth of deepwater corals may decrease, diminishing their associated ecosystem functions (Orr et al. 2005).

There are potential interactions between climate change and OCS activities that could affect EFH and managed species. For example, ocean acidification and increases in water temperature may slow the recovery of corals exposed to drilling muds or oil from an accidental spill. Another potential interaction could occur between oil and gas platforms and climate change in which new hard-bottom–associated species are able to expand northward due to warming and the availability of hard substrate in the form of active or decommissioned oil platforms. By acting as stepping stones across the GOM, oil platforms have been implicated in the introduction of a non-native coral species (*Tubastraea coccinea*) and fishes such as sergeant majors (*Abudefduf saxatilis*) and yellowtail snapper (*Ocyurus chrysurus*) into the FGB (Hickerson et al. 2008).

Oil spills from OCS and non-OCS activities may cumulatively affect several resources that contribute to EFH, including sediments, water quality, fish resources, coastal habitats, and seafloor habitats and benthic communities (see Sections 4.6.2 and 4.6.3). Large, potentially catastrophic spills could result from pipeline ruptures, tanker spills associated with an FPSO system, or loss of well control. Other potential sources of oil spills that could affect EFH include non-OCS oil and gas development activities and non-OCS tankering activities. Spills from import tankers could occur offshore in shipping lanes or in coastal waters as tankers prepare to make landfall.

Oil from shallow-water spills could impact life stages of managed fish species that use surface waters as part of their lifecycle, especially those that release pelagic eggs and have pelagic larvae. Unlike adult fish that can move away from oiled waters, pelagic eggs and larvae are largely transported by wind and water currents. Those that come into contact with surface oil could be injured or killed through smothering or an accumulation of oil on the gills. Thus, oiled surface waters would temporarily reduce the amount of EFH available for these life stages. Detailed discussion of the impacts of oil spills on fish can be found in Section 4.4.7.3.1.

In marine waters, several individual reefs and banks located offshore of the Louisiana-Texas border have been designated HAPCs by the GMFMC (NMFS 2010a). As identified in Section 4.4.6.2.1, NTL No. 2009-G39 has several protections in place to minimize and mitigate the adverse effects of oil and gas exploration and development on these banks. However, large or catastrophic spills could adversely affect hard-bottom HAPC by causing lethal or sublethal impacts to corals (Section 4.4.6.2.1). The HAPC for bluefin tuna extends from the 100 m (328 ft) isobath seaward to the EEZ. The HAPC could also be affected by oil spills, and population-level impacts to bluefin tuna could result from catastrophic spills. Habitat areas of particular concern in nearshore areas include intertidal and estuarine habitats with emergent and submerged vegetation, sand and mud flats, and shell and oyster reefs that may provide food and rearing for managed juvenile fish and shellfish. Shallow-water spills may reach these coastal EFH areas and have negative impacts. Shallow-water wave action could increase entrainment of oil and tar balls in the water column. This could temporarily diminish the quality and quantity of benthic EFH. Settled tar balls may be ingested by bottom-feeding fishes and may harm or prove fatal to them. During a spill, aquatic vegetation, which provides habitat for juveniles and for prey of some managed species, could become coated with oil. In such cases, organisms that are sessile or that have limited ability to avoid spills could be killed. These areas represent important nursery areas for fishes and invertebrates that contribute to estuarine, coastal, and shelf food webs. Loss of such habitat by oil spills would be compounded by the existing high natural loss of wetlands.

The actual locations of the spills will determine the degree to which EFH would be affected. The HAPC in the Eastern Planning Area that could be affected by oil spills from the Central or Western Planning Areas include the Florida Middle Grounds, the Madison-Swanson Marine Reserve. Pulley Ridge, and Tortugas North and South Ecological Reserve are also located in the southern tip of Florida, and are unlikely to be contacted by oil. Spills have the greatest potential to harm EFH resources if they occur in shallow waters, where benthic habitats or wetlands can be affected, or if they occur when large numbers of pelagic eggs and larvae of managed species are present. If the location of a spill coincided with the location of eggs and larvae, large numbers of these organisms would be injured or killed. Oil reaching the surface from deepwater pipeline spills and deepwater tanker spills could affect EFH for the eggs and larvae of federally managed pelagic fish species, neuston prey species, and *Sargassum* and its associated fauna. Pelagic eggs and larvae contacting the spilled oil would be smothered, and *Sargassum* within affected areas would be fouled and potentially killed.

Conclusion. Impact-producing factors for EFH include those from both OCS and non-OCS activities. Non-OCS activities with the potential to impact EFH in the GOM include oil and gas production in State waters, sediment dredging and disposal, and vessel traffic. Impacts from OCS activities would be limited by specific lease stipulations. Overall, the cumulative impacts on EFH would be moderate to major. The incremental contribution of routine Program activities to these impacts would range from negligible to medium (see Section 4.4.6.3.1).

Accidental oil spills could result from both OCS and non-OCS activities. Overall, the cumulative impacts on EFH from oil spills would range from moderate to major. The incremental impacts of expected oil spills would range from negligible to medium, depending on the location, timing, duration, and size of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities (Section 4.4.6.3.1). While most accidents related to OCS activities assumed under the cumulative scenario would be small (less than 50 bbl) and would have relatively small incremental impacts on EFH, spills that reach coastal wetlands could have more persistent impacts and could require remediation. Spills in deeper water, whether from OCS or non-OCS sources, are unlikely to have overall population-level effects on fish resources because of the relatively small proportion of similar available fish habitats that would come in contact with released oil at concentrations great enough to elicit toxic effects. Oil spills that have the greatest potential to impact EFH and managed species are those that occur in shallower subtidal and intertidal areas and spills that reach areas at the same time where substantial numbers of eggs or larvae of managed species are present. Impacts associated with an unexpected, low-probability CDE affecting shallow and intertidal habitats could be moderate to major, depending on the size, duration, timing, and location of the spill.

4.6.3.2 Alaska – Cook Inlet

4.6.3.2.1 Coastal and Estuarine Habitats. Section 4.4.6.1.2 discusses direct and indirect impacts on coastal and estuarine habitats in Cook Inlet resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on these resources result from the incremental impacts of the Program (described in Section 4.4.6.1.2), when added to impacts from ongoing and reasonably foreseeable future actions, including those of future OCS programs[55] and other non-OCS activities. Table 4.6.1-3 presents the exploration and development scenario for the Cook Inlet cumulative case, which takes into account activities associated with the Program in combination with those from future OCS programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in Cook Inlet are summarized in Table 4.6.1-6 and discussed below, as applicable.

A number of activities associated with the Program could result in impacts on coastal and estuarine habitats in the Cook Inlet Planning Area (Section 4.4.6.1.2). These activities include construction of pipelines and pipeline landfalls and operation of service vessels and existing facilities. Impacts could include losses of beach and wetland habitat and indirect effects that contribute to reductions in these habitats or impacts on biota. There are no past or ongoing OCS activities in the Cook Inlet Planning Area.

Pipeline landfalls could directly disturb tidal marshes, beaches, rocky shores, or other coastal habitats, depending on the location of the landfalls. Sedimentation from physical disturbance of substrates may affect biota in intertidal or shallow subtidal habitats. In addition, accidental spills may impact shoreline habitat.

Ongoing non-OCS activities that could affect coastal and estuarine habitats include those related to State oil and gas development, commercial shipping (and other marine vessel traffic), coastal development, discharge of municipal wastes and other effluents, domestic transportation of oil and gas, and logging (Table 4.6.1-6). These activities can be reasonably expected to continue into the future.

Factors that impact coastal wetlands include the direct elimination of wetland habitat by excavation or filling and the degradation of wetland communities by reduced water quality or hydrologic changes. The construction of pipelines, docks, or shore bases associated with State oil and gas exploration and development could result in direct losses of habitat. Habitats and associated biota within the Cook Inlet Planning Area could also be affected by routine discharges from marine vessels, discharges of municipal and industrial wastewater, or sedimentation from upland areas, including erosion from logging operations within the Cook Inlet watershed. Activities that increase wave action along beaches could contribute to their erosion. Barge and service vessel traffic supporting State oil and gas development may result in wake erosion. The direct and indirect impacts on wetlands from pipeline construction, service vessel operation, and operation of existing facilities under the Program would represent a very small contribution to

[55] Currently, there are no ongoing OCS activities within Cook Inlet.

the past, ongoing, and expected future impacts on coastal and estuarine habitats from non-OCS activities.

Accidental spills of oil or other liquid hydrocarbons, resulting from activities conducted under the Program, could impact shoreline habitats. The majority of these spills are assumed to be small (less than 50 bbl) for the cumulative case (Table 4.6.1-4). Spills from onshore pipelines and facilities could impact freshwater wetlands, or tidal wetlands if carried to coastal habitats by streams. Non-OCS activities, such as State oil and gas development, domestic transportation of oil or refined petroleum products, including LNG from Cook Inlet and the Alaska Peninsula, the production and storage of petroleum products and LNG, and commercial shipping (and other marine vessel traffic), may also result in accidental spills that could potentially impact shoreline habitats. Oil spills have resulted in past impacts on beaches and other intertidal habitats, as in the case of the *Exxon Valdez* oil spill. Spills can result in short- or long-term effects on vegetation growth and changes in the composition of intertidal or shallow subtidal communities, or extensive mortality of biota associated with shoreline habitats, and may persist in substrates for decades. The amount of oil contacting shoreline habitats from a spill depends on a number of factors such as the location and size of the spill, waves and water currents, and containment actions. Naturally occurring seeps may also be a source of crude oil introduced into nearshore waters (Kvenvolden and Cooper 2003). The magnitude of resulting impacts and the persistence of oil would depend on factors such as the amount of oil deposited, remediation efforts, substrate grain size, and localized erosion and deposition patterns. Recovery of affected wetlands could require several decades. The impacts of potential spills associated with the Program would be expected to add a small contribution to the impacts of other sources of oil in the planning area.

Indirect effects on coastal and estuarine habitats could result from global climate change. Potential thermal expansion of ocean water and melting of glaciers and ice caps could result in a global rise in mean sea level (Section 4.6.1.6). Sea-level rise could result in increased inundation of shorelines and erosion of beach habitat and conversion of wetlands to open water. In addition, large changes in river flows into nearshore marine waters could affect salinity and water circulation in estuaries, which, in turn, could impact estuarine wetland communities.

Conclusion. Future OCS program and ongoing and future non-OCS program activities in combination with naturally occurring events have resulted in losses of coastal habitats in Cook Inlet; cumulative impacts on these resources, therefore, are considered to be moderate to major. Operations under the Program would result in minor localized impacts, primarily due to facility construction, pipeline landfalls, channel dredging, and vessel traffic; therefore, the incremental contribution of routine Program activities to cumulative impacts would range from small to medium (see Section 4.4.6.2.2).

The cumulative impacts of past, present, and future oil spills on coastal and estuarine habitats would be moderate. The incremental impacts of expected accidental oil spills associated with the Program on these resources would be negligible to large, depending on the location, timing, duration, and size of the spill; the proximity of the spill to particular habitats; and the timing and nature of spill containment and cleanup activities (see Section 4.4.6.2.2). The majority of these spills would be small (less than 50 bbl). Impacts associated with large oil spills (1,000 bbl or greater) or an unexpected, low-probability CDE that occur in or reach shallower nearshore areas have the greatest potential to affect extensive areas of shoreline and coastal habitats. Although these are rare events, the impacts of such releases on coastal habitats could range from moderate to major if they were to occur.

4.6.3.2.2 Marine Benthic and Pelagic Habitats. Sections 4.4.6.2.2 and 4.4.6.3.2 discuss direct and indirect impacts, respectively, on marine benthic and pelagic habitats in Cook Inlet resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on these resources result from the incremental impacts of the Program (described in Sections 4.4.6.2.2 and 4.4.6.3.2), when added to impacts from ongoing and reasonably foreseeable future actions, including those of future OCS programs and other non-OCS activities.[56] Table 4.6.1-3 presents the exploration and development scenario for the Cook Inlet cumulative case, which takes into account activities associated with the Program in combination with those from future OCS programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in Cook Inlet are summarized in Table 4.6.1-6 and discussed below, as applicable.

Cumulative impact-producing factors for marine benthic and pelagic habitats in Cook Inlet Planning Area include both OCS and non-OCS activities. Potential impacts on marine benthic and pelagic habitat resulting from ongoing and future routine OCS program activities, including those of the Program, could result from noise (vessel, seismic surveys, construction, operations), well drilling, pipeline placement (trenching, landfalls, and construction), platform placement (anchoring, mooring, and removal), and discharges (drilling, vessel and platform). All these activities have the potential to adversely affect marine benthic habitats in the Cook Inlet Planning Area. Accidental oil spills are also counted among OCS program-related activities; assumptions for oil spills under the cumulative case scenario are provided in Table 4.6.1-4, and catastrophic spill assumptions are provided in Table 4.4.2-2.

Because there is no ongoing OCS activity in Cook Inlet Planning Area, the new OCS activities under the Program represent a 100% increase in all associated OCS activities in Cook Inlet. Over the life of the Program, up to 110 production wells and up to three oil platforms are anticipated. In addition, up to 241 km (150 mi) of new offshore pipeline is anticipated. Bottom disturbance resulting from OCS program activities degrades water quality by increasing water turbidity in the vicinity of the operations and adding contaminants to the water column. It also changes sediment composition as suspended sediments (and contaminants, if present) are entrained in currents and deposited in new locations. Construction of platforms in areas previously lacking hard substrate could have localized effects on the biodiversity and distribution of benthic communities by favoring organisms that prefer a hard substrate. Impacts of OCS routine operations (exploration, production and decommissioning activities) on marine benthic and pelagic habitat in the Cook Inlet Planning Area are discussed in detail in Sections 4.4.6.2.2 and 4.4.6.3.2. Overall, routine operations represent a negligible to moderate long-term disturbance, with the severity of the impacts generally decreasing dramatically with distance from the well site.

---

[56] Currently, there are no ongoing OCS activities within Cook Inlet.

The increased amount of drilling in Cook Inlet anticipated under the Program will result in OCS discharges of drill muds and cuttings from exploration and delineation wells. Drilling muds and cuttings from production wells as well as all produced waters will be disposed of in the well rather than discharged into Cook Inlet. The OCS discharges of drill muds, cuttings, and produced waters could potentially affect benthic and pelagic habitat by increasing turbidity and altering grain size distributions and chemical characteristics of sediments. The impacts of drilling discharges on benthic and pelagic habitats are discussed in detail in Sections 4.4.6.2.3 and 4.4.6.3.3.

Various non-OCS activities in Cook Inlet, including State oil and gas programs, dredging and disposal of dredging spoils in OCS waters, anchoring, and commercial or sportfishing activities, and commercial shipping (including imported oil) could contribute to cumulative effects on pelagic and seafloor habitats, along with OCS activities. Drilling of wells in State waters could also require construction of platforms and pipelines in waters of Alaska. Effects on seafloor and pelagic habitat and biota would be similar to those described above for OCS oil and gas programs (Sections 4.4.6.2.2 and 4.4.6.3.2). Dredging operations in conjunction with ship channel maintenance and construction, pipeline placement and burial, and support facility access occur throughout the Cook Inlet Planning Area as part of non-OCS activities. Non-OCS dredging and marine disposal activities would involve excavation of nearshore sediments and subsequent disposal in offshore or nearshore areas, thereby disturbing seafloor habitats and generating temporary turbidity in the water column. Sediments dredged and sidecast or transported to approved dredged material disposal sites could cause smothering and some mortality of sessile animals in the vicinity of the activity. Anchoring of non-OCS activity vessels on these features could cause significant chronic disturbance to benthic and bottom water habitat and biota. Anchoring could involve boats used for recreational and commercial fishing and commercial ship traffic. The amount of damage that could result from anchoring activity would depend upon vessel size, the size of the anchor and chain, sea conditions at the time of anchoring, and the location or position of the anchor on the feature. Similarly, some fishing methods, such as trawling and shellfish dredging, could damage seafloor habitats and increase the turbidity of the water column (Jones 1992). The effects of dredging, anchoring, and trawling activities on marine benthic and pelagic habitats are expected to be similar to those described for OCS bottom disturbing activities (Sections 4.4.6.2.2 and 4.4.6.3.2). Impacts on pelagic habitat would be localized and temporary, while benthic habitat damaged by anchors may take more than 10 years to recover, depending upon the nature of the habitat and severity of the damage. Benthic habitat disturbances from OCS activities (e.g., pipeline trenching and placement and platform placement) would add to the existing impacts to benthic habitat from these non-OCS sediment-disturbing activities.

Cook Inlet is a heavily river-influenced system. Therefore, climate change relating to the temporal variability of key chemical and physical parameters could have important effects in the Cook Inlet Planning Area — particularly to hydrology, dissolved oxygen, salinity, and temperature. These changes could significantly alter the existing benthic and pelagic habitat and biota. A predicted increase in river discharge could change the salinity, temperature, and turbidity regimes in nearshore areas and alter the composition of existing phytoplankton and benthic communities. Other changes could result from:

- Ocean acidification from increasing CO_2 inputs into the ocean that may reduce the availability of calcite and aragonite to calcifying marine organisms.

- Reduction in landfast ice extent and duration expected as a result of rising temperatures which may reduce the scouring of intertidal and shallow subtidal habitats on the western side of Cook Inlet.

- Increases or decreases in phytoplankton productivity. Studies in the Gulf of Alaska suggest phytoplankton productivity is controlled by a number of factors, especially light, microzooplankton consumption, nutrients, and water column stratification, all of which could be affected by climate change (Strom et al. 2010). Therefore, climate change could increase or decrease phytoplankton productivity, potentially resulting in greater or lesser food inputs to benthic habitats and a subsequent increase or decrease in the productivity of benthic biota.

Oil spills from both OCS and non-OCS activities could affect benthic and pelagic habitat in Cook Inlet. The total number of oil spills and the extent of affected seafloor habitat would likely increase under the cumulative scenario, in conjunction with increased levels of petroleum exploration and production. Accidental hydrocarbon releases can occur at the surface from tankers or platforms or at the seafloor from the wellhead or pipelines. Non-OCS activities, such as oil and gas development in State waters, domestic transportation of oil or refined petroleum products, and commercial shipping (and other marine vessel traffic), may also result in accidental spills that could affect benthic and pelagic habitats within the Cook Inlet Planning Area.

For both OCS and non-OCS oil spills, it is assumed the magnitude and severity of potential impacts on benthic and pelagic habitat would be a function of the location (including habitats affected), timing, duration, and size of the spill and containment and cleanup activities. It is anticipated that most small to medium spills would have limited effects because of the relatively small areas likely to be exposed to high concentrations of hydrocarbons and the short period of time during which potentially toxic concentrations would be present. Oil spills would likely have the greatest impacts on benthic habitat and communities in shallow subtidal waters and in intertidal areas. Although pelagic habitat is likely to recover following an oil spill, the recovery time for intertidal and shallow subtidal benthic habitat directly affected by oil spills could be long term (Section 4.4.6.2.2). Multiple spills would further contribute to cumulative effects. Detailed discussion of the impacts of OCS accidental hydrocarbon releases on marine benthic and pelagic habitat can be found in Sections 4.4.6.2.2 and 4.4.6.3.2.

Impact-producing factors for marine benthic and pelagic habitats in Cook Inlet include those from both OCS and non-OCS activities. Non-OCS activities with the potential to impact these resources include oil and gas development in State waters, commercial fishing and sportfishing, sediment dredging and disposal, anchoring, and tankering of imported oil. Disturbances from these activities including noise, marine vessel discharges, and bottom disturbance would add to similar impacts from OCS activities. Overall, cumulative impacts on marine benthic and pelagic habitats, as a result of OCS and non-OCS program activities, would be moderate to major. The incremental contribution of routine Program activities to these impacts would range from negligible to medium (see Section 4.4.6.2.2).

Accidental oil spills could result from both OCS and non-OCS activities. Overall, the cumulative impacts on marine habitats from oil spills would range from minor to moderate. The incremental impacts of expected oil spills, most of which would be small (less than 1,000 bbl), would range from negligible to small, depending on the location, timing, duration, and size of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities (Section 4.4.6.2.2). Spills in deeper water, whether from OCS or non-OCS sources, are unlikely to have overall community-level effects on seafloor habitats because of the relatively small proportion of seafloor area that would come in contact with released oil at concentrations great enough to elicit toxic effects. Impacts associated with an unexpected, low-probability CDE affecting shallow and intertidal habitats could be minor to moderate, depending on the habitats affected. Although pelagic habitat is likely to recover following a CDE, the recovery time for intertidal and shallow subtidal benthic habitat directly affected by such oil spills could be long term.

4.6.3.2.3 Essential Fish Habitat. Section 4.4.6.4.2 discusses direct and indirect impacts on EFH in Cook Inlet resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on these resources result from the incremental impacts of the Program (described in Section 4.4.6.4.2) when added to impacts from ongoing and reasonably foreseeable future actions, including those of future OCS programs and other non-OCS activities.[57] Table 4.6.1-3 presents the exploration and development scenario for the GOM cumulative case, which takes into account activities associated with the Program in combination with those from future OCS programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in Cook Inlet are summarized in Table 4.6.1-6 and discussed below, as applicable.

Cumulative impacts on EFH could result from future OCS and ongoing and future non-OCS activities that have a potential to directly kill managed fish species, disturb ocean bottom habitats, increase sediment suspension, degrade water quality, or affect the food supply for fishery resources (there are no ongoing OCS programs in Cook Inlet). Future OCS activities (resulting from the Program) include seismic surveys (noise), well drilling, pipeline placement (trenching, landfalls, and construction), platform placement (anchoring, mooring, and removal), and routine discharges (drilling, platform, and vessel). Accidental oil spills are also counted among OCS and non-OCS activities.

Because there is no ongoing OCS activity in Cook Inlet Planning Area, the new OCS activities under the Program represent a 100% increase in all associated OCS activities in Cook Inlet. Over the life of the Program, up to 110 production wells and up to three oil platforms are anticipated. In addition, up to 241 km (150 mi) of new offshore pipeline are anticipated, as is one pipeline landfall. Implementation of the Program would also result in seismic survey activity and the release of drilling muds and cuttings to offshore areas (Table 4.6.1-3).

[57] Currently, there are no ongoing OCS activities within Cook Inlet.

Although there are is no oil and gas development in OCS waters, oil and gas operations have existed in State waters of Cook Inlet for decades. Impact-producing factors from OCS and non-OCS oil and gas activities would be similar. Overall, it is expected that the cumulative impacts of exploration and site development activities on marine EFH would be moderate, and impacts are not expected to permanently reduce the EFH available to managed species or result in population-level impacts on managed species. The most sensitive benthic habitats, such as those associated with hard-bottoms and kelp communities, are not expected to be affected by routine operations, and effects would be minimized or eliminated by existing protections. The construction of all platforms and pipelines would disturb bottom habitats to some degree. Deposition of drilling fluids and cuttings could potentially affect EFH by altering grain size distributions and chemical characteristics of sediments such that benthic prey of some managed fish species or water quality in offshore areas would be affected in the immediate area surrounding drill sites. Although muds and cuttings from exploration and delineation wells could be discharged to surrounding waters, it is assumed that muds, cuttings, and produced waters from production wells would be discharged into wells and not released to open waters. See Section 4.4.6.4.2 for a detailed discussion of the impacts of routine operations on EFH and managed species in Cook Inlet Planning Area.

Freshwater areas used by salmon and other anadromous fish are considered to be EFH and could be affected by nearshore OCS and non-OCS oil and gas activity such as pipeline dredging or by onshore pipelines that cross bodies of water, especially streams. The primary effects of pipeline crossings would be increasing turbidity and sedimentation of the benthic environment during construction and blocking migration of anadromous fish following construction. As a consequence, crossings of anadromous fish streams would be minimized and consolidated with other utility and road crossings of such streams. In addition, onshore pipelines would be designed, constructed, and maintained to reduce risks to fish habitats from a spill, pipeline break, or construction activities. Other non-OCS activities, such as logging, road construction, and development in general could also contribute to water quality degradation and blockage of fish passage in anadromous fish streams.

Other ongoing and future non-OCS activities that could impact fish communities include land use practices, point and non-point source pollution, logging, dredging, and disposal of dredging spoils in OCS waters, anchoring, and commercial or sportfishing activities, and commercial shipping (including imported oil). Many of these activities would result in bottom disturbance that would affect bottom dwelling fishes as well as their food sources in a manner similar to those described for OCS activities (Section 4.4.7.3.2). These non-OCS activities when combined with OCS activities could over time result in cumulative impacts on EFH and managed species especially if these impacts occur frequently or are of sufficient magnitude that habitat recovery times are prolonged. See Section 4.6.3.2.1 and Section 4.6.3.2.2 for a discussion of impacts of these non-OCS activities on benthic and pelagic EFH.

Logging could also degrade riverine habitats that are important reproductive and juvenile habitat for managed migratory fish species. Erosion from areas undergoing commercial logging could increase the silt load in streams and rivers, which could reduce levels of invertebrate prey species and adversely affect spawning success and egg survival. The introduction of fine sediments into spawning gravels may render these habitats unsuitable for salmon spawning.

Logging could also remove riparian canopies along some streams, which could increase solar heating of freshwater habitats. Downed timber could physically block salmon migrations. Because of past damage inflicted by commercial logging, improved forestry practices have been initiated, and timber harvests have been curtailed. Continued implementation of effective forest management techniques would help mitigate the adverse effects of logging in the future. Cumulative impacts on migratory species could also occur as a result of activities that obstruct fish movement in marine environments during migration periods.

Commercial fishing practices that are indiscriminate, such as trawling and pots, are responsible for significant amounts of bycatch that can injure or kill juveniles of many fish species. These types of fishing practices could damage future year classes, reduce available prey species, and damage benthic habitat for many Cook Inlet fish resources. A wide variety of methods are used to target numerous species of fishes and shellfishes, including longlines, seines, setnets, trawls, and traps. Some fisheries target particular fish species returning to their natal stream or river, while other fisheries take place in pelagic waters and target mixed stocks of fishes or shellfishes.

As a consequence of the pressure commercial fishing places on fishery resources, appropriate management is required to reduce the potential for depletion of stocks due to overharvesting. Fisheries in Alaskan waters and in adjacent offshore areas are managed by the Alaska Department of Fish and Game and the North Pacific Fishery Management Council of the National Marine Fisheries Service through implementation of fishing regulations such as fishing seasons and harvest limits and through hatchery production of some fishery resources (primarily salmon). Even with management, the possibility of overfishing still exists. Occasionally fisheries are closed when stocks are considered insufficient to support harvesting, and will sometimes remain closed for multiple seasons before stocks are deemed sufficient. While occasional or sustained declines in fishery stocks may not be fully attributable to commercial fishing, it appears that commercial fishing is an important factor in the abundance, or lack thereof, of fishery resources.

Although the magnitude of harvests is considerably smaller than for commercial fisheries (Fall et al. 2009), sportfishing also contributes to cumulative effects on the abundance of some fishery resources. Recreational fisheries are managed to prevent overharvesting, but recreational harvests can be a substantial portion of fisheries landings. Consequently, recreational fishing activities have a potential to result in overharvest of managed species over the life of the Program. However, recreational fishing methods are less destructive of EFH compared to commercial fisheries.

Subsistence fishing may also contribute to the cumulative effects on the abundance of some fishery resources. Alaska State law defines subsistence as the “noncommercial customary and traditional uses” of fish and wildlife. The Alaska Department of Fish and Game defines subsistence fishing to include “the taking of, fishing for, or possession of fish, shellfish, or other fisheries resources by a resident of the State for subsistence uses with gill net, seine, fish wheel, long line, or other means defined by the Board of Fisheries.” These fishing methods have more limited impacts on EFH compared to commercial fishing methods. Subsistence fishing is subject to harvest limits that reduce the potential for overfishing and much of Cook Inlet is defined as a nonsubsistence area, and subsistence fishing is therefore not authorized. Consequently, subsistence fishing makes a relatively minor contribution to the reduction in fish stocks compared to commercial fishing (Fall et al. 2009).

Another source of cumulative impacts to fishery resources are personal use fisheries which are a legally defined as "the taking, fishing for, or possession of finfish, shellfish, or other fishery resources, by Alaska residents for personal use and not for sale or barter, with gill or dip net, seine, fish wheel, long line, or other means defined by the Board of Fisheries." In the Cook Inlet Planning Area, there are areas designated for personal use fisheries for salmon, tanner crab, herring, and eulachon, all of which are managed species. All personal use fisheries are subject to harvest limits that reduce the potential for overfishing. Personal use fishing makes a relatively minor contribution to the reduction in fish stocks compared to commercial fishing.

See individual sections on water quality, coastal habitats, and marine and pelagic habitats for a discussion of the effects of climate change on EFH in the Cook Inlet Planning Area. As a heavily river-influenced system, climate change may cause the temporal variability of key chemical and physical parameters, which could significantly alter the existing benthic and pelagic habitat and biota. A predicted increase in river discharge could change the salinity, temperature, and turbidity regimes in nearshore areas and alter the composition of existing phytoplankton and benthic communities. Other changes could result from ocean acidification, reduction in landfast ice extent and duration, and increase phytoplankton productivity.

The total number of oil spills and the extent of affected EFH areas would likely increase under the Program in conjunction with increased levels of petroleum exploration and production. The Program would contribute 100% of the OCS spills in the Cook Inlet Planning Areas. See Table 4.6.1-4 for oil spill assumptions for Alaska. Catastrophic spills assumptions are provided in Table 4.4.2-2. Non-OCS activities, such as oil and gas development in State waters, domestic transportation of oil or refined petroleum products, and commercial shipping (and other marine vessel traffic), may also result in accidental spills that could potentially impact fish resources within the Cook Inlet Planning Area. While effects on EFH resources would depend on the timing, location, and magnitude of specific oil spills, it is anticipated that most small to medium spills that occur in OCS waters would have limited effects on EFH, due to the relatively small areas likely to be exposed to high concentrations of hydrocarbons and the short period of time during which potentially toxic concentrations would be present. See Section 4.4.6.4 for a detailed discussion of the impact of oil spills on EFH.

Because of the high concentrations of individuals likely to be present, EFH for anadromous salmon are at higher risk from an OCS oil spill in the Cook Inlet Planning Areas. The greatest potential for damage to salmon stocks would be if a spill were to occur along migration routes. However, because of the limited area affected by even large oil spills relative to the wide pelagic distribution and migratory patterns of salmonids, it is anticipated that most impacts would be limited to small fractions of exposed salmon populations. Oil spills occurring at constrictions in migration routes would have an increased potential for adversely affecting salmon. Adverse effects of oil spills on EFH for groundfishes of southern Alaska would also be a function of spill magnitude, location, and timing. Adult groundfishes are primarily demersal and would generally be subjected only to the insoluble oil and water-soluble fractions of oil that reach deeper strata. Insoluble oil fractions would sink to the bottom and be distributed diffusely as tar balls over a wide area, and would be unlikely to produce a reduction in the population of adult fishes. Egg and larval stages would be at greater risk of exposure to oil spills because spawning aggregations of many groundfish species produce pelagic eggs that could come into contact with surface oil slicks. Herring are also potentially susceptible to oil spills because they spawn in nearshore waters for protracted periods of time.

Managed shellfish stocks (such as tanner, snow, and red king crab) are unlikely to be exposed to surface oil. However, oil reaching shallow subtidal and intertidal shellfish or crab habitat could measurably reduce crab populations. Pelagic crab larvae could also be affected if a large surface oil spill occurred during the spring spawning season. However, because the area affected by most spills would be expected to be small relative to overall distributions of crab larvae, overall population levels are unlikely to be noticeably affected.

Conclusion. Impact-producing factors for EFH include those from both OCS and non-OCS activities. Non-OCS activities with the potential to impact EFH in the Cook Inlet Planning Area include oil and gas production in State waters, coastline development, commercial and recreational fishing, sediment dredging and disposal, and vessel traffic. Impacts from OCS activities would be limited by specific lease stipulations. Overall, the cumulative impacts on EFH would be minor to moderate, considering ongoing and future OCS and non-OCS activities. The incremental contribution of routine Program activities to these impacts would be negligible to medium (see Section 4.4.6.3.2).

Accidental oil spills could result from both OCS and non-OCS activities. Overall, the cumulative impacts on EFH from oil spills would range from minor to moderate. The incremental impacts of expected oil spills would range from negligible to medium, depending on the location, timing, duration, and size of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities (Section 4.4.6.3.2). While most accidents related to OCS activities assumed under the cumulative scenario would be small (less than 50 bbl) and would have relatively small incremental impacts on EFH, spills that reach coastal wetlands could have more persistent impacts and could require remediation. Spills in deeper water, whether from OCS or non-OCS sources, are unlikely to have overall population-level effects on fish resources because of the relatively small proportion of similar available fish habitats that would come in contact with released oil at concentrations great enough to elicit toxic effects. Oil spills that have the greatest potential to impact EFH and managed species are those that occur in shallower subtidal and intertidal areas and spills that reach areas at the same time where substantial numbers of eggs or larvae of managed species are present. Impacts associated with an unexpected, low-probability CDE affecting shallow and intertidal habitats could be moderate to major, depending on the size, duration, timing, and location of the spill.

4.6.3.3 Alaska Region – Arctic

4.6.3.3.1 Coastal and Estuarine Habitats. Section 4.4.6.1.3 discusses direct and indirect impacts on coastal and estuarine habitats in the Arctic region resulting from the

2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on these resources result from the incremental impacts of the Program (described in Section 4.4.6.1.3), when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS activities. Table 4.6.1-3 presents the exploration and development scenario for the Arctic region cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future OCS programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in the Arctic are summarized in Table 4.6.1-7 and discussed below.

Coastal Barrier Beach and Dunes. Vessel traffic associated with the Program could result in indirect impacts on coastal barrier beaches and dunes in the Arctic region (Section 4.4.6.1.3). Onshore pipeline construction may impact sand beaches and dunes on the margins of lakes and rivers on the Arctic Coastal Plain (ACP). Similar activities are associated with current and planned OCS sales in the Alaska region and would occur during the life of the Program (see Table 4.6.1-5). In the Beaufort Sea and Chukchi Sea Planning Areas, vessel traffic associated with the Program would represent approximately 25–35% of such OCS activities, and onshore pipelines associated with the Program would represent approximately 30% for the Beaufort Sea Planning Area.

Impacts on barrier beaches and dunes primarily result from factors that contribute to increased erosion of beaches and dunes. Activities may disturb dune vegetation, thereby promoting dune erosion, or directly disturb beach and dune substrates, resulting in increased erosion of beaches and dunes. Increases in wave action could also contribute to the erosion of beaches. Sedimentation from physical disturbance of substrates or erosion may affect biota in intertidal or shallow subtidal habitats. In addition, accidental spills may impact beach or dune habitat.

Ongoing non-OCS activities that could affect barrier beaches and dunes include those related to State oil and gas development, commercial shipping (and other marine vessel traffic), and coastal development. These activities can be reasonably expected to continue into the future.

The construction of pipelines, docks, causeways, or shorebases associated with State oil and gas exploration and development could result in direct losses of beach or dune habitat. Construction of facilities on barrier islands could impact beach, dune, or tundra habitat. Erosion of beach or dune substrates adjacent to these constructions may result in additional habitat losses. Intertidal and shallow subtidal organisms in nearby areas may be buried by excavated materials or indirectly affected by turbidity and sedimentation. Sand beaches and dunes along lagoon shorelines and on the margins of lakes and rivers on the ACP may also be affected by pipeline construction. The impacts on barrier beaches and dunes from substrate-disturbance activities associated with construction under the Program would represent a small contribution to the past, ongoing, and expected future impacts on barrier beaches and dunes from non-OCS activities. Vegetated dunes in the Arctic region may be affected by vehicles associated with seismic activities (ADNR 2009d). Beaches and associated biota within the Beaufort Sea and Chukchi Sea Planning Areas could also be affected by routine discharges from marine vessels, discharges of municipal and industrial wastewater, or sedimentation from upland areas.

Activities that increase wave action along barrier beaches and dunes could contribute to their erosion. Barge and service vessel traffic supporting State oil and gas development may result in wake erosion along barrier islands in the Beaufort Sea and Chukchi Sea Planning Areas. A portion of the impacts related to vessel traffic would be associated with the Program; however, activities conducted under the proposed action would contribute a relatively small number of vessel trips to the total.

Accidental spills of oil or other liquid hydrocarbons, resulting from activities conducted under the proposed action, could impact beaches and dunes. Such spills would represent approximately 20–40% of the spills resulting from ongoing OCS activities and planned future sales in the Beaufort Sea and Chukchi Sea Planning Areas (Table 4.6.1-4). As under the Program, the majority of these spills would be small (less than 50 bbl). Non-OCS activities, such as State oil and gas development, domestic transportation of oil or refined petroleum products, and commercial shipping (and other marine vessel traffic), may also result in accidental spills that could potentially impact coastal barrier beaches and dunes. Spills can result in short- or long-term changes in the composition of intertidal or shallow subtidal communities, or extensive mortality of biota associated with coastal habitats, and may persist in substrates for decades. The amount of oil contacting beaches from a spill depends on a number of factors such as the location and size of the spill, waves and water currents, and containment actions. Naturally occurring seeps may also be a source of crude oil introduced into nearshore waters (Kvenvolden and Cooper 2003). The magnitude of resulting impacts and the persistence of oil would depend on factors such as the amount of oil deposited, remediation efforts, substrate grain size, and localized erosion and deposition patterns. The impacts of potential spills associated with the Program would be expected to add a small contribution to the impacts of other sources of beach degradation in the Arctic region.

Indirect effects on coastal barrier beaches and dunes could result from global climate change. Potential thermal expansion of ocean water and melting of glaciers and ice caps could result in a global rise in mean sea level (Section 4.6.1.6). Sea-level rise could result in increased inundation of barrier landforms and erosion of beach habitat. In the Arctic, greater wave activity during storms due to decreases in sea-ice cover, as well as changes in permafrost due to temperature increases, could result in increased coastal erosion.

Wetlands. A number of activities associated with the Program could result in impacts on coastal wetlands in the Alaska region (Section 4.4.6.1.3). These activities include construction of pipelines, road construction, and facility maintenance, and activities that result in poorer water and air quality and altered hydrology. Impacts associated with these activities could include elimination of wetland habitat and indirect effects that contribute to reductions in wetland habitat. Similar activities are associated with current and planned OCS lease sales in the Beaufort Sea and Chukchi Sea Planning Areas, and would occur during the life of the Program (see Table 4.6.1-3). In the Beaufort Sea Planning Area, the activities associated with the Program would represent approximately 30% of such OCS activities; the Program does not include new onshore pipelines in the Chukchi Sea Planning Area.

Factors that impact coastal wetlands include the direct elimination of wetland habitat by excavation or filling and the degradation of wetland communities by reduced water or air quality or hydrologic changes. Construction projects may fill wetlands for facility siting or excavate wetlands for the construction of pipelines, causeways, or shore bases or for gravel mining. A number of activities may degrade wetlands or promote wetland losses indirectly by causing changes to wetland hydrology or introducing contaminants.

Ongoing non-OCS activities that could affect coastal wetlands include those related to State oil and gas development, commercial shipping and other marine traffic, coastal development, discharge of municipal wastes and other effluents, and domestic transportation of oil and gas. These activities can reasonably be expected to continue into the future.

A number of these activities result in the localized destruction of wetlands. The construction of pipeline landfalls, docks, or shorebases associated with State oil and gas exploration and development could result in direct losses of tidal wetlands. The construction of onshore facilities to support State oil and gas development and the exploration of oil reserves on the NPR-A on the ACP have affected freshwater wetlands, and future impacts associated with oil and gas development are expected to continue. The construction of buried pipelines results in direct impacts on wetlands due to excavation, and the construction of gravel pads and gravel roads eliminates wetland habitat by filling. Current technology allows for smaller and fewer drilling pads, and some new developments in the Arctic region would not include interconnecting roads. On the ACP, gravel has been used in support of oil and gas development to construct pads for camps, drilling sites, operations and maintenance facilities, airports, and roads for facility access as well as the Dalton Highway/haul road, offshore islands, and causeways (MMS 2003a). Gravel mining operations often result in the excavation of wetland habitat in and near rivers and other water bodies. Over 730 ha (1,800 ac) of tundra have been removed by gravel mining on the ACP (MMS 2003a). The construction of vertical support members for elevated pipelines also contributes to small localized wetland losses. Although activities that impact wetlands are regulated by State and Federal agencies, construction of industrial facilities, commercial sites, and residential developments would be expected to result in continued wetland losses. On the ACP, over 3,900 ha (9,600 ac) of tundra habitat, most of which is wetland, have been affected by oil and gas development activities (MMS 2002b, 2003a). The direct impacts on coastal wetlands from pipeline construction under the Program would represent a very small contribution to the past, ongoing, and expected future losses of wetlands from non-OCS activities.

Indirect impacts of many activities have also resulted in wetland losses. The construction of gravel roads and pads has resulted in altered hydrology in some areas, by blocking natural drainage patterns, converting vegetated wetlands to open water, or drying wetlands by restricting water inflow. Snow accumulations adjacent to pads and roads can result in vegetation changes and thermokarst. Windblown dust near gravel pads and roads causes changes in plant communities, reduction of vegetation, and thermokarst, leading to wetland losses. Sedimentation from gravel pads, roads, gravel mining operations, and vehicular impacts on streambanks adversely affect wetlands and may result in losses of vegetation or other associated biota. Ice roads in the Arctic could result in compression of vegetation, microtopography, and tundra soils, altering wetland communities. Vehicles used for seismic surveys could compress microtopography and cause changes in the vegetation community. Organisms in wetland areas near construction activities may be buried by excavated materials or indirectly affected by turbidity and sedimentation. Degradation of wetlands could result from water quality impacts due to discharges of waste water from vessels, municipal treatment plants, and industrial facilities, and stormwater discharges. Water quality may also be affected by waste storage and disposal sites. Spills of produced water could kill vegetation and other biota in freshwater wetlands. Impacts on air quality near construction sites or industrial facilities could result in local effects on wetland vegetation, and may include sources such as fugitive dust, off-gassing from processing facilities, or exhaust emissions. Indirect impacts on wetlands from non-OCS activities are expected to continue to contribute to wetland degradation and losses in the Arctic region. The indirect impacts on wetlands from pipeline construction under the Program would represent a very small contribution to the past, ongoing, and expected future impacts on wetlands from non-OCS activities.

Accidental spills of oil or petroleum products as a result of activities conducted under the Program could impact tidal or freshwater wetlands (see Section 4.4.6.1.3). Such spills would represent approximately 20–40% of the spills resulting from ongoing OCS activities and planned future sales in the Beaufort Sea and Chukchi Sea Planning Areas (Table 4.6.1-4). Most of these spills (1,350–1,950) would be small (less than 50 bbl), as under the Program. Spills in shallow water, primarily those from vessel accidents and pipelines, would be most likely to affect coastal wetlands, whereas deepwater spills, such as those from platforms, would be less likely to impact wetlands. Spills from onshore pipelines and facilities could impact freshwater wetlands or tidal wetlands if carried to coastal habitats by streams. Non-OCS activities such as State oil and gas development, the domestic transportation of oil or refined petroleum products, the production and storage of petroleum products, and commercial shipping (and other marine vessel traffic) may also result in accidental spills that could potentially impact wetlands. Naturally occurring seeps may also be a source of crude oil that could potentially affect coastal wetlands. The amount of oil contacting wetlands, the magnitude of resulting impacts, and the length of time for recovery would depend on a number of factors such as the location and size of the spill, containment actions, waves and water currents, type of oil, types of remediation efforts, amount of oil deposition, duration of exposure, season, substrate type, and extent of substrate penetration. Impacts from oil spills would be expected to range from short-term effects on vegetation growth to extensive mortality. Recovery of affected wetlands could require several decades. The impacts of potential oil spills associated with the Program would be expected to constitute a small addition to the impacts of all other sources of oil in the Arctic region.

Global climate change could result in indirect effects on coastal wetlands. Potential thermal expansion of ocean water and melting of glaciers could result in a global rise in mean sea level (Section 4.6.1.6). Sea-level rise would result in greater inundation of coastal wetlands, and likely result in conversion of wetlands to open water. In addition, large changes in river flows into nearshore marine waters could affect salinity and water circulation in estuaries, which, in turn, could impact estuarine wetland communities.

Conclusion. Future OCS program and ongoing and future non-OCS program activities in combination with naturally occurring events have resulted in losses of coastal habitats in the Arctic region; cumulative impacts on these resources, therefore, are considered to be moderate to major. Operations under the Program would result in small localized impacts, primarily due to facility construction, pipeline landfalls, channel dredging, and vessel traffic; however, the incremental contribution of routine Program activities to cumulative impacts would be small to medium (see Section 4.4.6.1.3).

The cumulative impacts of past, present, and future oil spills on coastal and estuarine habitats would be moderate. The incremental impacts of expected accidental oil spills associated with the Program on these resources would be negligible to large, depending on the location, timing, duration, and size of the spill; the proximity of the spill to particular habitats; and the timing and nature of spill containment and cleanup activities (see Section 4.4.6.1.3). The majority of these spills would be small (less than 50 bbl) and most of them would not likely contact and affect coastal and estuarine habitats. Impacts associated with large oil spills (1,000 bbl or greater) or an unexpected, low-probability CDE have the greatest potential to affect extensive areas of shoreline and coastal habitats. Although these are rare events, the impacts of such releases on coastal habitats could range from moderate to major if they were to occur.

4.6.3.3.2 Marine Benthic and Pelagic Habitats. Sections 4.4.6.2.3 and 4.4.6.3.3 discuss direct and indirect impacts on marine benthic and pelagic habitats in the Arctic region resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on these resources result from the incremental impacts of the Program (described in Sections 4.4.6.2.3 and 4.4.6.3.3), when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS activities. Table 4.6.1-3 presents the exploration and development scenario for the Arctic region cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future OCS programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in the Arctic are summarized in Table 4.6.1-7 and discussed below.

Cumulative impact-producing factors for marine benthic and pelagic habitats in Beaufort Sea and Chukchi Sea Planning Areas include those from both OCS and non-OCS activities. Potential impacts on marine benthic and pelagic habitat resulting from future routine OCS program activities, including those of the Program, could result from noise (vessel, seismic surveys, construction, operations), well drilling, pipeline placement (trenching, landfalls, and construction), discharges (drilling, vessel and platform), and platform placement (anchoring, mooring, and removal). All these activities have the potential to adversely affect marine benthic and pelagic habitats in the Beaufort Sea and Chukchi Sea Planning Areas. Accidental oil spills are also counted among OCS program-related activities; assumptions for oil spills under the cumulative case scenario are provided in Table 4.6.1-4, and catastrophic spill assumptions are provided in Table 4.4.2-2.

Potential environmental impacts associated with the building and operation of OCS facilities such as platforms, subsea wells, artificial islands, and pipelines would increase in conjunction with the increased number of wells (approximately 9 ha [22 ac] for artificial islands versus less than 1.5 ha [3.7 ac] for platforms) and complete burial of existing substrates during construction. Under the cumulative scenario, it is anticipated that up to 1,450 production wells, up to 26 oil platforms, and up to 922 km (573 mi) of new offshore pipeline would be constructed in the Beaufort Sea and Chukchi Sea Planning Areas. Bottom substrates would be significantly altered by the construction of artificial islands. Marine benthic and pelagic habitats would be affected by bottom disturbance, by temporary increases in turbidity, and by deposition of disturbed sediment. Construction of artificial islands would result in a more complete loss of benthic habitat, due to larger footprints. Bottom disturbance degrades water quality by increasing water turbidity in the vicinity of the operations and adding contaminants to the water column. It also changes sediment composition as suspended sediments (and contaminants, if present) are entrained in currents and deposited in new locations. Construction of platforms and artificial islands in areas previously lacking hard substrate could have localized effects on the biodiversity and distribution of benthic communities by favoring organisms that prefer a hard substrate. Impacts of OCS routine operations (exploration, production and decommissioning activities) on marine benthic and pelagic habitat in the Beaufort Sea and Chukchi Sea Planning Areas are discussed in detail in Sections 4.4.6.2.3 and 4.4.6.3.3. Regulations and mitigating measures would preclude construction of platforms or artificial islands and placements of pipelines or wells in environmentally sensitive areas, such as the Stefansson Sound Boulder Patch in the Beaufort Sea (Section 4.4.6.2.3). Overall, routine operations represent a negligible to moderate long-term disturbance, with the severity of the impacts generally decreasing dramatically with distance from the well site.

The increased amount of drilling anticipated under the Program will result in OCS discharges of drill muds and cuttings from exploration and delineation wells. Deposition of drilling fluids and cuttings could potentially affect benthic and pelagic habitat by increasing turbidity and altering grain size distributions and chemical characteristics of sediments. The impacts of drilling discharges on benthic and pelagic habitats are discussed in detail in Sections 4.4.6.2.3 and 4.4.6.3.3.

Along with future OCS activities, various ongoing and future non-OCS activities, including oil and gas activities in State waters, commercial shipping (including tankers), dredging and disposal of dredging spoils in OCS waters, and anchoring could contribute to cumulative effects on pelagic and seafloor habitats in the Beaufort Sea and Chukchi Sea Planning Areas. Drilling of wells and oil and gas activities in State waters could also require construction of artificial islands, platforms, and pipelines in waters of Alaska. Effects on seafloor and pelagic habitat and biota would be similar to those described above for OCS oil and gas programs (Sections 4.4.6.2.3 and 4.4.6.3.3). Dredging operations in conjunction with ship channel maintenance and construction, pipeline placement and burial, and support facility access occur throughout the Beaufort Sea and Chukchi Sea Planning Areas as part of non-OCS activities. Dredging and marine disposal activities would involve excavation of nearshore sediments and subsequent disposal in offshore or nearshore areas and could cause temporary turbidity in the water column and smothering of sessile animals in the vicinity of the activity. Anchoring of non-OCS activity vessels on these features could cause significant chronic disturbance to benthic and bottom water habitat and biota. The amount of damage that could result from anchoring activity would depend upon vessel size, the size of the anchor and chain, sea conditions at the time of anchoring, and the location or position of the anchor on the feature. Benthic habitat disturbances from OCS activities (e.g., pipeline trenching and placement and platform placement) would add to the existing impacts to benthic habitat from these non-OCS sediment-disturbing activities. The effects of dredging, anchoring, and trawling activities on marine benthic and pelagic habitats are expected to be similar to those described for the installation of pipelines (Sections 4.4.6.2.2 and 4.4.6.3.2). Impacts on pelagic habitat would be localized and temporary, with recovery time depending upon the nature of the habitat and severity of the damage.

Climate change is expected to have multiple effects on the Beaufort Sea and Chukchi Sea Planning Areas that could impact benthic and pelagic habitat. Increased river discharge could alter the salinity, temperature, and turbidity regimes in nearshore areas (Hopcroft et al. 2008). Several rivers flow into the Beaufort shelf, and this region may be more heavily affected than the western Chukchi shelf. The increase in total suspended solids due to coastal erosion and the greater riverine sediment loading could increase turbidity in the water column and consequently decrease the penetration of photosynthetically active radiation available for kelp production (Hopcroft et al. 2008).

Climate change is expected to decrease the spatial extent and temporal duration of sea ice and make the ice thinner. Several possible consequences could result, including:

- Reduction in the spatial and temporal extent of subtidal and intertidal benthic scouring, but an increase in wave generated subtidal and intertidal disturbance;

- An increase in the sloughing of sediments from shoreline during storms, adding to the sediment loads and changing water chemistry in nearshore areas;

- An overall increase in biological productivity in the open water with increasing temperature and ice retreat and a shift to a pelagic-based rather than a benthic-based food web (Hopcroft et al. 2008); and

- Reduction in the amount and seasonal availability of sea ice algae.

In addition, ocean acidification from increasing CO_2 inputs into the ocean is also predicted to continue in Arctic waters, which may reduce the availability of calcite and aragonite to calcifying marine organisms in the sediment and water column.

Oil spills from both OCS and non-OCS activities could affect benthic and pelagic habitat in the Beaufort Sea and Chukchi Sea Planning Areas. The total number of oil spills and the extent of affected seafloor habitat would likely increase under the cumulative scenario, in conjunction with increased levels of petroleum exploration and production. Accidental hydrocarbon releases can occur at the surface from tankers or platforms or at the seafloor from the wellhead or pipelines. The total number of oil spills and the extent of affected seafloor habitat would likely increase under the cumulative scenario, in conjunction with increased levels of petroleum exploration and production. Non-OCS activities, such as oil and gas development in State waters and domestic transportation of oil, may also result in accidental spills that could affect benthic and pelagic habitats within the Beaufort Sea and Chukchi Sea Planning Areas.

For both OCS and non-OCS oil spills, it is assumed the magnitude and severity of potential impacts on benthic and pelagic habitat would be a function of the location (including habitats affected), timing, duration, and size of the spill and containment and cleanup activities. It is anticipated that most small to medium spills would have limited effects because of the relatively small areas likely to be exposed to high concentrations of hydrocarbons and the short period of time during which potentially toxic concentrations would be present. However, oil spilled during periods of ice cover could persist months or years trapped in or under the ice until the ice melted. Oil could also be transported within the ice to areas far from the spill. Oil spills would likely have the greatest impacts on benthic habitat and communities in shallow subtidal waters and in intertidal areas. Although pelagic habitat is likely to recover following an oil spill, the recovery time for intertidal and shallow subtidal benthic habitat directly affected by oil spills could be long term. If a large amount of oil from a spill were to sink and inundate sensitive boulder communities, the recovery of sensitive species could be long term (Section 4.4.6.2.3). Detailed discussion of the impacts of accidental hydrocarbon releases on marine benthic and pelagic habitat potentially resulting from the Program in the Beaufort Sea and Chukchi Sea Planning Areas can be found in Sections 4.4.6.2.3 and 4.4.6.3.3.

Conclusion. Impact-producing factors for marine benthic and pelagic habitats include those from both OCS and non-OCS activities. Ongoing and future non-OCS activities with the potential to impact marine benthic and pelagic habitats in the Beaufort Sea and Chukchi Sea Planning Areas include oil and gas production in State waters, sediment dredging and disposal, and vessel traffic. Disturbances from these activities including noise, vessel discharges, and bottom disturbance would occur in addition to similar impacts from OCS activities. For OCS activities, planning and permitting procedures would minimize the potential for direct impacts on sensitive boulder habitats during routine OCS activities. Overall, the cumulative impacts on benthic and marine habitats would be moderate to major, considering ongoing and future OCS and non-OCS activities. The incremental contribution of routine Program activities to these impacts would be negligible to medium (see Section 4.4.6.2.3).

Accidental oil spills could result from both OCS and non-OCS activities. Overall, the cumulative impacts on marine habitats from oil spills would range from minor to moderate. The incremental impacts of expected oil spills, most of which would be small (less than 1,000 bbl), would range from negligible to small, depending on the location, timing, duration, and size of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities (Section 4.4.6.3.2). Spills in deeper water, whether from OCS or non-OCS sources, are unlikely to have overall community-level effects on seafloor habitats because of the relatively small proportion of seafloor area that would come in contact with released oil at concentrations great enough to elicit toxic effects. Impacts associated with an unexpected, low-probability CDEs affecting shallow and intertidal habitats could be minor to moderate, depending on the habitats affected. Although pelagic habitat is likely to recover following a CDE, the recovery time for intertidal and shallow subtidal benthic habitat directly affected by such oil spills could be long term.

Oil spills could result from both OCS and non-OCS activities. The impacts of accidental oil spills associated with the Program on these resources would be negligible to moderate, depending on the location, timing, duration, and size of spills; the proximity of spills to particular seafloor habitats; and the timing and nature of spill containment and cleanup activities (see Section 4.4.6.2.3). Spills in deeper water, whether from OCS or non-OCS sources, are unlikely to have overall community-level effects on seafloor habitats because of the relatively small proportion of seafloor area that would come in contact with released oil at concentrations great enough to elicit toxic effects. Catastrophic oil releases that affect shallow and intertidal habitats have the potential to be of greatest significance. Although pelagic habitat is likely to recover following an oil spill, the recovery time for intertidal and shallow subtidal benthic habitat directly affected by oil spills could be long term. The incremental contribution of accidental oil spills associated with the Program would range from small to medium.

4.6.3.3.3 Essential Fish Habitat. Section 4.4.6.4.3 discusses direct and indirect impacts on EFH in the Arctic region resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on these resources result from the incremental impacts of the Program (described in Section 4.4.6.4.3) when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS activities. Table 4.6.1-2 presents the exploration and development scenario for the Arctic region cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future OCS programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in the Arctic are summarized in Table 4.6.2-7 and discussed below.

Cumulative impacts on EFH could result from future OCS and ongoing and future non-OCS activities that have the potential to directly kill managed fish species, disturb ocean bottom habitats, increase sediment suspension, degrade water quality, or affect the food supply for fishery resources (there are only offshore exploratory drilling and seismic studies in Beaufort and Chukchi Seas). Future OCS activities (resulting from the Program) include seismic surveys (noise), well drilling, pipeline placement (trenching, landfalls, and construction), subsea production well and platform placement (anchoring, mooring, and removal), and routine discharges (drilling, platform, and vessel). Accidental oil spills are also counted among OCS and non-OCS activities.

Under the cumulative scenario it is anticipated that up to 1,450 production wells, up to 26 oil platforms, and up to 922 km (573 mi) of new offshore pipeline would be constructed in the Beaufort Sea and Chukchi Sea Planning Areas over the period of the Program. Drilling muds and cuttings from exploration wells would also be released in to OCS waters.

Overall, it is expected that the impacts of exploration and site development activities on marine EFH would be moderate, and impacts are not expected to permanently reduce the EFH available to managed species or result in population-level impacts on managed species. The most sensitive benthic habitats, such as those associated with hard-bottoms and kelp communities, are not expected to be affected by routine operations since impacts would be minimized or eliminated by existing protections. Although construction of platforms, artificial islands, and pipelines would all disturb bottom habitats to some degree, artificial islands (Beaufort and Chukchi Seas only) would result in a more complete loss of benthic habitat due to larger footprints (approximately 9 ha [22 ac] for artificial islands versus less than 1.5 ha [3.7 ac] for platforms) and complete burial of existing substrate. Deposition of drilling muds and cuttings could potentially affect EFH by altering sediment characteristics such that benthic prey of some managed fish species, certain stages of the managed species themselves, or water quality in offshore areas would be affected in the immediate area surrounding drill sites. See Section 4.4.6.4.3 for a detailed discussion of the impacts of routine operations on EFH and managed species in the Arctic.

Ongoing and future non-OCS activities, such as subsistence fishing, commercial shipping (including tankers and other marine vessels), coastal modifications, hardrock mining, dredging and disposal of dredging spoils in OCS waters, and anchoring could contribute to cumulative effects on pelagic and seafloor EFH in the Beaufort Sea and Chukchi Sea Planning Areas. Commercial fishing does not occur in the Beaufort Sea and Chukchi Sea Planning Areas and sportfishing is minor in the Arctic region, but could increase if regulations change and if warming temperatures allow an increase in vessel traffic. Impacts from these non-OCS activities including noise, vessel discharges, and bottom disturbance would occur in addition to similar impacts from OCS activities. Many of these activities would result in bottom disturbance that would affect bottom dwelling fishes as well as their food sources in a manner similar to those described for OCS activities (MMS 2008b; ADEC 2007a; Section 4.4.7.3.3).

EFH and managed species in the Beaufort and Chukchi Seas fall in the Kotzebue Sound and Northern Subsistence fishing areas (http://www.adfg.alaska.gov/index.cfm?adfg=subsistence.main). Subsistence fishing may contribute to the cumulative effects on the abundance of some fishery resources. Alaska State law defines subsistence as the "noncommercial customary and traditional uses" of fish and wildlife. The Alaska Department of Fish and Game defines subsistence fishing to include "the taking of, fishing for, or possession of fish, shellfish, or other fisheries resources by a resident of the State for subsistence uses with gill net, seine, fish wheel, long line, or other means defined by the Board of Fisheries." These fishing methods have more limited impacts on EFH compared to commercial fishing methods. In addition, subsistence fishing is subject to harvest limits that reduce the potential for overfishing. Consequently, subsistence fishing makes a relatively minor contribution to the reduction in fish stocks.

Cumulative impacts on anadromous or diadromous managed species could also occur as a result of activities that obstruct fish movement in marine environments during migration periods. For example, some structures along the Beaufort Sea mainland (e.g., the West Dock) have been shown to block the movements of diadromous fishes, particularly juveniles, under certain meteorological conditions (Fechhelm 1999; Fechelm et al. 1999). Causeways such as the 40 m (131 ft) wide and 60 m (197 ft) long structure associated with the Red Dog Mine may impede coastal movement either by directly blocking fish or by modifying nearshore water conditions to the point where they might become too cold and saline for some species (Fechhelm et al. 1999). Although the presence of causeways has been an issue associated with oil and gas development activities in the Beaufort Sea, the small size of the Red Dog causeway would likely have little effect on the coastal movements and distributions of Chukchi Sea fishes and shellfishes. However, it is anticipated that proper placement and design considerations for future causeway construction along the North Slope would alleviate the potential for such effects on fish movement.

There are several contaminant sources in the Beaufort Sea and Chukchi Sea Planning Areas. The Red Dog Mine in Alaska is the largest lead and zinc mine in the world, and is presently the only base-metal lode mine operating in northwest Alaska. A study for the National Park Service (Hasselbach et al. 2004) showed extensive airborne transport of cadmium and lead from Red Dog Mine; although the study was focused only on the limits of the Cape Krusenstern National Monument, these contaminants are probably carried out into the Chukchi Sea. There are also natural sources of metals and hydrocarbons. Sediments, peats, and soils from the Sagavanirktok, Kuparuk, and Colville Rivers are the largest source of dissolved and particulate metals and saturated and polycyclic aromatic hydrocarbons in the development area. However, concentrations of these contaminants in fish sampled in the Arctic planning areas are typically at background levels (Neff & Associates, LLC 2010).

There are also State oil and gas activities that can affect EFH in the Beaufort and Chukchi Seas. Factors that could affect EFH from these activities would be similar to those described above for OCS activities including underwater noise, habitat loss and disturbance, seismic survey and exploratory drilling, as well as other ancillary activities. However, the effects from non-OCS oil and gas activities could possibly be more severe than the effects from routine OCS activities because the activities are closer to shore and in shallower environments. As a consequence, more benthic EFH may be damaged, and resulting changes in sedimentation and turbidity could affect a greater proportion of the water column.

Freshwater areas used by salmon and other anadromous fish are considered to be EFH and could be affected by nearshore OCS and non-OCS oil and gas activities such as pipeline dredging or by onshore pipelines that cross bodies of water, especially streams. The primary effects of pipeline crossings would be increasing turbidity and sedimentation of the benthic environment during construction and blocking migration of anadromous fish following construction. Any pipeline route would be required to comply with various Alaska Coastal Management Program policies. As a consequence, crossings of anadromous fish streams would be minimized and consolidated with other utility and road crossings of such streams. In addition, onshore pipelines would be designed, constructed, and maintained to reduce risks to fish habitats from a spill, pipeline break, or construction activities.

See individual sections on water quality, coastal habitats, and marine and pelagic habitats for a discussion of the effects of climate change on EFH in the Beaufort Sea and Chukchi Sea Planning Areas. As a heavily river-influenced system, increased river discharge could alter the salinity, temperature, and turbidity regimes in nearshore areas (Hopcroft et al. 2008). Climate change is also expected to decrease the spatial extent and temporal duration of sea ice as well as make the ice thinner, an overall increase in biological productivity in the open water, and a shift to a pelagic-based rather than a benthic-based food web (Hopcroft et al. 2008). In addition, ocean acidification may reduce the availability of calcite and aragonite to marine organisms.

The total number of oil spills and the extent of affected EFH areas would likely increase under the Program in conjunction with increased levels of petroleum exploration and production. See Table 4.6.1-4 for oil spill assumptions for Alaska. Non-OCS activities, such as oil and gas development in State waters, domestic transportation of oil, and commercial shipping (and other marine vessel traffic), may also result in accidental spills that could potentially impact fish resources within the Arctic. While effects on EFH resources would depend on the timing, location, and magnitude of specific oil spills, it is anticipated that most small to medium spills that occur in OCS waters would have limited effects on EFH, due to the relatively small areas likely to be exposed to high concentrations of hydrocarbons and the short period of time during which potentially toxic concentrations would be present. Large or catastrophic spills could result in long-term impacts to EFH habitat quality and managed species populations. See Section 4.4.6.4 for a detailed discussion of the impact of oil spills on EFH.

Arctic fishes could also be susceptible to adverse effects of oil spills (see Section 4.4.6.4.2). Most offshore spills would be small and likely have little effect on overall populations, since the areas with significant hydrocarbon concentrations would be localized relative to the broad distributions of most marine and anadromous fishes of the Beaufort and Chukchi Seas. However, population level effect could occur if large amounts of oil from a catastrophic spill were to reach shallow subtidal and intertidal sediments. Some anadromous species of the Alaskan North Slope could be at greater risk because of their unique life-history cycles. Juveniles of some species of whitefish (including broad whitefish, humpback whitefish, and least cisco) are intolerant of highly saline marine conditions. During their summer feeding dispersals in the Beaufort Sea, these species tend to remain within a narrow band of warm, low-salinity water along the coast. Offshore barrier islands offer additional protection by helping to maintain low-salinity corridors. Thus, unlike most subarctic fishes, whitefish along the North Slope have a reduced capacity to bypass localized disruptions to their migration corridor by moving offshore and around the impasse. An oil spill, even one of limited area, could block the narrow nearshore corridor and prevent fishes from either dispersing along the coast to feed or returning to their overwintering grounds in rivers of the North Slope. If a spill were localized in the sensitive nearshore zone, its location would also make it more amenable to cleanup by environmental response teams. There is no tanker traffic on the North Slope, which eliminates the possibility of a collision spill in that area.

Oil from spills occurring under the ice in the Beaufort and Chukchi Seas could remain trapped there throughout the winter unless removed, which, while difficult, could be done. Water quality would be negatively affected, and overwintering eggs, larvae, and invertebrate prey would likely be killed in affected areas. Surface spills occurring in the summer months would temporarily reduce EFH for surface-dwelling eggs, larvae, and pelagic prey species. Oil reaching nearshore areas could travel short distances upriver in anadromous fish streams as a result of tidal water movements, and some oil could become trapped in the interstitial spaces of the sediments. In such cases, EFH for salmon eggs and larvae could be affected. See Section 4.4.3.3 for a detailed discussion of accidental oil spills in ice and ice-free conditions.

Conclusion. Impact-producing factors for EFH include those from both OCS and non-OCS activities. Non-OCS activities with a potential to impact EFH in the Beaufort Sea and Chukchi Sea Planning Areas include oil and gas production in State waters, sediment dredging and disposal, and vessel traffic. Impacts from OCS activities would be limited by specific lease stipulations. Overall, the cumulative impacts on EFH would be moderate to major, considering ongoing and future OCS and non-OCS activities. The incremental contribution of routine Program activities to these impacts would be negligible to medium (see Section 4.4.6.3.3).

Accidental releases of oil and gas from OCS and non-OCS activities could also have effects on EFH. The incremental contribution of accidental spills associated with the Program on EFH would be negligible to medium, depending on the location, timing, duration, and size of spills; the proximity of spills to particular fish habitats; and the timing and nature of spill containment and cleanup activities (see Section 4.4.6.3.2). While most accidents related to OCS activities assumed under the cumulative spill scenario would be small and would have relatively minor incremental impacts on EFH, oil that reaches coastal wetlands could have more persistent impacts and could require remediation. Spills in deeper water, whether from OCS or non-OCS sources, are unlikely to have overall population-level effects on fish resources because of the relatively small proportion of similar available fish habitats that would come in contact with released oil at concentrations great enough to elicit toxic effects. Oil spills that have the greatest potential to impact EFH and managed species are those that occur in shallower subtidal and intertidal areas and spills that reach areas at the same time substantial numbers of eggs or larvae of managed species are present. Impacts associated with an unexpected, low-probability CDE affecting shallow and intertidal habitats could be moderate to major, depending on the size, duration, timing, and location of the spill.

4.6.3.4 Summary for Gulf of Mexico Region

4.6.3.4.1 Coastal and Estuarine Habitats. Cumulative impacts on barrier beaches and dunes result from factors that reduce sediment input to downdrift areas and increase erosion of beach and dune sands. Past actions such as channelization and diversion of Mississippi River flows (through dams and reservoirs) and beach stabilization projects (using groins, jetties, and seawalls) have contributed to sediment deprivation and submergence of coastal lands, particularly along the Louisiana coast, and are expected to continue into the foreseeable future. Ongoing and future actions/trends that affect barrier beaches and dunes include those related to oil and gas development in State and OCS waters, coastal development (onshore industry and wastewater discharge), vessel traffic, recreation, and climate change. Cumulative impacts on barrier beaches and dunes in the GOM are considered to be moderate to major.

Cumulative impacts on wetlands result from direct elimination of wetland habitat by excavation or filling, reduction of sediment inputs, erosion of wetland substrates, and degradation of wetland communities (by reduced water quality or hydrologic changes). Construction of canals or pipelines may require filling or excavating of wetlands. Other projects may reduce the sediment delivered to coastal wetlands from inflowing rivers. Losses of coastal wetlands have been occurring along the GOM coast for decades (especially in Louisiana) and are expected to continue into the foreseeable future. Many factors contribute to coastal land loss, including the effects of large storm events, subsidence, sea level rise, saltwater intrusion, drainage and development, canal construction, and reduced flooding. Upstream alterations of the Mississippi River drainage system are also important factors because construction of dams on upstream tributaries has reduced the sediment loads to the GOM by as much as 50%. Ongoing and future actions/trends that affect wetlands include those related to oil and gas development in State and OCS waters, coastal development (onshore industry and wastewater discharge), vessel traffic, dredging operations, and climate change. In addition, a number of coastal habitat protection and restoration projects have been initiated along the GOM coast to address erosion and land loss. Cumulative impacts on coastal wetlands in the GOM are considered to be moderate to major.

Seagrass beds grow in shallow, relatively clear and protected waters with predominantly sand bottoms; they are uncommon where freshwater inflow is high and salinities average less than 20 ppt. Most seagrass beds are in the Eastern GOM, where there are no past or present OCS activities and none proposed as part of the Program. Seagrass beds are found only within a few scattered, protected locations in the Western and Central GOM, although seagrass meadows occur in nearly all bay systems along the Texas coast. The distribution of seagrass beds in coastal waters of Western and Central GOM has diminished in recent decades, possibly due to high turbidity caused by increased marine vessel traffic. Ongoing and future actions/trends that affect seagrass habitats include onshore development, commercial and recreational fishing (trawling and anchoring), vessel traffic (anchoring), recreation (diving), and climate change. Cumulative impacts on seagrass beds in the GOM are considered to be moderate to major.

Routine operations under the Program in the GOM would result in minor localized impacts primarily due to facility construction, pipeline trenching and landfalls, channel dredging, and marine vessel traffic. The contribution of the Program to cumulative impacts therefore would generally be small to medium. The effects of expected accidental oil spills on coastal and estuarine habitats could be negligible to large, depending on the location, timing, duration, and size of the spill, and the timing and nature of spill containment and cleanup activities. Most expected oil spills are small (less than 50 bbl) and would not likely contact and affect coastal and estuarine habitats. Impacts associated with large oil spills (1,000 bbl or greater) or an unexpected, low-probability CDE that occur in or reach shallower nearshore areas have the greatest potential to affect extensive areas of shoreline and coastal and estuarine habitats. Although these are rare events, the impacts of such releases on coastal and estuarine habitats could range from moderate to major if they were to occur.

4.6.3.4.2 Marine Benthic and Pelagic Habitats. Cumulative impacts on marine benthic and pelagic habitats in the GOM result from any activities that disturb ocean bottom or marine habitats, increase sediment suspension (turbidity), degrade water quality, or affect the food supply of biota living in these habitats. Ongoing and future actions/trends that affect these resources include oil and gas activities in State waters, commercial shipping (including tankers), dredging and disposal of dredging spoils in OCS waters, and anchoring. Ongoing and future State and OCS oil and gas activities could also affect seafloor and pelagic habitats; these activities include marine vessel traffic, seismic surveys, and construction (all noise-producing activities), well drilling, pipeline placement (trenching, landfalls, and construction), platform placement (anchoring, mooring, and removal, except in deep waters), and routine discharges (drilling, production, platform, and vessel). Accidental oil spills are included among these actions. Cumulative impacts on benthic and pelagic habitats in the GOM are considered to be moderate to major.

Routine operations under the Program in the GOM could result in mainly temporary and localized impacts from ground disturbance during drilling and pipeline and platform placement, as well as the discharge of drilling muds and cuttings and produced water (sensitive habitats could have long term affects depending on their proximity to these activities). The incremental contribution to cumulative impacts on marine benthic habitats could range from negligible to medium and would be limited by existing mitigation measures. The incremental impacts of expected accidental oil spills on benthic habitats (most of which are less than 1,000 bbl) could range from negligible to small, depending on the size, duration, timing, and location of the spill, and the nature (i.e., sensitivity) of the benthic habitat contacted by oil. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could result in minor to moderate impacts if they were to occur. Major impacts to coral reef habitats could occur if the Flower Gardens Banks are heavily oiled and high mortality occurs.

4.6.3.4.3 Essential Fish Habitat. Cumulative impacts on EFH in the GOM result from any activities that kill managed fish species, disturb ocean bottom habitats, increase sediment suspension (turbidity), degrade water quality, or affect the food supply for fishery resources. Ongoing and future actions/trends that affect these resources include commercial fishing, commercial shipping (and other marine vessel traffic), land development, water quality degradation, dredge/fill and disposal operations, the construction of channel stabilization structures such as jetties, and climate change. Ongoing and future State and OCS oil and gas activities affect EFH; these include the generation of noise, well drilling, pipeline placement, subsea production well and platform placement, and routine discharges. Accidental oil spills are also among these actions. Cumulative impacts on EFH in the GOM are considered to be moderate to major.

Routine operations under the Program in the GOM could result in moderate short- and long-term impacts to EFH and managed species, mainly as a result of bottom disturbance and the creation of artificial reefs by production platforms. The incremental contribution to cumulative impacts on EFH could be negligible to medium and would be limited by specific lease stipulations. The incremental impacts of expected accidental oil spills on EFH (most of which are less than 1,000 bbl) would range from negligible to small, depending on the size of the spill, its location, environmental factors, and the uniqueness of the affected EFH. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could result in minor to moderate impacts if they were to occur.

4.6.3.5 Summary for Alaska – Cook Inlet

4.6.3.5.1 Coastal and Estuarine Habitats. Sensitive shoreline habitats in the lower Cook Inlet include marshes, sheltered tidal flats, sheltered rocky shores, and exposed tidal flats. Coastal habitats along Cook Inlet are influenced by dynamic tidal currents. Cumulative impacts on coastal and estuarine habitats result from the loss of beach and wetland habitat in Cook Inlet. While there are no past or ongoing OCS activities in the Cook Inlet Planning Area, other ongoing and future actions/trends that affect these resources include those related to State oil and gas development, commercial shipping (and other marine vessel traffic), coastal development, discharge of municipal wastes and other effluents, domestic transportation of oil and gas, logging, and climate change. These activities can be reasonably expected to continue into the future. Cumulative impacts on coastal and estuarine habitats in Cook Inlet are considered to be moderate.

Routine operations under the Program in Cook Inlet would result in minor localized impacts, primarily due to pipeline, road, and onshore facility construction, and marine vessel traffic. The contribution of the Program to cumulative impacts therefore would generally be negligible to medium. The effects of accidental oil spills on coastal and estuarine habitats could be negligible to medium, and depending on the location, timing, duration, and size of the spill, and the timing and nature of spill containment and cleanup activities. Most expected oil spills are small (less than 50 bbl) and would not likely contact and affect coastal and estuarine habitats. Impacts associated with large oil spills (1,000 bbl or greater) or an unexpected, low-probability CDE that occur in or reach shallower nearshore areas have the greatest potential to affect extensive areas of shoreline and coastal and estuarine habitats. Although these are rare events, the impacts of such releases on coastal and estuarine habitats could range from moderate to major if they were to occur.

4.6.3.5.2 Marine Benthic and Pelagic Habitats. Cumulative impacts on marine benthic and pelagic habitats in Cook Inlet result from any activities that disturb ocean bottom or marine habitats, increase sediment suspension (turbidity), degrade water quality, or affect the food supply of biota living in these habitats. Ongoing and future actions/trends that affect these resources include oil and gas activities in State waters, commercial shipping (including tankers), dredging and disposal of dredging spoils in OCS waters, and anchoring. State oil and gas activities (in upper Cook Inlet) and future OCS activities could affect seafloor and pelagic habitats; these include the generation of noise, well drilling, pipeline placement, subsea production well and platform placement, and routine discharges. Accidental oil spills are also among these actions. Cumulative impacts on benthic and pelagic habitats in Cook Inlet are considered to be moderate to major.

Routine operations under the Program in Cook Inlet could result in negligible to moderate impacts from ground disturbance during drilling and pipeline and platform placement, as well as the discharge of drilling muds and cuttings and produced water. The incremental contribution to cumulative impacts on marine benthic habitats could range from negligible to medium and would be limited by existing mitigation measures. The incremental contribution to cumulative impacts on marine benthic habitats could range from negligible to medium and would be limited by existing mitigation measures. The incremental impacts of expected accidental oil spills on benthic habitats (most of which are less than 1,000 bbl) could range from negligible to small, depending on the size, duration, timing, and location of the spill, and the nature (i.e., sensitivity) of the benthic habitat contacted by oil. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could result in minor to moderate impacts if they were to occur.

4.6.3.5.3 Essential Fish Habitat. Cumulative impacts on EFH in Cook Inlet result from any activities that kill managed fish species, disturb ocean bottom habitats, increase sediment suspension (turbidity), degrade water quality, or affect the food supply for fishery resources. Ongoing and future actions/trends that affect these resources include land use practices (e.g., logging), point and non-point source pollution, dredging and disposal operations, anchoring, fishing (commercial, subsistence, personal use, and sportfishing), and commercial shipping (including imported oil). Subsistence fishing is subject to harvest limits that reduce the potential for overfishing, and much of Cook Inlet is defined as a nonsubsistence area where subsistence fishing is not authorized. For this reason, the impacts related to subsistence are considered minor. State oil and gas activities (in upper Cook Inlet) and future OCS activities could affect EFH (there are no ongoing OCS activities in the inlet); these include the generation of noise, well drilling, pipeline placement, subsea production well and platform placement, and routine discharges. Accidental oil spills are also among these actions. Cumulative impacts on EFH in the Cook Inlet are considered to be minor to moderate.

Routine operations under the Program in Cook Inlet could result in moderate short- and long-term impacts to EFH and managed species, mainly as a result of bottom disturbance during the placement of pipelines and production platforms. The incremental contribution to cumulative impacts on EFH could be negligible to medium and would be limited by specific lease stipulations. The incremental impacts of expected accidental oil spills on EFH (most of which are less than 1,000 bbl) would range from negligible to small, depending on the size of the spill, its location, environmental factors, and the uniqueness of the affected EFH. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could result in moderate to major impacts if they were to occur.

4.6.3.6 Summary for Alaska – Arctic

4.6.3.6.1 Coastal and Estuarine Habitats. Arctic coastal habitats are greatly influenced by a short growing season and extremely cold winters; onshore sediments are underlain by permanently frozen soil (permafrost). They are also greatly affected by the dynamics of sea ice, which dominates coastal habitats during most of the year. The Arctic coastline is highly disturbed due to the movement of sea ice that frequently is pushed onshore, scouring and scraping the coastline. The effects of climate change on Arctic habitats are also significant. These include decreases in sea ice cover, warming of permafrost, a longer growing season, and changes in precipitation. Portions of the coast have experienced considerable erosive losses (up to 457 m [1,500 ft]) over the past few decades; the erosion rate in areas of the Beaufort Sea coast more than doubled between 1955 and 2005. Projections for future climate change indicate that these changes are expected to continue.

Cumulative impacts on barrier beaches and dunes result from factors that increase erosion of beach and dunes, such as disturbance of dune vegetation or beach and dune substrates. Increases in wave action also contribute to the erosion of beaches. Accidental oil spills may also affect these resources. While there are no past or ongoing OCS activities in the Beaufort Sea and Chukchi Sea Planning Areas (other than exploratory drilling), other ongoing and future actions/trends that affect beaches and sand dunes include those related to State oil and gas development, commercial shipping (and other marine vessel traffic), coastal development, and climate change. These activities can be reasonably expected to continue into the future. Cumulative impacts on coastal and estuarine habitats in the Arctic region are considered to be moderate.

Routine operations under the Program in the Arctic region would result in minor localized impacts primarily due to pipeline, road, and onshore facility construction, and marine vessel traffic. The contribution of the Program to cumulative impacts therefore would generally be small to medium. The effects of expected accidental oil spills on coastal and estuarine habitats could be negligible to large, depending on the location, timing, duration, and size of the spill, and the timing and nature of spill containment and cleanup activities. Most expected oil spills are small (less than 50 bbl) and would not likely contact and affect coastal and estuarine habitats. Impacts associated with large oil spills (1,000 bbl or greater) or an unexpected, low-probability CDE, however, can affect extensive areas of shoreline and coastal and estuarine habitats. Although these are rare events, the impacts of such releases on coastal habitats could range from moderate to major if they were to occur.

4.6.3.6.2 Marine Benthic and Pelagic Habitats. Cumulative impacts on marine benthic and pelagic habitats in the Arctic region result from any activities that disturb ocean bottom or marine habitats, increase sediment suspension (turbidity), degrade water quality, or affect the food supply of biota living in these habitats. Ongoing and future actions/trends that affect these resources include oil and gas activities in State waters, commercial shipping (including tankers), dredging and disposal of dredging spoils in OCS waters, and anchoring. State oil and gas activities (especially along the Beaufort Sea coastline) and future OCS activities could affect seafloor and pelagic habitats; these activities include the generation of noise, well drilling, pipeline placement, subsea production well and platform placement, and routine discharges. Accidental oil spills are also among these actions. Cumulative impacts on benthic and pelagic habitats in the Arctic region are considered to be moderate to major.

Routine operations under the Program in the Arctic region could result in impacts from ground disturbance during drilling and pipeline and platform placement, as well as the discharge of drilling muds and cuttings and produced water (sensitive habitats could have long term affects depending on their proximity to these activities). The incremental contribution to cumulative impacts on marine benthic habitats could range from negligible to medium and would be limited by existing mitigation measures. The incremental impacts of expected accidental oil spills on benthic habitats (most of which are less than 1,000 bbl) would range from negligible to small, depending on the size, duration, timing, and location of the spill, and the nature (i.e., sensitivity) of the benthic habitat contacted by oil. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could result in minor to moderate impacts if they were to occur.

4.6.3.6.3 Essential Fish Habitat. Cumulative impacts on EFH in the Arctic region result from any activities that kill managed fish species, disturb ocean bottom habitats, increase sediment suspension (turbidity), degrade water quality, or affect the food supply for fishery resources. Ongoing and future actions/trends that affect these resources include subsistence fishing, commercial shipping (including tankers and other marine vessels), coastal modifications, hardrock mining, dredging and disposal operations, anchoring, and climate change. Commercial fishing does not occur in the Beaufort Sea and Chukchi Sea Planning Areas. Sportfishing in the Arctic region is currently a minor activity, but could increase if regulations change and warming temperatures allow an increase in marine vessel traffic. State oil and gas activities (especially along the Beaufort Sea coastline) and future OCS activities could affect EFH; these activities include the generation of noise, well drilling, pipeline placement, subsea production well and platform placement, and routine discharges. Accidental oil spills are also among these actions. Cumulative impacts on EFH in the Arctic region are considered to be moderate to major.

Routine operations under the Program in the Arctic region could result in moderate short- and long-term impacts to EFH and managed species, mainly as a result of bottom disturbance during the placement of pipelines and production platforms. The incremental contribution to cumulative impacts on EFH could be negligible to medium and would be limited by specific lease stipulations. The incremental impacts of expected accidental oil spills on EFH (most of which are less than 1,000 bbl) would range from negligible to small, depending on the size of the spill, its location, environmental factors, and the uniqueness of the affected EFH. Large spills (1,000 bbl or greater) and unexpected CDEs would also depend on these factors, and could result in minor to moderate impacts if they were to occur.

4.6.4 Marine and Coastal Fauna

Previous BOEM/MMS NEPA documents for OCS lease sales have addressed cumulative impacts on marine and coastal fauna. Unless referenced otherwise, the following cumulative impacts discussion includes information provided in those NEPA documents prepared for the GOM (see http://www.gomr.boemre.gov/homepg/regulate/environ/nepa/nepaprocess.html) and for Alaska (see http://alaska.boemre.gov/ref/eis_ea.htm).

4.6.4.1 Gulf of Mexico Region

4.6.4.1.1 Mammals. Section 4.4.7.1.1 discusses direct and indirect impacts on marine and terrestrial mammals in the GOM region resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on these resources result from the incremental impacts of the Program (described in Section 4.4.6.1.1) when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS activities. Table 4.6.1-2 presents the exploration and development scenario for the GOM cumulative case, which takes into account activities associated with the Program in combination with those from other ongoing and future OCS programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in the GOM are summarized in Table 4.6.1-5 and discussed below, as applicable.

Marine Mammals. The cumulative analysis considers past, ongoing, and foreseeable future human and natural activities that may occur and adversely affect marine mammals in the same general area. These activities include effects of the OCS Program (proposed action and prior and future OCS sales), oil and gas activities in State waters, commercial shipping, commercial fishing, recreational fishing and boating activities, military operations, scientific research, and natural phenomena. Specific types of impact-producing factors considered include noise from numerous sources, pollution, ingestion and entanglement in marine debris, vessel strikes, habitat degradation, military activities, industrial development, community development, climate change, and natural catastrophes. Section 4.4.7.1.1 provides the major impact-producing factors related to the Program.

Routine Activities.

OCS Activities. Marine mammals and their habitats in the GOM could be affected by a variety of exploration, development, and production activities as a result of the proposed and future OCS leasing actions (see Section 4.4.7.1.1). These activities include seismic exploration, offshore and onshore infrastructure construction, discharge of operational wastes, vessel and aircraft traffic, and explosive removal of platforms. Impacts on marine mammals from these activities may include physical injury or death; behavioral disturbances; lethal or sublethal toxic effects; and loss of reproductive, nursery, feeding, and resting habitats.

Potential impacts (primarily behavioral disturbance) on marine mammals from OCS-related seismic activity would be short term and temporary, and not expected to result in population level impacts for any affected species with implementation of appropriate mitigation measures.

Impacts from OCS construction and operation activities could include the temporary disturbance and displacement of individuals or groups by construction equipment and long-term disturbance of some individuals from operational noise. No long-term, population-level effects are expected because individuals most affected by these impacts would be those in the immediate vicinity of the construction site or operational platform and disturbance of individuals during construction would be largely temporary.

Operational and waste discharges (e.g., produced water, drilling muds, and drill cuttings) would be disposed of through downhole injection into NPDES-permitted disposal wells, and would not be expected to result in any incremental impacts on marine mammals. Liquid wastes (such as bilge water) may also be generated by OCS support vessels and on production platforms. While these wastes may be discharged (if permitted) into surface waters, they would be rapidly diluted and dispersed, and are expected to result in minor incremental impacts on marine mammals. Drilling and production wastes may contain materials such as metals and hydrocarbons, which can bioaccumulate through the food chain into the tissues of marine mammals. Although the bioaccumulation of anthropogenic chemicals has been reported for a variety of marine mammals, adverse impacts or population-level effects resulting from such bioaccumulation have not been demonstrated (Norstrom and Muir 1994; Muir et al. 1999).

Marine mammals could be temporarily disturbed by OCS vessel traffic (all species) or incur injury or death from collisions with support vessels (primarily larger, slower moving cetaceans). The addition of up to 1,900 OCS vessel trips per week under the Program could result in minor to moderate incremental impacts to marine mammals, be largely short term, and not result in population-level effects. Noise from helicopter overflights would be transient. Impacts on marine mammals would be behavioral in nature, primarily resulting in short-term disturbance in normal activities, and would not be expected to result in population-level effects. Appropriate mitigation measures could lessen the potential for incremental impacts from vessel and helicopter traffic.

There have been no documented losses of marine mammals resulting from explosive removals of offshore oil and gas structures, but there are sporadic incidents reported of marine mammals being killed by underwater detonations (Continental Shelf Associates 2004b; MMS 2007e, 2008a). Harassment of marine mammals as a result of a non-injurious physiological response to the explosion-generated shock wave as well as to the acoustic signature of the detonation is also possible. However, explosive platform removals would comply with BOEM guidelines and would not be expected to adversely affect marine mammals in the GOM.

All of the marine mammals in the GOM are potentially exposed to OCS-industrial activities (particularly noise) due to the rapid advance into the GOM deep oceanic waters by the oil and gas industry in recent years; whereas, over two decades ago, the confinement of industry to shallower coastal and continental shelf waters generally only exposed the bottlenose dolphin, Atlantic spotted dolphin, and West Indian manatee to industry activities and their related sounds. Industry noise sources include seismic operations, fixed platforms and drilling rigs, drilling ships, helicopters, vessel traffic, and explosive operations (particularly for structure removal).

Non-OCS Activities. A number of non-OCS activities such as State oil and gas exploration and development, commercial and recreational fishing, marine vessel traffic, industrial and municipal discharges, climate change, and invasive species could also affect marine mammals in the GOM.

Oil and Gas Exploration and Development in State Waters. Exploration, construction, and operation activities associated with State leases would occur in nearshore and coastal areas, while OCS platforms and pipelines would be located away from coastal areas (with the exception of relatively few pipeline landfalls and onshore bases and processing facilities). Thus, State oil and gas leasing activities may be expected to have a greater potential for affecting marine mammals in coastal habitats than would the proposed OCS actions. The marine mammal species most likely affected by State leases are the bottlenose dolphin, Atlantic spotted dolphin, and the West Indian manatee.

Commercial Fisheries. Commercial fisheries are an impacting factor for marine mammals in the GOM. These fisheries employ a variety of methods, such as longlines, seines, trawls, and traps, which can result in the entanglement, injury, and death of mammal mammals. For more than a decade, however, few human-induced mortalities or serious injuries of marine mammals due to commercial fishery interactions have occurred in the GOM. The following interactions with commercial fisheries were reported by Waring et al. (2010):

- In 2008, one mortality and two serious injuries of Risso's dolphins in the GOM related to entanglement interactions with the pelagic longline fishery.

- In 2008, there was one killer whale released alive after an entanglement incident with the pelagic longline fishery.

- In 1999, there was one reported stranding of a false killer whale that was likely caused by fishery interactions or other human-related causes evidenced by its fins and flukes having been amputated.

- From 1998 through 2007, there were no reported fishing-related mortalities of short-finned pilot whales in the GOM. However, one animal was released alive after an entanglement interaction with the pelagic longline fishery.

- From 1998 through 2007, there were no reported fishing-related mortalities of beaked whales in the GOM. However, during 2007, one unidentified beaked whale was released alive after an entanglement interaction with the pelagic longline fishery.

- From 1998 through 2008, there were no reported fishing-related mortalities of sperm whales in the GOM. However, one animal was released alive with no serious injuries after an entanglement interaction with the pelagic longline fishery.

- Some bottlenose dolphins have suffered mortalities associated with the shark bottom longline fishery, pelagic longline fishery, shrimp trawl fishery, blue and stone crab trap/pot fisheries, menhaden purse seine fishery, and gillnet fishery. Strandings of bottlenose dolphins have also occurred throughout the northern GOM from both human-caused and natural events. Human-caused strandings result from gear entanglement, mutilation, gunshot wounds, vessel strikes, contaminants, and ingestion of foreign objects.

- Fishery interactions likely caused the stranding of two Atlantic spotted dolphins in 2004.

- A stranded spinner dolphin had monofilament line around its tail and abrasions around its flukes as though it had been towed. It also had possible propeller marks.

Marine Vessel Traffic. There are a number of non-OCS activities that are occurring in the GOM that could result in collisions between marine mammals and ships. These activities include dredging and marine disposal, the domestic transportation of oil and gas, State oil and gas development, foreign crude oil imports, commercial shipping and recreational boating, commercial fisheries, and military training and testing activities. Vessel traffic associated with these activities may also disturb normal behaviors with unknown long-term consequences. With all of these activities, the GOM is one of the world's most concentrated shipping areas (USACE 2010). The GOM also supports an extensive commercial fishery, as well as recreational boating. Because of the very large number of vessels typically present in the GOM, the potential for vessel-marine mammal collisions is high, and may be expected to increase for the foreseeable future. The amount of OCS-related vessel traffic anticipated as a result of the Program is provided in Table 4.4.1-1.

Contaminants. There are a number of non-OCS facilities or activities that discharge wastes to GOM waters, and thus may expose marine mammals to potentially toxic materials or solid debris that they could become entangled in or ingest. These facilities or activities include sewage treatment plants, industrial manufacturing or processing facilities, electric generating plants, cargo and tanker shipping, cruise ships, commercial fishing, and recreational pleasure craft. In addition, the Mississippi River (and to a lesser extent, other rivers and streams that discharge to the northern GOM) discharges waters containing suspended sediments, fertilizers, herbicides, and urban runoff (Rabalais et al. 2001, 2002a). While marine mammals are exposed to a variety of contaminants from these discharges, little is known about the levels of contaminants at which lethal or sublethal effects may be incurred. These discharges may also affect habitat quality in the vicinity of the discharges.

The role of exposure to toxins to marine mammal mortality is unknown. Elevated levels of chemicals such as polychlorinated biphenyls (PCBs) and pesticides have been measured in individuals sampled from waters that receive municipal, industrial, and agricultural inputs and have high concentrations of contaminants (Waring et al. 2010; see discussion on bottlenose dolphins, GOM eastern coastal stock). There is little information, however, regarding the level at which tissue concentrations of contaminants may result in lethal or sublethal effects.

Climate Change. Marine mammal populations throughout the GOM may be adversely affected by climate change and, to a lesser extent, by hurricane events. There is growing evidence that climate change is occurring, and potential effects in the GOM may include a change (i.e., rise) in sea level or a change in water temperatures. Such changes could affect the distribution, availability, and quality of feeding habitats and the abundance of food resources. It is not possible at this time to identify the likelihood, direction, or magnitude of any changes in the environment of the GOM due to changes in the climate, making it also difficult, if not impossible, to speculate on the climate change impacts on marine mammals. Such information is not, however, essential to a reasoned choice among the alternatives in this PEIS (see Section 1.4.2). Climate change is occurring independently of OCS Program activity, and choosing any alternative presented herein will likely have little or no effect on the occurrence of climate change.

Natural Catastrophes. Severe storm events such as hurricanes may result in direct or indirect mortality of manatees and have the potential to impact their nearshore habitats (Langtimm and Beck 2003). Heightened wave action and intensity could alter nearshore channels affecting the abundance and distribution of shallow-water habitats such as lagoons and bays, while sediments deposited into foraging habitats by storm waves may alter the thermal environment and affect aquatic vegetation in feeding habitats. Because hurricanes are annual events that are an inherent component of the overall GOM ecosystem, it may be assumed that marine mammals of the GOM have experienced hurricane impacts in the past and may be expected to continue to experience future hurricane events.

***Other Impacting Factors*.** Marine mammals may also be impacted by other factors such as unusual mortality events (UMEs) and invasive species. A UME is an unexpected stranding that involves a significant die-off of any marine mammal population, and demands immediate response (NMFS 2011b). Since establishment of the UME program in 1991 through December 2011, there have been 55 formally recognized UMEs in the U.S., with a third of them occurring in the GOM (NMFS 2011b). Species in the GOM most commonly involved in UMEs are bottlenose dolphins and manatees. An ongoing UME in the GOM is discussed in Section 3.8.1.1.1. Causes of UMEs have been determined for 26 of the UMEs, and include infections, biotoxins (particularly domoic acid and brevetoxin), human interactions, and malnutrition. Red tides in the GOM, caused by annual blooms of the dinoflagellate Karenia brevis, are the source of UMEs caused by biotoxins in the GOM (NMFS 2011b). Invasive species could affect some marine mammals by disrupting local ecosystems and fisheries of the GOM. As examples, the Australian jellyfish (Phylloriza punctata) introduced to the northern GOM may feed heavily on juvenile fish and fish eggs (Ray 2005), while exotic shrimp viruses may affect shrimp and other crustaceans such as copepods and crabs (Batelle 2001). These could affect the prey base for some marine mammals.

***Accidents*.** Marine mammals could be exposed to oil accidentally released from platforms, pipelines, and vessels (Table 4.4.2-1). Potential non-OCS sources of oil spills in the GOM include the domestic transportation of oil, State oil and gas development, and natural sources such as oil seeps. Accidental oil releases from OCS activities and other sources could expose marine mammals to oil by direct contact or through the inhalation or ingestion of oil or tar deposits. The magnitude and duration of exposure will be a function of the location, timing, duration, and size of the spill; the proximity of the spill to feeding and other important habitats; the timing and nature of spill containment; and the status of the affected animals. Depending on their location, as well as the location of non-OCS oil sources, accidental spills associated with the Program could contribute to the overall exposure of marine mammals in the northern GOM. Most expected small to medium spills (less than 1,000 bbl) would have limited effects on marine mammals due to the relatively small areas likely to incur high concentrations of hydrocarbons and the short period of time during which potentially toxic concentrations would be present. The magnitude of impact would be expected to increase should a spill occur in habitats important to marine mammals or affect a number of individuals from a population listed under the ESA. However, some spills from OCS activity may locally represent the principal source of oil exposure for some species, especially for spills contacting important coastal and island habitats.

Cumulative impacts on marine mammals in the GOM as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be minor to moderate over the next 40 to 50 years. Non-OCS activities or phenomena include climate change, natural catastrophes, contaminant releases, vessel traffic, commercial fishing, and invasive species. The incremental contribution of routine Program activities to these impacts would be negligible to medium (see Section 4.4.7.1.1).

Marine mammals may also be adversely affected by exposure to oil that is accidentally released from OCS and non-OCS activities as well as naturally occurring seeps. The cumulative impacts of past, present, and future oil spills on marine mammals would be minor to moderate. The incremental impacts of expected accidental spills associated with the Program on marine mammals would be small to large, depending on the location, timing, and volume of the spills; the environmental settings of the spills; and the species exposed to the spills (Section 4.4.7.1.1). Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from moderate to major if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to the impacts of spills regardless of size, but their incremental contribution to cumulative impacts is generally expected to be small. A more detailed discussion of the effects of oil spills on marine mammals in the GOM is presented in Section 4.4.7.1.1.

Terrestrial Mammals. Under the Program, terrestrial mammals in the GOM are not expected to be affected by routine OCS-related activities (Section 4.4.7.1.1). The terrestrial mammals considered in the impact analysis for the Program are four federally endangered GOM coast beach mouse subspecies and the federally endangered Florida salt marsh vole. Because of the listing of these species under the ESA, as well as their occurrence in protected areas, the siting and construction of any onshore facilities associated with the Program would be required to take into account these species and their habitats, and construction activities would not be allowed in the habitats of these species.

Present beach mice habitat is no longer of optimal quality because of historical beach erosion, construction, and tropical storm damage. Dredge-and-fill activities occur throughout the nearshore areas of the U.S. and disrupt beach and transport, which could affect coastal systems of dunes where beach mice live. Coastal construction and traffic can be expected to threaten beach mice populations on a continual basis. Natural catastrophes including storms, floods, droughts, and hurricanes can substantially reduce or eliminate beach mice. Storms can wash large amounts of debris into dune and marsh habitats. Trash and debris may be mistakenly consumed by beach mice or may entangle them. Cleanup efforts to remove debris could result in adverse habitat impacts. Other activities that threaten beach mice and the Florida salt marsh vole include predation and competition, artificial lighting, and coastal spills. Predation from feral and free-ranging cats and dogs, feral hogs, coyotes, and red foxes, and competition with common house mice could reduce beach mice and Florida salt marsh vole populations. Isolation of small populations of beach mice due to habitat fragmentation can preclude gene flow between populations and cause a loss of genetic diversity. Separation of frontal dune habitat from scrub habitat by a highway can make a beach mouse especially vulnerable to hurricane impacts. Global climate change and sea level rise could also impact the Florida salt marsh vole and beach mice (Bird et al. 2009; USFWS 2008, 2009; Wooten 2008).

Activities in the GOM that could result in the accidental release of oil and may affect terrestrial mammals and their habitats include oil production from prior, proposed, and future OCS sales; domestic transportation of oil; State oil development; foreign crude oil imports; and military training activities involving open-water ship refueling. If spills from these activities occur in the vicinity of, or are transported by GOM currents to, the habitats of the beach mice or the Florida salt marsh vole, potential impacts would be similar in nature to those identified for the Program. Impacts associated with an oil spill may include loss of thermoregulatory ability from oiling of fur, lethal and sublethal toxic effects from inhalation or ingestion of oil or oil-contaminated foods, a decrease in food supply due to oiled vegetation, a decrease in habitat quantity and quality due to oiling of beach sands, and the fouling of burrows and nests. In addition, spill response activities could further impact habitats due to beach cleanup activities and vehicle and pedestrian traffic.

Given the relatively small number of spills that are expected under the Program and during the life of the Program (Table 4.6.1-4), the requirement under the *Oil Pollution Act of 1990* to prevent contact of protected or sensitive habitats (such as the habitats of the beach mice and the salt marsh vole) with spilled oil, and the need of a spill to be associated with environmental conditions (such as a storm surge sufficient to transport the spilled oil over foredunes) that could favor exposure of the species and their habitats, relatively minor cumulative impacts are expected from accidental oil spills from all potential sources, and the incremental contribution of spills associated with the Program is expected to be small.

Conclusion. Cumulative impacts on terrestrial mammals in the GOM as a result of ongoing and future OCS and non-OCS program activities could be minor to moderate over the next 40 to 50 years. Non-OCS activities or phenomena that may affect populations of terrestrial mammals include climate change, natural catastrophes, contaminant releases, vehicle traffic, and invasive and feral species. The incremental contribution of routine Program activities to these impacts would be negligible to medium (see Section 4.4.7.1.1).

Terrestrial mammals may also be adversely affected by exposure to oil that is accidentally released from OCS and non-OCS operations. The cumulative impacts of past, present, and future oil spills on terrestrial mammals could be minor to moderate. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on terrestrial mammals would be small to large, depending on the location, timing, duration, and size of the spill; the proximity of the spill to feeding and other important habitats; the timing and nature of spill containment; and the status of the affected animals (see Section 4.4.7.1.). It is unlikely that the Florida salt marsh vole would be affected by an oil spill because its habitat is located far from areas where oil and gas leasing and development occur. However, if their habitat is oiled, the incremental contribution to cumulative impacts on this species could be small to medium (depending on the size of the spill).

An unexpected, low-probability CDE has a greater potential to affect the habitats of beach mice and the Florida salt marsh vole; therefore, impacts would range from moderate to major if one were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to the impacts of spills regardless of size, but their incremental contribution to cumulative impacts is generally expected to be small. A more detailed discussion of the effects of oil spills on terrestrial mammals in the GOM is presented in Section 4.4.7.1.1.

4.6.4.1.2 Marine and Coastal Birds. Section 4.4.7.2.1 discusses direct and indirect impacts on marine and coastal birds in the GOM resulting from the Program (OCS program activities from 2012 to 2017). Cumulative impacts on marine and coastal birds result from the incremental impacts of the Program when added to impacts from existing and reasonably foreseeable future OCS program activities (that are not part of the Program) and other non-OCS program activities. Table 4.6.1-1 presents the exploration and development scenario for the GOM cumulative case (encompassing the Program and other OCS program activities) over the next 40 to 50 years. A number of OCS program activities could affect GOM marine or terrestrial birds or their habitats; these include offshore structure placement and pipeline trenching, offshore structure removal, operational discharges and wastes, service vessel and aircraft traffic, construction and operation of onshore infrastructure (including new pipeline landfalls), and noise. Potential impacts on marine and coastal birds from service program activities include injury or mortality of birds from collisions with platforms, vessels, and aircraft; exposure to operational discharges and ingestion of trash or debris; loss or degradation of habitat due to construction activities; and behavioral disturbance due to the presence of, and noise generated by, equipment and human activity.

Non-OCS program activities affecting marine and coastal birds include dredging and marine disposal; coastal and community development; onshore and offshore construction and operations of facilities associated with State oil and gas development and with the extraction of nonenergy minerals; commercial and recreational boating; and small aircraft traffic. Potential impacts on marine and coastal birds from these activities are similar to those under the OCS program and include injury or mortality of birds from collisions with platforms associated with State oil and gas development and other onshore and offshore structures (e.g., radio, television, cell phone towers or wind towers); non-energy mineral mines (e.g., sand and gravel and other hard minerals mined in the northern part of the GOM; onshore industrial, commercial, and residential development; exposure to discharges from permitted point sources such as sewage treatment discharges and nonpoint sources such as irrigation runoff, or accidental releases (e.g., oil spills), as described in Section 4.6.2.1.1 and summarized in Table 4.6.1-5; exposure to emissions from various onshore and offshore sources (e.g., power generating stations, refineries, and marine vessels), as described in Section 4.6.2.1.2; ingestion of trash or debris; loss or degradation of habitat due to construction and operations activities; and behavioral disturbance due to the presence of noise generated by equipment and human activity. Other trends such as sea level rise and increasing seawater temperature brought on by global climate change, as well as extreme wind conditions from storm events, are also expected to adversely affect marine and coastal birds over the next 40 to 50 years.

Injury or Mortality from Collisions. Birds are drawn to lighted platforms and often circle the platform before moving on or stopping. This behavior increases the potential for platform collision (Russell 2005). Annual bird collision mortalities under the Program (estimated at about 10,000 to 22,500) represent less than 0.01% of the hundreds of millions of birds that annually migrate across the GOM (Russell 2005). Under the cumulative scenario, annual collision mortality (estimated at 200,000 birds under current OCS activities in the GOM) could increase by about 8%. During the life of the Program from 2012 to 2017, older platforms would be decommissioned and removed as new platforms are installed, so it is likely that the estimated 200,000 collision-related deaths per year would persist throughout the life of the program. The Program would likely result in a small incremental increase of the total annual bird collision mortality in the GOM that occurs from collisions with other OCS and non-OCS structures (Klem 1990; Kerlinger 2000).

Exposure to Wastewater Discharges and Air Emissions. The discharge of operational wastes and air emissions from current OCS- and non-OCS-related marine vessel traffic and platform operations is strongly regulated and would continue to be regulated over the next 40 to 50 years. However, such wastes and emissions would still expose marine and coastal birds to potentially toxic materials or to solid debris that could be ingested or result in entanglement. In addition, the Mississippi River, and, to a lesser extent, other rivers and streams annually discharge waters containing suspended sediments, agricultural fertilizers and herbicides, and urban runoff to the northern GOM (Rabalais et al. 2001, 2002b). Birds and their habitats in the vicinity of these discharges may be exposed to lethal and sublethal levels of contaminants. Operational wastewater discharges and air emissions associated with the Program would contribute to the overall cumulative risk of toxic exposure and debris ingestion or entanglement of existing OCS and non-OCS wastewater discharges and air emissions in the GOM, but the incremental increase in impact is expected to be small relative to these other activities.

Under the Program, marine and coastal birds could be exposed to oil accidentally released from platforms, pipelines, and marine vessels, and would be most susceptible to adverse impacts from spills occurring in coastal areas and affecting feeding and nesting areas. Accidental oil releases occur in the GOM from a variety of non-OCS related activities, such as the domestic transportation of oil, import of foreign crude oil, and State development of oil. Crude oil may also enter the environment of the northern GOM from naturally occurring seeps (MacDonald et al. 1996; MacDonald 1998; NRC 2003b). Oil releases from all sources may expose marine and coastal birds via direct contact or through the inhalation or ingestion of oil or tar deposits (see Section 4.4.7.2.1).

The spills that could occur in the cumulative scenario are shown in Table 4.6.1-3. Spills from non-OCS sources could occur from import tankers, State oil and gas operations, and coastal transportation of crude and refined petroleum products. Releases from natural seeps in the northern part of the GOM have been estimated at about 73,000 tons (526,000 bbl) per year (Kvenvolden and Cooper 2003). Most spills associated with the Program would be relatively small (less than 50 bbl) (Table 4.4.2-1). Depending on their location, accidental spills associated with the Program could represent a major component of the overall exposure of marine and coastal birds in the GOM OCS Planning Areas.

The magnitude and duration of exposure, and any subsequent adverse effects, would be a function of the location, timing, duration, and size of the spill; the proximity of the spill to feeding habitats; and the timing and nature of spill containment. Spills in nearshore coastal areas have the greatest potential for impacting high concentrations of bird populations. Most activities associated with the Program would take place in deep or ultra-deep waters. Some seabirds spend a significant amount of time offshore and could be exposed to accidental oil spills that occur in these deep waters, but even marine birds that remain in coastal waters could be exposed to accidental oil spills if they were to occur closer to shore.

Loss and Degradation of Habitat. Marine and coastal birds could be affected by platform construction and removal activities, and pipeline trenching, which could disrupt behaviors of nearby birds. Platforms constructed under the Program would increase the number of offshore platforms present in open-water areas of the northern GOM; and these structures may be used by birds to rest or avoid bad weather conditions during spring and fall migrations across the GOM (see Section 4.4.7.2). The Program would increase the number of platforms to be removed by only 9% of current OCS numbers, and up to 75% of the construction of new platforms would occur in deep water (i.e., 300 m [1,000 ft] or greater), well away from coastal areas. Under the Program, there would also be construction associated with no more than 12 new pipeline landfalls and offshore pipeline placement (Table 4.4.1-1). These platform and pipeline construction activities could add to the overall disturbance level of birds and their habitats from all construction sources in the GOM.

Platform construction and removal under the Program would be localized (primarily in deep water areas) and short in duration, and would result in only a small increase in the overall level of disturbance incurred by birds and their habitats from all construction activities in the GOM OCS Planning Areas. Pipeline trenching and landfall construction that would occur under the Program would similarly be of short duration and limited in extent (associated with no more than 12 new landfalls), and would be expected to contribute little to overall levels of bird disturbance that occur in coastal areas of the GOM on a much more regular basis from existing OCS and non-OCS construction activities, such as channel construction and maintenance, creation of harbor and docking areas and facilities, State oil and gas development (including platform construction and removal), non-energy minerals extraction, and pipeline emplacement.

Marine vessel traffic potentially disturbs, feeding and nesting birds with unknown long-term consequences. The GOM is one of the world's most concentrated commercial shipping areas (COE 2003a, b), and it supports extensive commercial fishing and recreational boating. As a result, OCS and non-OCS program-related vessel traffic disturbs birds on a daily basis. This trend is expected to increase as marine traffic in the GOM increases over the next 40 to 50 years (see Table 4.6.2-1). OCS program-related marine vessel traffic in the GOM could be as high as 1,900 trips per week over the next 40 to 50 years; marine vessel traffic associated with the Program represents about 27% of this traffic (Section 4.6.2.1). Non-OCS program traffic includes that related to crude oil and natural gas imports, commercial container vessels, military and USCG vessels, cruise ships, commercial fishing, and small watercraft. In 2010, the Port of New Orleans alone handled about 7,500 vessel calls (mainly tanker and dry bulk carrier), about 140 vessel calls per week (USDOT 2011b). Impacts on water quality from marine traffic arise from regular discharges of bilge water and waste, leaching of antifouling paints, and incidental spills (MMS 2001d), although operational discharges and spillage from marine vessels have declined substantially in the past few decades (NRC 2003b). Vessel traffic associated with the Program would result in a small increase in the overall disturbance of birds in the GOM region.

Disturbance Due to Noise. Noise generated during construction activities and normal operations (e.g., helicopter overflights) may disturb marine and coastal birds, causing a short-term change in normal behavior and potentially disrupting feeding and nesting activities. Non-OCS activities that currently generate noise in the GOM include construction and/or operation of offshore structures for State oil and gas development; offshore LNG facilities and tankers; marine mineral mining; dredging and marine disposal; commercial and recreational vessel traffic; small aircraft flight; and military training and testing activities. These activities are expected to continue or increase into the foreseeable future. Although noise generated as a result of the Program would likely add only a small increment to the overall (cumulative) noise levels in the GOM, locally it could represent the dominant noise in the environment, resulting in more moderate impacts on marine and coastal birds.

Climate Change and Storm Events. Populations of marine and coastal birds throughout the GOM may be adversely affected by climate change and, to a lesser extent, by storm events (including hurricanes). As discussed in Section 3.3, there is growing evidence that climate change is occurring, and potential effects in the GOM may include sea level rise and increases in water temperatures in the GOM. Over time these changes will result in a loss of wetlands in the GOM, important water bird habitat. Climate change could also affect the distribution, availability, and quality of feeding habitats and the abundance of food resources. It is not possible at this time to identify the likelihood, direction, or magnitude of any changes in the environment of the GOM due to changes in climate; therefore, it is not possible to predict the extent of effects on GOM populations of marine and coastal birds as a result of climate change. It should be noted that such information is not essential to a reasoned choice among OCS program alternatives, even in a cumulative analysis, because the information missing here is missing across the board for all action alternatives (see Section 1.4.2).

Severe storm events such as hurricanes may result in direct or indirect mortality of marine and coastal birds and may impact important coastal habitats. Heightened wave action and intensity could alter nearshore channels, affecting the abundance and distribution of shallow-water habitats such as lagoons and bays, while sediments deposited into foraging habitats by storm waves may alter the thermal environment and affect aquatic vegetation in feeding habitats. Extreme wind conditions could damage or destroy historic rookery sites or disrupt nesting birds. Because storms (including hurricanes) are annual events that are an inherent component of the overall GOM ecosystem, it could be assumed that marine and coastal birds have experienced and largely tolerated extreme weather conditions in the past and may be expected to continue to do so in the foreseeable future. The occurrences and aftermaths of Hurricanes Katrina and Rita in 2004, however, have impacted avian habitats on a large scale throughout the GOM. Large areas of coastal wetlands have been converted to open-water habitat, potentially affecting avian species that utilized the wetlands for foraging, nesting, and as stopover points during migration (Congressional Research Service 2005). Impacts on these habitats have the potential to result in population-level impacts affecting both abundance and distribution of some species.

Hurricane impacts on bottomland forest habitat along the Louisiana and Mississippi coasts represent further loss of avian habitat affecting many species. For example, all forested areas at the Big Branch Marsh National Wildlife Refuge were heavily damaged, with some areas that were previously densely forested left with few standing trees (USFWS 2007). These damaged areas provided habitat for a variety of avian species, and included cavity trees used by the endangered red-cockaded woodpecker. The long-term effects of avian habitat loss due to these hurricanes is not known, and agencies such as the USFWS and USGS are implementing numerous studies and monitoring programs to determine the extent and magnitude of impacts on affected avian populations. The occurrence of similar magnitude storms during the life of the 5-year OCS program could result in population-level impacts on some bird species.

Conclusion. Marine and coastal birds in the GOM could be adversely affected by activities associated with the Program as well as those associated with other OCS program and non-OCS program activities. Potential impacts include injury or mortality of birds from collisions with platforms associated with OCS and State oil and gas development and other onshore and offshore structures (e.g., radio, television, cell phone, or wind towers), non-energy mineral mines; onshore industrial, commercial, and residential development; exposure to discharges from permitted point sources or accidental releases; exposure to emissions from various onshore and offshore sources; ingestion of trash or debris; loss or degradation of habitat due to construction and operations activities; and behavioral disturbance due to the presence of, and noise generated by, equipment and human activity. Other trends such as sea level rise and increasing seawater temperature brought on by global climate change, as well as extreme wind conditions from storm events, are also expected to adversely affect marine and coastal birds over the next 40 to 50 years. While the cumulative impact of all OCS and non-OCS activities in the GOM is expected to be moderate (some impacts are unavoidable, but mitigation can help to alleviate some of the stress on species), the incremental contribution due to the Program would be negligible to medium as most impacts would be temporary and would not be expected to cause population-level impacts (see Section 4.4.7.2.1).

Marine and coastal birds may also be adversely affected by exposure to oil (via direct contact or through the inhalation or ingestion of oil or tar deposits) that is accidentally released from OCS and non-OCS activities, especially near coastal areas and affecting feeding and nesting areas. The incremental contribution of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on marine and coastal birds would be small to large, depending on the location, timing, duration, and size of the spill; the proximity of the spill to feeding and nesting areas; the timing and nature of spill containment; and the status of the affected birds (see Section 4.4.7.2.1). Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from moderate to major if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to the impacts of spills regardless of size, but their incremental contribution to cumulative impacts is generally expected to be small. A more detailed discussion of the effects of oil spills on marine and coastal birds in the GOM is presented in Section 4.4.7.2.1.

4.6.4.1.3 Fish. Section 4.4.7.3.1 discusses direct and indirect impacts on fish communities in the GOM resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on these resources result from the incremental impacts of the Program (described in Section 4.4.6.1.1) when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS activities. Table 4.6.1-2 presents the exploration and development scenario for the GOM cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future OCS programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in the GOM are summarized in Table 4.6.1-5 and discussed below, as applicable.

There are numerous fish species that inhabit different niches throughout the surface waters, water column, and benthic environments of the GOM. Routine activities will have varied cumulative effects on fish populations depending on their habitat and life history. Impacts on fish resulting from ongoing and future routine OCS program activities, including those of the

Program, could result primarily from noise (marine vessel traffic, seismic surveys, and construction), well drilling, pipeline placement (trenching, landfalls, and construction), platform placement (anchoring, mooring, and removal, except in deep waters) and routine discharges (drilling, production, platform, and vessel). Accidental oil spills are also counted among OCS program-related activities. Cumulative impacts could result from the combination of the Program and past, present, and reasonably foreseeable future OCS and non-OCS activities.

Routine OCS activities that temporarily disturb sediments and increase turbidity include installation of new pipelines and platforms and discharges of drill cuttings and associated fluids. This could cause soft-bottom fish such as Atlantic croaker, sand sea trout, Atlantic bumper, sea robins, and sand perch to temporarily move from or be attracted to the disturbed area. Fish species that are normally associated with reefs, such as snappers, groupers, grunts, and squirrelfishes, may also move from areas of increased turbidity. Sedimentation could smother eggs, larvae, and juvenile fishes as well as the benthic prey of some of these fish species (see Table 4.6.1-2 for bottom area of disturbance and drilling and operational discharges expected during the life of the Program). The impacts of routine activities (exploration and site development, production and decommissioning) on fish communities are discussed in detail in Section 4.4.7.3.1. Overall, routine activities would result in a minor impact, primarily from disturbance affecting demersal fishes, with the severity of the impacts generally decreasing dramatically with distance from bottom-disturbing activities.

Up to 2,000 new platforms could be constructed under ongoing and future OCS activities, including up to 450 from the Program (Table 4.6.1-2). The addition of new platforms may act as fish attracting devices (FADs) that will significantly alter local fish communities and food web relationships. Many reef species, as well as highly migratory species, use platforms as habitat. There has been some speculation that an increase in FADs could impact the migration patterns of highly migratory species. While many platforms may be allowed to remain as artificial reefs, removal of platforms will reduce available substrate and structures for these fish and some of their prey species. Some fish will be killed in the process of these platform removals, especially when explosives are used to accomplish the removals. A total of up to 1,200 platforms would be subject to explosive removal over the life of the Program, including up to 275 platforms under the Program. A detailed discussion of oil platforms as FADs can be found in Section 4.4.7.3.1.

Non-OCS actions may also negatively influence fish resources in various life stages and habitats. Non-OCS oil and gas exploration and production activities in GOM State waters occur primarily off Louisiana and Texas, and off Alabama in the vicinity of Mobile Bay. The States of Florida and Mississippi have had limited activities in State waters, with a moratorium on drilling activity now in effect in Florida waters. The increasing presence of offshore LNG facilities could lead to impacts associated with entrainment and impingement of eggs, larvae, and juvenile lifestages and discharges of water used in the vaporization process. In addition to the thermal discharge, biocides are also discharged from the facilities. Other non-OCS activities that could impact fish communities include non-OCS activities with a potential to impact marine benthic and pelagic habitats, such as sand mining, sediment dredging and disposal, anchoring, offshore marine transportation, and pollutant inputs from point and non-point sources. Many of these activities would affect bottom-dwelling fishes at various life stages as well as their food sources in a manner similar to OCS bottom-disturbing activities (Section 4.4.7.3.1).

Commercial fishing practices that are indiscriminate, such as some types of trawling and pots, are responsible for significant amounts of bycatch that can injure or kill juveniles of many fish species. These types of fishing practices could damage future year classes, reduce available prey species, and damage benthic habitat for many GOM fish resources. Sportfishing may also contribute significantly to cumulative effects on some fishery resources, and in some cases may affect fish stocks more than commercial fishing. As a consequence of the pressure fishing places on fishery resources, NOAA manages fish stocks using catch and gear limits and regulations in order to prevent the depletion of fish stocks due to overharvesting. A variety of natural and anthropogenic factors influence fish populations; these include food availability, climate, habitat loss, and pollution. Consequently, the possibility of fish stocks declining still exists even for managed species. Currently, gag, tray triggerfish, greater amberjack, and red snapper are overfished in the GOM (NOAA 2011e). OCS Program activities may interact with fishing activities. For example, continued platform placement may increase fishing pressure on overfished reef associated species like snapper and grouper. Large numbers of reef fish may also be killed by explosive platform removal.

The eutrophication that has contributed to the hypoxic zone in the GOM will continue to act as a source of lethal and sublethal stress to fish communities. In addition, natural events, including hurricanes and turbidity plumes, could also cause localized damage to important habitat areas and could affect individuals or populations. However, the GOM fish community as a whole should be adapted to such natural events.

Climate change could affect fish communities through direct physiological action, habitat loss, and by altering large-scale oceanographic and ecosystem processes (Section 3.8.4.1). At the level of individual behavior and physiology, increasing water temperature could increase the spread and virulence of new and existing pathogens, and alter reproductive rates by speeding growth and altering the timing of migrations (including reproductive movements). Fish in river-influenced systems such as the GOM would be particularly susceptible to changes in salinity, turbidity, and temperature linked to changes in the hydrology of the Mississippi River and Atchafalaya River. At larger scales, climate change could promote the range expansion of new species into the GOM, reduce or eliminate critical fish habitats including estuarine waters and coral reef due to sea level rise, and increase the size of the GOM “dead zone,” reducing the amount of benthic habitat available to demersal fishes (Rabalais et al. 2010). Physiological and ecosystem-level stressors related to climate change may interact with the non-climate anthropogenic stressors such as overfishing, pollution, and habitat loss discussed above. For example, a climate change related increase in water temperature that results in physiological stress could also make individuals more susceptible to pollution stress or the effects of an accidental oil spill. Another potential interaction could occur between oil and gas platforms and climate change, in which new hard-bottom associated species are able to expand northward due to warming and the availability of hard substrate in the form of active or decommissioned oil platforms. By acting as stepping stones across the GOM, oil platforms have been implicated in the introduction of a non-native fishes such as sergeant majors (*Abudefduf saxatilis*) and yellowtail snapper (*Ocyurus chrysurus*) into the FGB (Hickerson et al. 2008).

Oil spills resulting from both OCS and non-OCS activities could impact fish communities in the GOM. See Table 4.6.1-4 for anticipated oil spills over the life of the Program.

Catastrophic spill assumptions are provided in Table 4.4.2-2. Crude oil may also enter the environment from naturally occurring seeps. Large spills may also occur from tankers carrying imported oil in the GOM. The potential effects of spills from non-OCS activities would be similar to those described for OCS activities (Section 4.4.7.3.1). Most adult fish in marine environments are highly mobile and are capable of avoiding high concentrations of hydrocarbons, although they may be subject to sublethal exposures. However, eggs and larvae do not have the ability to avoid spills and may therefore suffer lethal or sublethal effects. Any oil spills reaching shallow seagrass, estuarine, or coastal marine habitats could affect fish species that use the affected areas as spawning or juvenile nursery habitat. Coastal pelagic fish and highly migratory species throughout the GOM could come into contact with surface oil, but would most likely move away from affected areas. Because of the wide dispersal of early life history stages of fishes in the GOM surface waters, it is anticipated that only a relatively small proportion of early life stages present at a given time would be impacted by a particular oil spill, which would limit the potential for population-level effects. However, the impact magnitude would also depend on the temporal and spatial scope of the oil spill. Since some species of fish spawn in a limited geographic area(s) during a small temporal window, a spill could have population-level impacts if the spill coincided in time and space with spawning activity. In addition, fish species such as tuna, swordfish, and billfish that currently have depressed populations and important spawning grounds in the GOM could experience population-level impacts if high numbers of early life stages were killed by a spill. The potential impacts of oil spills on fish communities are discussed in detail in Section 4.4.7.3.1.

In addition to effects on individuals and species, impacts to fish can result in ecosystem-level effects if the population impacts are significant. For example, fish in the GOM can occupy a number of trophic levels ranging from herbivore to top level carnivore. As such, fish are critical to energy flow within nearshore and marine food webs. They are also seasonally important food sources to transient carnivores. Consequently, impacts to fish can propagate throughout the food web, affecting sea turtles, birds, and marine mammals. In addition, many GOM fishes migrate between and within marine, estuarine, and freshwater habitats. In doing so, they transfer nutrients and carbon over a broad area and connect offshore and coastal ecosystems (Deegan et al. 2002; Kneib 2002; Haertel-Borer et al. 2004). Significant impacts to fish populations could reduce this transfer, resulting in local changes in productivity.

Fish Species Listed under the Endangered Species Act. Routine activities such as placement and removal of structures, discharges of operational wastes, and accidental spills of oil have the potential to physically harm or disturb individual Gulf sturgeon, smalltooth sawfish, or their respective habitats; cause sedimentation of areas that provide food; or elicit lethal or sublethal toxic effects. As described in Section 3.8.4.1.4, most routine activities would not take place in shallow nearshore habitat preferred by Gulf sturgeon. Gulf sturgeon are also not likely to be directly affected by routine operations that impact estuarine areas because the more vulnerable egg and larval stages are not present in estuarine areas and juveniles and adults will be able to avoid most disturbances. Consequently, it is anticipated that effects on Gulf sturgeon from routine OCS activities would be limited. Smalltooth sawfish are primarily found in peninsular Florida away from the Central and Western Planning Areas. Vulnerable early life stages of smalltooth sawfish exist only in shallow estuarine areas far removed from most routine OCS activities. Adults and larger juveniles do occupy coastal waters where OCS activities would occur. However, it is expected that, given their size, they will be able to avoid direct impacts from routine operations, although their habitat would be disturbed.

In addition to potential effects from OCS oil and gas activities identified above, Gulf sturgeon and smalltooth sawfish could be affected by non-OCS activities such as commercial fishing, water quality degradation, coastal and upland development, dredge and fill activities, and damming of major spawning rivers (Section 3.8.4.1.4). Even though it is illegal to fish for Gulf sturgeon or smalltooth sawfish, some individuals, particularly smalltooth sawfish, may be harmed or killed when captured as bycatch during trawling activities. Dredging and fill activities in estuaries may disturb smalltooth sawfish and Gulf sturgeon habitat. Increased barriers (e.g., locks or dams) to major spawning sites may result in Gulf sturgeon reproducing in less desirable locations. The eggs and fry of Gulf sturgeon are also susceptible to other fish and invertebrate predators as well as anthropogenic effects, such as artificially increased water temperatures due to the release of cooling water from power plants and exposure to pesticides and heavy metals.

Other events, including hurricanes, turbidity plumes, and hypoxia, could also affect Gulf sturgeon, smalltooth sawfish, or their habitat. Regardless, a severe event could cause localized damage to important habitat areas and could result in the introduction of contaminants via surface-water runoff. Therefore, such events could affect individual Gulf sturgeon or population levels for some period of time.

Oil is released in GOM waters by accidental oil spills (OCS and non-OCS) and natural seepage. Non-OCS oil and gas exploration and production activities in GOM State waters occur primarily off Louisiana and Texas, and off Alabama in the vicinity of Mobile Bay. The States of Florida and Mississippi have had limited activities in State waters, with a moratorium on drilling activity now in effect in Florida waters. Non-OCS spills in the GOM could have impacts similar to those for OCS spills. Smalltooth sawfish are primarily found in peninsular Florida and are uncommon in most of the Central and Western GOM Planning Areas. Therefore, oil spills in the GOM have the greatest potential to impact Gulf sturgeon populations. Most spills would be minor and are unlikely to reach estuarine and shelf habitat of adult sturgeon. Spills in shallow areas have the greatest potential to affect Gulf sturgeon. As identified in Section 3.8.4.1, eggs and larvae of Gulf sturgeon are typically located in freshwater areas, and oil from OCS-related spills are unlikely to come into contact with these life stages. Because adult sturgeons are benthic feeders, they are relatively unlikely to come into contact with surface oil in deeper waters.

Conclusion. Cumulative impacts on fish communities in the GOM as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be moderate to major over the next 40 to 50 years. Non-OCS activities or phenomena affecting these resources include oil and gas development in State waters, sand mining, sediment dredging and disposal, LNG facilities, hypoxia, anchoring, fishing/trawling, commercial shipping, and pollutant inputs from point and non-point sources. Many of these activities would affect bottom-dwelling fish at various life stages as well as their food sources in a manner similar to OCS bottom-disturbing activities. The incremental contribution of routine Program activities to these impacts (primarily as a result of disturbance affecting demersal fishes) would be negligible to small, with the severity of impacts generally decreasing with distance from the disturbance. Fish could also be affected by naturally occurring oil seeps and the environmental changes predicted to result from climate change.

Fish communities may also be adversely affected by exposure to oil that is accidentally released from OCS and non-OCS activities as well as naturally occurring seeps. The cumulative impacts of past, present, and future oil spills on these resources would be minor to moderate. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on fish would be negligible to medium, depending on the location, timing, duration, and volume of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could range up to moderate if they were to occur. Oil from large spills or a CDE has the greatest potential to contact shoreline areas used for spawning or providing habitat for early life stages of fish and, therefore, could result in large-scale lethal and long-term sublethal effects on fish. Overall population levels for individual species would not likely be affected; however, fish species that currently have depressed populations or have critical spawning grounds present in the affected area could experience population-level impacts. A more detailed discussion of the effects of oil spills on fish in the GOM is presented in Section 4.4.7.3.1.

Although Gulf sturgeon may be affected by a variety of OCS and non-OCS activities, most OCS activities occur in deeper areas that are outside of the normal habitat areas used by Gulf sturgeon. Similarly, smalltooth sawfish are primarily found in peninsular Florida away from the Central and Western Planning Areas. Consequently, it is anticipated that the cumulative effects of OCS and non-OCS activities on Gulf sturgeon and smalltooth sawfish would be similar to the effects of non-OCS activities alone, and the Program is expected to contribute little if any overall incremental impacts on these species.

4.6.4.1.4 Reptiles. Section 4.4.7.4 discusses direct and indirect impacts on reptiles in the GOM coastal environment resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on these resources result from the incremental impacts of the Program when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS activities. Table 4.6.1-2 presents the exploration and development scenario for the GOM cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future OCS programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in the GOM are summarized in Table 4.6.1-5 and discussed below, as applicable.

Ongoing and future routine OCS program activities include seismic surveys, onshore and offshore construction (including pipeline trenching and removal of offshore structures), the discharge of operational wastes (such as produced water and ship wastes), and marine vessel traffic. All these activities have the potential to adversely affect reptiles in the GOM via physical injury or death, lethal or sublethal toxic effects, or loss of reproductive, nursery, and feeding habitats (Section 4.4.7.4). Accidental oil spills are also counted among OCS program-related activities; assumptions for oil spills under the cumulative case scenario are provided in Table 4.6.1-4.

Non-OCS program activities contributing to adverse cumulative impacts on reptiles include activities associated with offshore construction (e.g., seismic surveys, dredging and marine disposal, extraction of nonenergy minerals, State oil and gas development, domestic transportation of oil and gas, and foreign crude oil imports), onshore construction (e.g., coastal and community development), the discharge of municipal and other waste effluents, and vessel traffic (e.g., commercial shipping, recreational boating, and military training and testing activities).

Anthropogenic mortality in sea turtles has been attributed to a number of sources (NRC 1990; NOAA 2003). Human activities responsible for mortality of sea turtle eggs and hatchlings include (in descending order of relative importance) beach development, beach lighting, beach use, entanglement in trash and debris, and beach replenishment. Each of these activities is associated, either exclusively or to a large degree, with coastal development. In addition, the contributions of exposure of eggs and hatchlings to toxins and of the ingestion of plastics and debris by hatchlings are unknown (NRC 1990; NOAA 2003). Human activities responsible for mortality of juvenile and adult turtles include shrimp trawling and other fisheries, beach lighting, beach use, vessel collisions, dredging, entanglement, power plant entrainment, and oil platform removal (NRC 1999; NOAA 2003). The role of exposure to toxins in overall sea turtle mortality is unknown. However, this information is not necessary to make a reasoned choice among the alternatives (see Section 1.4.2).

Non-OCS offshore (deepwater and nearshore) construction activities in the GOM that could affect sea turtles include channel construction and maintenance activities (e.g., dredging) conducted by Federal, State, and local governments and the public; the offshore extraction of nonenergy minerals; State oil and gas development; and the transport of domestic and foreign oil and gas (requiring loading and offloading facilities). Potential impacts on sea turtles from these activities may include physical injury or death of individuals present in the immediate construction area. In addition, construction or removal of offshore OCS facilities may result in a relatively small incremental increase in the potential for adverse impacts on sea turtles within the GOM planning areas. However, the mitigation measures established by BOEM for construction and platform removal activities may be expected to reduce the contribution of these proposed activities to cumulative impacts to sea turtles from all offshore construction activities throughout the GOM planning areas (MMS 2003d, 2004a, 2005d).

Onshore construction activities can impact nesting habitat for sea turtles and the Alabama red-belly turtle, as well as impact terrestrial habitat for the gopher tortoise. Coastal development is an ongoing activity throughout the GOM and may be expected to continue or increase for the foreseeable future. Residential (i.e., housing developments) and commercial (i.e., casinos) development near nesting beaches may disrupt nesting adults and disorient emerging hatchlings, while increasing the potential for recreational human activities on nesting beaches. Compliance with regulatory requirements and the implementation of appropriate mitigation measures may be expected to reduce the potential for the siting, construction, and operation of onshore facilities.

There are a number of types of facilities or activities that discharge wastes to GOM waters and thus expose sea turtles to potentially toxic materials or solid debris that could entangle or be ingested by sea turtles. These facilities or activities include sewage treatment plants, industrial manufacturing or processing facilities, electric generating plants, cargo and tanker shipping, cruise ships, commercial fishing, pleasure craft, and vessel traffic associated with the Program. In addition, the Mississippi River (and to a lesser extent other rivers and streams that discharge to the northern GOM) annually discharges waters containing suspended sediments, agricultural fertilizers and herbicides, and urban runoff (Rabalais et al. 2001, 2002b). The exposure of sea turtles to these discharges may result in physical injury or death, or a variety of lethal or sublethal toxic effects on adults, juveniles, and hatchlings. These discharges may also affect habitat quality in the vicinity of the discharges.

Operational discharges and wastes associated with OCS activities could adversely affect sea turtles, especially those in the immediate vicinity of discharging platforms and vessels (Section 4.4.7.4). However, discharges from OCS program-related vessels and platforms would be strongly regulated under the Program (as they are for current OCS program-related discharges). Thus, the potential for sea turtles to be exposed to discharges under the Program may be expected to be much less than the potential of exposure to many of the nonpoint and non-OCS related discharge sources. Similarly, because of existing USCG and USEPA regulations, the nature of the OCS discharges that could occur are expected to be less toxic or less likely to cause entanglement than discharges from non-OCS program sources.

The GOM is one of the world's most concentrated shipping areas, with extensive commercial traffic transporting a variety of materials ranging from agricultural products to domestic and foreign oil (USACE 2003). For example, in 2003, the Port of New Orleans handled over 255,000 domestic and foreign container vessels, while the port at Gulfport, Mississippi, handled more than 161,000 foreign container vessels (USACE 2003b). The GOM also supports extensive commercial fisheries as well as recreational boating. For example, there were 2 million recreational watercraft between 4 and 20 m (12 and 64 ft) in length registered in the GOM States, many of which are used in GOM waters (USCG undated). The GOM also supports training by U.S. Navy vessels as well as routine USCG activities. Because of the very large number of vessels typically present in the GOM, the potential for sea turtles colliding with watercraft is high, and may be expected to continue and increase into the foreseeable future. In comparison with the overall level of vessel traffic in the GOM, the additional numbers of vessel trips that would occur to support OCS Program activities is expected to result in a minor incremental increase to the overall potential for sea turtle–vessel collisions in the GOM planning areas.

The information on the extent to which sea turtles may be affected by noise is very limited (Section 4.4.7.4). However, this information is not necessary to make a reasoned choice among the alternatives (see Section 1.4.2). Current noise generating activities in the GOM unrelated to OCS activities or the Program include the construction of offshore structures (such as those supporting State oil and gas development or nonenergy minerals extraction), dredging, commercial and recreational vessel traffic, and military training and testing activities. These may be expected to continue or increase in the foreseeable future.

Sea turtles could be exposed to OCS oil spills that could occur from platform, pipeline, and/or vessel accidents (see Section 4.4.7.4). Most spills associated with the Program would be relatively small (less than 50 bbl), and most would be expected to occur in water depths of 300 m (984 ft) or more (BOEMRE 2011a).

Storms, operator error, and mechanical failures may result in accidental oil releases from a variety of non-OCS related activities, such as the domestic transportation of oil, the import of foreign crude oil, and State development of oil. Crude oil may also enter the environment of the northern GOM from naturally occurring seeps. At least 63 seeps have been identified in the northern GOM (mostly off the coast of Louisiana) (MacDonald et al. 1996), and more than 350 naturally occurring and constant oil seeps that produce perennial slicks of oil at consistent locations may be present in the GOM (MacDonald et al. [2002], as cited in Kvenvolden and Cooper [2003]). Seeps in the northern GOM have been estimated to discharge more than 1.2 million gal of crude oil annually to overlying GOM waters (MacDonald 1998). Using remotely sensed satellite data, Mitchell et al. (1999) identified approximately 1,000 km^2 (390 mi^2) of floating oil in the northern GOM, presumably from natural seeps.

Accidental oil releases from these activities and from naturally occurring seeps could impact reptiles by oiling (fouling) nesting beaches and nest sites and hatchlings, and through the inhalation or ingestion of oil or tar deposits. The magnitude and severity of potential effects on reptiles from such exposure will be a function of the location, timing, duration, and size of the spill; the proximity of the spill to nesting beaches and feeding habitats; and the timing and nature of spill containment and cleanup activities. Depending on their location, as well as the location of spills from other sources and releases from natural seeps, accidental spills associated with the Program could contribute to the overall exposure of nest beaches, eggs, and hatchlings to oil, and subsequent lethal and sublethal effects, in the GOM planning areas. For example, the American crocodile and Alabama red-belly turtle might be affected by natural seepage and accidental releases of oil in the Eastern Planning Area, but probably only by catastrophic spills in the Central and Western Planning Areas.

Reptile populations throughout the GOM may be adversely affected by climate change or hurricane events. As previously discussed (Section 4.4.7.4), there is growing evidence that climate change is occurring, and potential effects in the GOM may include a change (i.e., rise) in sea level or a change in water temperatures. Climate change could affect the availability or quality of nesting beaches, the location and duration of current convergence areas utilized by hatchlings in the open waters of the GOM, and the distribution, availability, and quality of feeding habitats. For reptiles that rely on temperature to determine the gender of offspring in incubating eggs (referred to as temperature-dependent sex determination), including sea turtles and crocodilians, subtle increases in atmospheric temperatures could skew sex ratios of hatchlings, which could have future population implications (Walther et al. 2002).

Severe storm events such as hurricanes have the potential to impact nesting beaches if they result in a change in beach topography or in the composition of beach materials. Heightened wave action and intensity could erode nesting beach sites, storm surges could flood beaches and drown eggs and hatchlings, and sediments deposited onto beach surfaces by storm waves may alter the thermal and structural environment of nest sites, potentially decreasing the availability and/or quality of the nesting areas (Milton et al. 1994; Hays et al. 2001; Holloman and Godfrey 2005). Hurricanes Katrina and Rita adversely affected sea turtle habitats in 2005. Approximately 50 Kemp's ridley sea turtle nesting sites were destroyed along the Alabama coast (Congressional Research Service 2005; USFWS 2006). The loss of beaches through the affected coastal areas has probably affected other existing nests and nesting habitats of this species, as well as the loggerhead turtle. Similarly, impacts on seagrass beds may affect the local distribution and abundance of species that use these habitats, such as the green sea turtle and Kemp's ridley sea turtle. Although hurricanes are annual events that are an inherent component of the overall GOM ecosystem, including sea turtle nesting beaches, if hurricanes similar in magnitude to Katrina and Rita occur during the life of the Program, population-level impacts on reptiles could occur, particularly since the availability of nesting habitat (e.g. beaches) has become limited because of coastal residential and commercial development.

Conclusion. Cumulative impacts on reptiles in the GOM as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be moderate to major over the next 40 to 50 years. Non-OCS activities or phenomena include climate change, natural catastrophes, onshore and offshore construction, contaminant releases (through waste effluents), vessel traffic, power plant entrainment, and human-related activity (e.g., beach use, noise, and shrimp trawling). The incremental contribution of routine Program activities to these impacts would be small to medium (see Section 4.4.7.4).

Expected accidental oil spills under the Program (most of which are less than 1,000 bbl) would result in a comparatively negligible to medium incremental increase in the overall impact of exposure to oil from other anthropogenic activities (such as spills from foreign tankers) because such spills are relatively easy to contain and would only affect small areas of habitat (and few individuals). However, large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could potentially result in population-level effects. Although such spills are rare events, impacts would be major and long-term if multiple individuals and their habitat (especially nesting habitat) are exposed to oil. Additional impacts on reptiles may occur as a result of habitat loss or alteration due to climate change and hurricanes, and from exposure to oil from naturally occurring seeps.

4.6.4.1.5 Invertebrates and Lower Trophic Levels. Section 4.4.7.5.1 discusses direct and indirect impacts on invertebrates and lower trophic levels in the GOM resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on these resources result from the incremental impacts of the Program (described in Section 4.4.6.1.1) when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS activities. Table 4.6.1-2 presents the exploration and development scenario for the GOM cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future OCS programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in the GOM are summarized in Table 4.6.1-5 and discussed below, as applicable.

Cumulative impacts could result from the combination of the Program and past, present, and reasonably foreseeable future OCS and non-OCS activities. Routine activities would cumulatively have varied effects on invertebrate populations in the sediment and water column depending on their habitat and life history. Impacts resulting from ongoing and future routine OCS program activities, including those of the Program, could result primarily from noise (vessel, seismic surveys, and construction), well drilling, pipeline placement (trenching, landfalls, and construction), platform placement (anchoring, mooring, and removal, except in deep waters) and routine discharges (drilling, production, platform, and vessel). Accidental oil spills are also counted among OCS program-related activities.

Routine activities that temporarily disturb sediments and increase turbidity include installation of new pipelines and platforms and discharges of drill cuttings and associated fluids. Under the cumulative scenario, as much as 81,000 ha (32,780 ac) of sea bottom would be disturbed by construction of platforms and pipelines over the period of the Program (Table 4.6.1-1). Bottom-disturbing impacts would most directly affect benthic and near bottom invertebrates. The impacts of routine activities (exploration and site development, production and decommissioning) on invertebrate communities are discussed in detail in Section 4.4.7.5.1. Overall, routine activities represent up to a moderate disturbance, with the severity of the impacts generally decreasing dramatically with distance from bottom-disturbing activities.

The addition of up to 2,000 new platforms over the life of the Program (up to 450 new platforms under the Program) would allow the colonization of invertebrates requiring hard substrate. While many platforms may be allowed to remain as artificial reefs, removal of platforms will reduce available substrate and structures for invertebrates and injure or kill them during removal.

Non-OCS actions may negatively influence invertebrate resources in various life stages and habitats. Non-OCS oil and gas exploration and production activities in GOM State waters occur primarily off Louisiana and Texas, and off Alabama in the vicinity of Mobile Bay. The States of Florida and Mississippi have had limited activities in State waters, with a moratorium on drilling activity now in effect in Florida waters. The increasing presence of offshore LNG facilities could lead to impacts associated with discharges of water used in the vaporization process. In addition to the thermal discharge, biocides are also discharged from the facilities. Other non-OCS activities that could impact invertebrate communities include non-OCS activities with a potential to impact marine benthic and pelagic habitats, such as sand mining, sediment dredging and disposal, anchoring, fishing/trawling, offshore marine transportation, and pollutant inputs from point and non-point sources. Many of these activities would affect bottom-dwelling invertebrates at various life stages as well as their food sources in a manner similar to OCS bottom-disturbing activities (Section 4.4.7.5.1).

The eutrophication that has contributed to the hypoxic zone in the GOM will continue to act as a source of lethal and sublethal stress to invertebrate communities. Natural events, including hurricanes and turbidity plumes, could also cause localized damage to important habitat areas and could affect individuals or populations, although the invertebrate community as a whole should be adapted to such natural events.

Commercial fishing practices that are indiscriminate, such as some types of trawling and pots, are responsible for significant amounts of bycatch that can injure or kill large numbers of invertebrates. Bottom trawling also degrades benthic habitats and temporarily increases the turbidity of the water, both of which represent chronic disturbances to invertebrates. Bottom trawling is particularly common in the GOM because of the importance of the shrimp fishery.

Several major classes of invertebrates could be affected by the environmental changes predicted to result from climate change. Climate change could affect invertebrate communities through direct physiological action, habitat loss, and by altering large-scale oceanographic and ecosystem processes (Section 3.8.5.1). A significant loss of habitat-forming invertebrates like corals could result from increased water temperature and ocean acidification. The impacts of climate change on habitat-forming invertebrates are discussed in detail in Section 3.7.2.1. Potential impacts on benthic and water column invertebrates resulting from climate change include:

- An increase in the range and temporal variability of a water column's oxygen, salinity, and temperature, which could significantly alter the existing invertebrate community structure, particularly in nearshore areas;
- A reduction in important estuarine habitats from sea level rise;
- A range expansion of new invertebrate species into the GOM;
- An increase in the extent and duration of the GOM hypoxic zone that could kill or displace existing invertebrate communities and reduce the amount of suitable habitat available; and
- Reduced oceanic pH, which could reduce the fitness of calcifying marine organisms like corals, echinoderms, foraminiferans, and mollusks.

In addition, physiological and ecosystem-level stressors related to climate change may interact with non-climate-related anthropogenic stressors; these include overfishing, pollution, and habitat loss. For example, an increase in water temperature that results in physiological stress could make individuals more susceptible to stress from pollution or accidental oil spills.

Oil spills resulting from both OCS and non-OCS activities could impact invertebrate communities in the GOM. See Table 4.6.1-4 for anticipated oil spills over the life of the Program. Crude oil also enters the environment from naturally occurring seeps. Spills could occur from tankers carrying imported oil in the GOM. The potential effects of spills from non-OCS activities would be similar to those described for OCS activities (Section 4.4.7.5.1). In general, larger benthic and water column invertebrates that come into contact with oil would most likely move away from affected areas, while zooplankton and sessile or small infauna would not be able to avoid spills. Oil contacting invertebrates could have lethal or sublethal impacts. Any oil spills reaching shallow seagrass, estuarine, or coastal marine habitats could affect commercially important species such as shrimp, oysters, and blue crab that use these areas as spawning or juvenile nursery habitat. If they were to occur, deepwater surface spills could also affect invertebrate eggs and larvae, neuston communities such as jellyfish species, and *Sargassum*, together with any associated vertebrate and its invertebrate organisms. Because of the wide dispersal of invertebrates in the GOM surface waters, it is anticipated that only a relatively small proportion of early life stages present at a given time would be impacted by a particular oil spill event, which would limit the potential for population-level effects. The potential impacts of oil spills on invertebrate communities are discussed in Section 4.4.7.5.1.

Benthic and pelagic invertebrates are important trophic links that connect primary producers to higher-trophic-level organisms. Consequently, oil spill contamination on a large scale could result in contaminant transfer to higher trophic levels and/or reduce food availability to higher trophic levels if invertebrate populations were severely depressed by a CDE. Multiple investigations of the long-term impacts of the DWH event on invertebrates are ongoing and, over time, these studies will add to our understanding on of the impact of oils spills on invertebrates and will allow a better understanding of the potential for impacts to invertebrates at the population level. A description of these studies can be found at http://www.gulfspillrestoration.noaa.gov/oil-spill/gulf-spill-data.

Species Listed under the Endangered Species Act.

Elkhorn Coral. In much of its natural range, elkhorn coral has been adversely affected by the same anthropogenic stressors as other coral communities. Climate change may add to these stressors in the form of higher water temperatures, diseases, and ocean acidification, all of which can increase the frequency of bleaching. However, increasing surface water temperature may promote the northern expansion of elkhorn coral, increasing their abundance on the topographic features in the northern GOM. As discussed in Section 4.4.7.5.1, potential impacts from routine OCS operations would be minimized by existing stipulations, which prohibit exploration and development activities in the vicinity of the FGBNMS. Overall, the cumulative impacts on invertebrates would be moderate to major when considering OCS routine operations along with the significant impact to coral communities resulting from past, present, and future activities.

As discussed in Section 4.4.7.5.1, a CDE could also affect elkhorn corals, although the likelihood would be significantly reduced by the infrequency of a CDE and the stipulations prohibiting oil and gas activities in the vicinity of the FGBNMS. There is no evidence that elkhorn corals have been affected by oil spills either in the past or as a result of the recent DWH event. However, impacts to or extirpation of the elkhorn corals in the FGBNMS would not result in overall population-level impacts, as this species is primarily located in the southern GOM, Caribbean, and south Florida. Overall, the cumulative impacts of accidental spills on elkhorn coral would range up to moderate.

Conclusion. Cumulative impacts on invertebrate communities in the GOM as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be moderate to major over the next 40 to 50 years. Non-OCS activities or phenomena affecting these resources include offshore LNG facilities, sand mining, sediment dredging and disposal, hypoxia, anchoring, fishing/trawling, offshore marine transportation, and pollutant inputs from point and non-point sources. The incremental contribution of routine Program activities to these impacts (mainly due to bottom-disturbing activities) would be negligible to medium, with the severity of the impacts generally decreasing with distance from bottom-disturbing activities. Several major classes of invertebrates could also be affected by naturally occurring oil seeps and the environmental changes predicted to result from climate change.

Invertebrate communities may also be adversely affected by exposure to oil that is accidentally released from OCS and non-OCS activities as well as naturally occurring seeps. The cumulative impacts of past, present, and future oil spills on these resources would be minor to moderate. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on invertebrates would be negligible to small, depending on the location, timing, duration, and size of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and would range up to moderate if they were to occur. Spills in deeper water, whether from OCS or non-OCS sources, are unlikely to have overall population-level effects on invertebrate resources because of the relatively small proportion of similar available habitats that would come in contact with released oil at concentrations great enough to elicit toxic effects. A more detailed discussion of the effects of oil spills on invertebrates in the GOM is presented in Section 4.4.7.5.1.

4.6.4.2 Alaska Region – Cook Inlet

4.6.4.2.1 Mammals.

Marine Mammals. The cumulative analysis considers past, ongoing, and foreseeable future human and natural activities that may occur and adversely affect marine mammals in the same general area. These activities include effects of the OCS Program (proposed action and prior and future OCS sales), oil and gas activities in State waters, commercial shipping, commercial and subsistence fishing, recreational fishing and boating activities, military operations, scientific research, and natural phenomena. Specific types of impact-producing factors considered include noise from numerous sources, pollution, ingestion and entanglement in marine debris, vessel strikes, habitat degradation, subsistence harvests, military activities, industrial development, community development, climate change, and natural catastrophes. Section 4.4.7.1.2 provides the major impact-producing factors for the Program in Cook Inlet.

Routine Activities.

OCS Activities. Marine mammals and their habitats in the Cook Inlet Planning Area could be affected by a variety of exploration, development, and production activities as a result of the proposed and future OCS leasing actions (see Section 4.4.7.1.2). These activities include seismic exploration, offshore and onshore infrastructure construction, the discharge of operational wastes, and vessel and aircraft traffic. Impacts on marine mammals from these activities may include physical injury or death; behavioral disturbances; lethal or sublethal toxic effects; and loss of reproductive, nursery, feeding, and resting habitats. The degree of impact at the population level depends greatly on the status of the population (reflected in its listing under the ESA) and the degree of disturbance or harm from OCS-related activities in areas important to species survival (i.e., feeding, breeding, molting, rookery, or haulout areas).

Potential impacts (primarily behavioral disturbance) on marine mammals from OCS-related seismic activity would be short-term and temporary and, therefore, would not result in greater than minor impacts on any affected species.

Impacts from OCS construction and operation activities could include the temporary disturbance and displacement of individuals or groups by construction equipment and long-term disturbance of some individuals from operational noise. No long-term, population-level effects would be expected because individuals most affected by these impacts would be those in the immediate vicinity of the construction site or operational platform and disturbance of individuals during construction would be largely temporary. In addition, appropriate mitigation measures could lessen the potential for impacts.

Operational and waste discharges (e.g., produced water, drilling muds, and drill cuttings) would be disposed of through downhole injection into NPDES-permitted disposal wells, and thus would not be expected to result in any incremental impacts on marine mammals. Liquid wastes (such as bilge water) may also be generated by OCS support vessels and on production platforms. While these wastes may be discharged (if permitted) into surface waters, they would be rapidly diluted and dispersed and would result in minor incremental impacts on marine mammals. Drilling and production wastes may contain materials such as metals and hydrocarbons, which can bioaccumulate through the food chain into the tissues of marine mammals. Although the bioaccumulation of anthropogenic chemicals has been reported for a variety of marine mammals, adverse impacts or population-level effects resulting from such bioaccumulation have not been demonstrated (Norstrom and Muir 1994; Muir et al. 1999).

Marine mammals could be temporarily disturbed by OCS vessel traffic (all species) or incur injury or death from collisions with support vessels (primarily larger, slower moving cetaceans). The low level of expected OCS vessel trips in the Cook Inlet Planning Area under the Program (one to three trips per week) would be a minor contribution to all vessel traffic occurring in the Cook Inlet. Noise from the one to three helicopter overflights expected each week would be transient in nature and be a minor component of all aircraft flights that occur within Cook Inlet. Overflights disturbing active rookery sites could result in decreased pup survival and in population-level impacts on some species, although overflight restrictions and flightline selection to avoid rookeries would greatly limit the potential for adversely affecting animals at these locations.

No platforms would be removed under the Program for the Cook Inlet Planning Area. It is possible that platforms would be removed from future lease sales or from platforms associated with oil and gas activities in State waters. There have been no documented losses of marine mammals resulting from explosive removals of offshore oil and gas structures, but there are sporadic incidents reported of marine mammals being killed by underwater detonations (Continental Shelf Associates 2004b; MMS 2007e, 2008a). Harassment of marine mammals as a result of a non-injurious physiological response to the explosion-generated shock wave, as well as to the acoustic signature of the detonation, is also possible. However, explosive platform removals would comply with appropriate BOEM or State guidelines and would not be expected to adversely affect marine mammals in Cook Inlet.

Non-OCS Activities. A number of non-OCS activities such as oil and gas exploration and development in State waters: commercial, subsistence, and recreational fishing; vessel traffic; and climate change could also affect marine mammals in the Cook Inlet Planning Area (or portions of the Gulf of Alaska that could be affected by activities in Cook Inlet). Many of the effects of these activities on marine mammals would be similar in nature to those resulting from OCS-related activities, namely, behavioral disturbance, habitat disturbance, injury or mortality, and exposure to toxic substances. Marine mammals may also be adversely affected by climate change.

Oil and Gas Exploration and Development in State Waters. The State of Alaska has made nearshore State lands available for leasing along the northern portion of Cook Inlet (above Homer). Exploration, construction, and operation activities associated with State leases would occur in nearshore and coastal areas, while OCS platforms and pipelines would be located away from coastal areas. Thus, State oil and gas leasing activities may be expected to have a greater potential for affecting marine mammals in coastal habitats than would the proposed OCS actions.

Commercial and Subsistence Fishing and Harvesting. Commercial and subsistence fishing has been identified as impacting many of the marine mammals in Alaskan waters (Allen and Angliss 2011). These fisheries employ a variety of methods, such as longlines, seines, trawls, and traps, and can result in the entanglement, injury, and death of individuals of marine mammal species. Fisheries also remove a portion of the prey base for some marine mammals. Subsistence harvest has targeted and continues to target some marine mammal species, especially some of the whale species.

The following are minimum reported estimated annual mortality rates incidental to commercial fisheries and subsistence harvests for marine mammals that occur in Cook Inlet and/or in the Gulf of Alaska that could be affected by the Program in Cook Inlet (Allen and Angliss 2011):

- The estimated minimum mortality rate for Western U.S. Stock of the Steller sea lion incidental to Alaska commercial fisheries is 26.2 animals per year. The best estimate of annual subsistence harvest of the Steller sea lion is 197 animals.

- The estimated minimum mortality rate for Eastern Pacific Stock of the northern fur seal incidental to Alaska commercial fisheries is 1.9 animals per year. The best estimate of annual subsistence harvest of the northern fur seal is 562 animals.

- The estimated minimum mortality rate for Gulf of Alaska Stock of the harbor seal incidental to Alaska commercial fisheries is 24 animals per year. The best estimate of annual subsistence harvest of the harbor seal is 807 animals.

- There are no reports of mortality incidental to commercial fisheries for the Cook Inlet Stock of the beluga whale. Annual subsistence harvest of Cook Inlet beluga whales ranged from 30 to over 100 between 1993 and 1999. Since 2000, subsistence harvests totaled only 11 whales, with no subsistence harvests allowed between 2008 and 2012 (Allen and Angliss 2011; NMFS 2008b).

- The estimated minimum mortality rate for the Alaska Resident Stock of the killer whale incidental to Alaska commercial fisheries is 1.2 animals per year. There are no reports of subsistence harvests of killer whales in Alaska.

- The estimated minimum mortality rate for the Gulf of Alaska, Aleutian Islands, and Bering Sea Transient Stock of the killer whale incidental to Alaska commercial fisheries is 0.4 animal per year. There are no reports of subsistence harvests of killer whales in Alaska.

- There are no reports of mortality incidental to commercial fisheries or subsidence harvest for the ATI Transient Stock of the killer whale.

- There were no serious injuries or mortalities observed or reported incidental to commercial fisheries between 2002 and 2006 for the North Pacific Stock of the Pacific white-sided dolphin. However, between 1978 and 1991, thousands of individuals died annually incidental to high seas fisheries (these fisheries have not operated in the central North Pacific since 1991). There are no reports of subsistence harvests of Pacific white-sided dolphins.

- The estimated minimum mortality rate for the Gulf of Alaska Stock of the harbor porpoise incidental to commercial fisheries is 71.4 animals per year. There are no reports of subsistence harvests of the harbor porpoise. Two harbor porpoises were taken incidentally in subsistence gillnets in 1995.

- The estimated minimum mortality rate for the Alaska Stock of the Dall's porpoise incidental to commercial fisheries is 29.6 animals per year. There are no reports of subsistence harvests of the Dall's porpoise.

- The estimated minimum mortality rate for the North Pacific Stock of the sperm whale incidental to commercial fisheries in the Gulf of Alaska is 2.01 animals per year. There are no reports of subsistence harvests of the sperm whale. The sperm whale was the dominant species killed by the commercial whaling industry in the North pacific in the years following the Second World War.

- The estimated annual mortality rate for the Alaska Stock of Cuvier's beaked whale incidental to commercial fisheries is zero. There are no reports of subsistence harvests of the Cuvier's beaked whale.

- Serious injuries to or mortalities of Eastern North Pacific Stock of the gray whale occur throughout their range incidental to commercial fisheries and from strandings due to various causes. The annual mortality rate incidental to U.S. commercial fisheries is 3.3 whales. Annual subsistence take averaged 121 whales between 2003 to 2007. Russian Chukotka people take most of the gray whales. The U.S. Makah Indian Tribe has a yearly average quota of only 4 whales. In 2005, an unlawful subsistence hunt and kill of a gray whale occurred in Alaska.

- The Western North Pacific Stock of the humpback whale's feeding area includes the Gulf of Alaska. The estimated annual mortality incidental to U.S. commercial fisheries is 0.2 humpback whales per year based on one mortality observed in the Bering Sea sablefish pot fishery from 2002 through 2006. Bycatch in Japan and Korea average 1.1 to 2.4 humpback whales per year. The annual mortality rate for subsistence takes for the 2003 to 2007 period was 0.2 whales. The species received full protection in 1965; however, the Union of Soviet Socialist Republics (USSR) continued illegal catches until 1972. From 1961 through 1971, 6,793 humpback whales were illegally killed. Many of these were taken from the Gulf of Alaska and the Bering Sea.

- The Central North Pacific Stock of the humpback whale feeding area includes the Gulf of Alaska area that encompasses Cook Inlet. Based on observations from 2003 through 2007, the estimated annual mortality in Alaska is 3.4 animals per year from commercial fishery, 0.2 animals per year from recreational fishery, and 1.6 animals per year from vessel collisions. Subsistence harvesting is not allowed for humpback whales from the Central North Pacific Stock.

- There was one observed incidental mortality of a fin whale from the Northeast Pacific Stock in the Bering Sea/Aleutian Island pollock trawl fishery. No current or historical subsistence takes of this stock are reported from Alaska or Russia. Between 1925 and 1975, commercial whaling throughout the North Pacific killed 47,645 fin whales.

- For the Alaska Stock of the minke whale, the total estimated mortality and serious injury incidental to U.S. commercial fisheries for 2002 through 2006 was zero. Prior to that time, whale mortalities were very rare. Subsistence take by Alaska Natives is rare (e.g., only nine between 1930 and 1995).

- There are no records of North Pacific right whale mortalities incidental to U.S. commercial fisheries. There are no reported subsistence takes of the species in Alaska or Russia. Up to 37,000 North Pacific right whales were killed by whaling from 1839 to 1909; while 742 were killed by whaling from 1900 to 1999, in addition to 372 killed illegally, taken by the U.S.S.R., from 1963 through 1967, primarily in the Gulf of Alaska and Bering Sea, that left the population at an estimated 50 individuals (Allen and Angiss 2011; Encyclopedia of Life 2011).

- Based on commercial fisheries observer program results, fishing mortality and serious injury for the south central Alaska Stock of the northern sea otter is insignificant (i.e., approaches zero mortalities and serious injuries). The mean annual report of subsistence take for the stock from 2002 through 2006 was 346 animals.

- The total fishery mortality and serious injury rate for the Southwest Alaska stock of the northern sea otter is less than 10 animals per year. The mean annual report of subsistence take for the stock from 2002 through 2006 was 91 animals.

In addition to the above, no serious injuries or mortalities due to fisheries or subsistence have been reported for blue whales in Alaska (Carretta et al. 2011).

Climate Change. A concern regarding marine mammals in polar regions is the potential for climate change and associated changes in the extent of sea ice in some Arctic and subarctic waters. It is not possible at this time to identify the likelihood, direction, or magnitude of any changes in the environment of Cook Inlet waters due to changes in the climate, or how climate change could impact marine mammals in these waters. The current state of climate change and its impacts on marine mammals would also be further considered in any subsequent environmental reviews for lease sales or other OCS-related activities; therefore, this information is not essential to a reasoned choice among the alternatives presented in this PEIS (see Section 1.4.2).

Other Impacting Factors. Marine mammals in the Cook Inlet area may also be impacted by other factors such as UMEs and invasive species. A UME is an unexpected stranding that involves a significant die-off of any marine mammal population, and demands immediate response (NMFS 2011b). Since establishment of the UME program in 1991, there have been 55 formally recognized UMEs in the United States; two UMEs occurred in southern Alaska and involved sea otters (NMFS 2011b). Causes have been determined for 26 of the UMEs; they include infections, biotoxins (particularly domoic acid and brevetoxin), human interactions, and malnutrition. The cause of the UMEs in Alaska is undetermined (NMFS 2011b). Invasive species could affect some marine mammals by disrupting local ecosystems and fisheries of the area of Cook Inlet. For example, introduced northern pike (*Esox lucius*) consume salmon, trout, and whitefish, affecting total populations of these prey species where pike become established. The potential introductions of other invasive species of concern, such as the Chinese mitten crab (*Eriocheir sinensis*), which could eat and/or out compete native invertebrate species, could adversely affect natural communities (McClory and Gotthardt 2008). These and other invasive species could affect the prey base for some marine mammals. As climate change continues to warm Alaskan waters, Alaska may become more susceptible to invasive species (McClory and Gotthardt 2008).

Accidents. Marine mammals could be exposed to oil accidentally released from platforms, pipelines, and vessels in each of the areas offshore Alaska included in the proposed Program (Table 4.4.2-1). Non-OCS sources of oil in Cook Inlet may include the domestic transportation of oil, State oil and gas development, and natural sources such as seeps. Accidental oil releases from OCS activities and other sources could expose marine mammals to oil by body contact or through the inhalation or ingestion of oil or tar deposits. Indirect effects may occur as a result of loss or displacement of prey resources or habitat loss resulting from oil. The magnitude and duration of exposure will be a function of the location, timing, duration, and size of the spill; the proximity of the spill to feeding and other important habitats; the timing and nature of spill containment; and the status of the affected animals. Most expected small to medium spills (less than 1,000 bbl) would have limited effects on marine mammals due to the relatively small areas likely to incur high concentrations of hydrocarbons and the short period of time during which potentially toxic concentrations would be present. The magnitude of impact would be expected to increase should a spill occur in habitats important to marine mammals or affect a number of individuals from a population listed under the ESA, and, as such, a significant spill would have a high probability of producing significant, population-level cumulative impacts on Cook Inlet marine mammals.

Conclusion**.** Cumulative impacts on marine mammals in the Cook Inlet Planning Area as a result of future OCS program and ongoing and future non-OCS program activities could be minor to moderate over the next 40 to 50 years. Non-OCS program activities or phenomena include climate change, natural catastrophes, contaminant releases, vessel traffic, commercial fishing, subsistence harvests, and invasive species. The incremental contribution of routine Program activities to these impacts would be negligible to small (see Section 4.4.7.1.2).

Marine mammals may also be adversely affected by exposure to oil that is accidentally released from OCS and non-OCS activities as well as naturally occurring seeps. The cumulative impacts of past, present, and future oil spills on marine mammals would be minor to moderate. The incremental impacts of expected accidental spills associated with the Program on marine mammals would be negligible to small, depending on the location, timing, and volume of the spills; the environmental settings of the spills; and the species exposed to the spills (Section 4.4.7.1.2). Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from minor to major if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to the impacts of spills regardless of size, but their incremental contribution to cumulative impacts is generally expected to be small. A more detailed discussion of the effects of oil spills on marine mammals in Cook Inlet is presented in Section 4.4.7.1.2.

Terrestrial Mammals. Terrestrial mammals and their habitats could be affected by a variety of activities associated with the proposed OCS actions (Section 4.4.7.1.2). These activities include the construction and operation of onshore pipelines and aircraft traffic. Impacts on terrestrial mammals may include physical injury or death; behavioral disturbances; lethal or sublethal toxic effects; and loss of reproductive, nursery, feeding, and resting habitats. There are currently no ongoing OCS activities in the Cook Inlet; thus all OCS development and any associated impacts on terrestrial wildlife in the Cook Inlet Planning Area would result from the Program and future actions.

Impacts from OCS pipeline construction and operation could include the injury or death of smaller mammals (such as mice and voles) and the disturbance and displacement of individuals or groups of larger species (such as deer and bear). Individuals most affected by these impacts would be those in the immediate vicinity of the pipeline. Because of the limited areal extent of new facilities under the Program, disturbance (primarily behavioral in nature) of most of these species during construction would be largely temporary, and no long-term population-level effects would be expected. However, careful siting of pipelines to avoid important habitats could minimize the potential impacts.

Under the Program, vehicle traffic associated with normal construction, operation, and maintenance of the onshore pipelines could disturb wildlife. Vehicle traffic could disturb wildlife foraging along pipelines or access roads, causing affected wildlife to temporarily stop normal activities (e.g., foraging, resting) or leave the area, while collision with vehicles could injure or kill some individuals. Because vehicle traffic would be infrequent, vehicle-related impacts associated with the Program would be minimal. In the Cook Inlet, vehicle traffic along any new access roads would be very light and infrequent and, thus, not expected to affect more than a few individuals or result in population-level impacts on wildlife.

In the Cook Inlet area, terrestrial mammals are mostly habituated to aircraft due to year-round military and civilian aircraft operations. Only up to three weekly helicopter trips are projected in the Cook Inlet Planning Area under the Program. Impacts on terrestrial mammals from helicopter overflights would be behavioral in nature, primarily resulting in short-term disturbance in normal activities, and would not result in population-level effects.

Terrestrial mammals could also be affected by a number of non-OCS activities, including oil and gas exploration and development in State waters, and coastal and community development. Many of the effects of these activities on terrestrial mammals would be similar in nature to those resulting from OCS-related activities, namely behavioral disturbance, habitat disturbance, and injury or mortality. The State of Alaska has made leases of State waters available along the northern portion of Cook Inlet (above Homer) since the 1950s. Impacts on terrestrial mammals that could result with oil and gas lease sales in State waters may exceed potential impacts that could occur under the OCS Program because of the greater extent of offshore and onshore development related to the State lease sales. In addition, much of the infrastructure is over 40 years old, and many of the pipes are aging and corroded (NMFS 2008c). Terrestrial mammals may be affected as a result of coastal and community development. Such development may result in the loss of habitat and the permanent displacement of some species from the developing areas. Implementation of the Program could increase coastal and community development, indirectly adding to impacts on terrestrial mammals and their habitats.

Terrestrial wildlife could be adversely affected by the accidental release of oil from an onshore pipeline, or by offshore spills contacting beaches and shorelines utilized by terrestrial mammals (such as Sitka black-tailed deer or brown bear). Impacts on terrestrial mammals from an oil spill would depend on such factors as the time of year, volume of the spill, type and extent of habitat affected, food resources used by the species, and home range or density of the wildlife species. Spills contacting high-use areas could locally affect a relatively large number of animals. It is anticipated that most of the spills would have limited effects on terrestrial mammals, due to the relatively small, mostly offshore, areas likely to be directly exposed to the spills and due to the small number and size of spills projected for the Program and for any future OCS oil and gas developments.

State oil and gas development poses a major potential for accidental oil releases in the Cook Inlet Planning Area. Because of the much greater level of oil and gas development in State waters and the aging infrastructure associated with many of these developments, accidental spills associated with the proposed OCS action could contribute relatively little to the overall potential exposure of terrestrial mammals to accidental oil releases in Cook Inlet.

Conclusion. Cumulative impacts on terrestrial mammals in the Cook Inlet Planning Area as a result of future OCS program and ongoing and future non-OCS activities could be minor to moderate over the next 40 to 50 years. Non-OCS activities or phenomena that may affect populations of terrestrial mammals include climate change, natural catastrophes, contaminant releases, and vehicle traffic. The incremental contribution of routine Program activities to these impacts would be negligible to small (see Section 4.4.7.1.2).

Terrestrial mammals may also be adversely affected by exposure to oil that is accidentally released from OCS and non-OCS operations. The cumulative impacts of past, present, and future oil spills on terrestrial mammals would be minor to moderate. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on terrestrial mammals would be negligible to small, depending on the location, timing, duration, and size of the spill; the proximity of the spill to feeding and other important habitats; the timing and nature of spill containment; and the status of the affected animals (see Section 4.4.7.1.2).

An unexpected, low-probability CDE has a greater potential to affect terrestrial habitats; therefore, impacts could range from minor to major if one were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to the impacts of spills regardless of size, but their incremental contribution to cumulative impacts is generally expected to be small. A more detailed discussion of the effects of oil spills on terrestrial mammals in Cook Inlet is presented in Section 4.4.7.1.2.

4.6.4.2.2 Marine and Coastal Birds. Section 4.4.7.2.2 discusses impacts on marine and coastal birds in Cook Inlet resulting from the Program (OCS program activities from 2012 to 2017). Cumulative impacts on marine and coastal birds result from the incremental impacts of the Program when added to impacts from reasonably foreseeable future OCS program activities (that are not part of the Program) and other non-OCS program activities. Table 4.6.1-2 presents the exploration and development scenario for the Cook Inlet cumulative case (encompassing the Program and other OCS program activities) over the next 40 years. A number of OCS program activities could affect Cook Inlet marine or terrestrial birds or their habitats; these include offshore exploration, construction of offshore platforms and pipelines, construction of onshore pipeline landfalls and pipelines, operations of offshore and onshore facilities, and OCS-related marine vessel and aircraft traffic. Potential impacts on marine and coastal birds from OCS program activities include injury or mortality from collisions with platforms, vessels, and aircraft; lethal and sublethal exposure to operational discharges; injury or mortality from the ingestion of trash or debris from OCS vessels and platforms; loss or degradation of habitat due to construction; and behavioral disturbance due to the presence of, and noise generated by, equipment and human activity.

Non-OCS program activities affecting marine and coastal birds in Cook Inlet (both inside and outside of the Planning Area proper) include dredging and marine disposal; coastal and community development; onshore and offshore construction and operations of facilities associated with State oil and gas development and other industrial complexes (e.g., at Nikiski); commercial and recreational boating; and small aircraft traffic. Potential impacts on marine and coastal birds from these activities are similar to those under the OCS program and include injury or mortality of birds from collisions with platforms associated with State oil and gas development and other onshore and offshore structures (e.g., radio, television, or cell phone towers), onshore industrial, commercial, and residential development; exposure to discharges from permitted point sources such as sewage treatment discharges and nonpoint sources such as urban runoff, or accidental releases (e.g., oil spills), as described in Section 4.6.2.1.2 and Table 4.6.1-4; exposure to emissions from various onshore and offshore sources (e.g., power generating stations, refineries, and marine vessels), as described in Section 4.6.2.1.2; ingestion of trash or debris; loss or degradation of habitat due to construction and operations activities; and behavioral disturbance due to the presence of, and noise generated by, equipment and human activity. Other trends such as extensive melting of glaciers (and increasing river discharges) and increased precipitation brought on by global climate change are also expected to adversely affect marine and coastal birds over the next 40 years.

Injury or Mortality from Collisions. Under the cumulative scenario, annual collision injury or mortality in Cook Inlet could increase in the near term as platforms are built under the Program. Such impacts would be minor relative to those that currently involve non-OCS structures. Over time, the injury or mortality impacts from collisions could decrease as oil and gas production in the inlet declines.

Exposure to Wastewater Discharges and Air Emissions. The discharge of operational wastes and air emissions from current non-OCS related vessel traffic and platform operations in Cook Inlet is strongly regulated and would continue to be so regulated over the next 40 years. However, such wastes and emissions would still expose marine and coastal birds to potentially toxic materials or to solid debris that could be ingested or result in entanglement. These facilities and activities include sewage treatment plants, industrial manufacturing or processing facilities, electric generating plants, dredging and marine disposal, and vessel traffic (e.g., cargo and tanker ships, cruise ships, commercial fishing vessels, and recreational vessels). Operational wastewater discharges and air emissions associated with the Program would contribute to the overall cumulative risk of toxic exposure and debris ingestion or entanglement of existing non-OCS wastewater discharges and air emissions in the inlet, but the incremental increase in impact is expected to be small relative to these other activities.

Under the Program, marine and coastal birds could be exposed to oil accidentally released from platforms, pipelines, and vessels, and would be most susceptible to adverse impacts from spills occurring in coastal areas and affecting feeding and nesting areas. Most of the oil released to Cook Inlet is from commercial and recreational vessels (Section 4.6.2.2.1). Oil releases from all sources may expose marine and coastal birds via direct contact or through the inhalation or ingestion of oil or tar deposits (see Section 4.4.7.2.1).

Marine and coastal birds may become entangled in, or ingest, floating, submerged, and beached debris (Heneman and the Center for Environmental Education 1988; Ryan 1987, 1990). Entanglement may result in strangulation, injury or loss of limbs, entrapment, or the prevention or hindrance of the ability to fly or swim; all of these effects may be considered lethal. Ingestion of debris may irritate, block, or perforate the digestive tract, suppress appetite, impair digestion of food, reduce growth, or release toxic chemicals (Fry et al. 1985; Dickerman and Goelet 1987; Ryan 1988; Derraik 2002). Because the discharge or disposal of solid debris into offshore waters from OCS structures and vessels is prohibited by BOEM (30 CFR 250.40) and the USCG (MARPOL, Annex V, Public Law 100 220 [101 Statute 1458]), entanglement in or ingestion of OCS-related trash and debris by marine and coastal birds would not be expected under normal operations.

Oil Spills and Cleanup Activities. Oil spills under the cumulative scenario are shown in Table 4.6.1-3. No more than one large spill (between 1,000 and 5,300 bbl from either a platform or a pipeline) and 18 small spills (less than 1,000 bbl) would be expected as a result of the Cook Inlet Planning Area OCS program over the next 40 years. Previous modeling of similar-sized oil spills in Cook Inlet indicates that land segments with the highest chance of contact with an offshore platform or pipeline spill are generally along the western shore of lower Cook Inlet in Kamishak Bay and Shelikof Strait (MMS 2002b). A large number of seabird colonies occur in these areas (USGS undated) and could be affected by oil spills reaching these areas.

Nesting and brood-rearing seabirds, waterfowl, and a few shorebirds, as well as the many species of waterfowl/loons, seabirds, and shorebirds that molt, stage, migrate through, or overwinter in large numbers in south central Alaska would be vulnerable to the potential disturbance resulting from elevated vessel and aircraft activity associated with cleanup of an oil spill. For all species, the degree of impact depends heavily on the location of the spill and cleanup response and its timing with critical natural behaviors (e.g., breeding, molting, feeding). Survival and fitness of individuals may be affected, but this infrequent disturbance is not expected to result in significant population losses.

As a result of response to the *Exxon Valdez* oil spill of 1989, and subsequent study of its effect on regional bird populations, there exists an extensive literature concerning the effects of a large oil spill in the South Alaska region (e.g., Agler and Kendall 1997; Boersma et al. 1995; Day et al. 1997a, b; *Exxon Valdez* Oil Spill Trustee Council 2004; Irons et al. 2000; Klowsiewski and Laing 1994; Lanctot et al. 1999; Murphy et al. 1997; Piatt and Ford 1996; Piatt et al. 1990; Rosenberg and Petrula 1998; van Vliet and McAllister 1994; Wiens et al. 2001). An estimated 100,000 to 300,000 marine birds died as a result of this spill (Piatt and Ford 1996), which occurred in March, when substantial numbers of overwintering birds were present in Prince William Sound and downstream to the west, and large numbers of seabirds were aggregating near colonies from Prince William Sound to the western Gulf of Alaska, prior to the breeding season. Although surveys and other studies carried out every year since the spill occurred indicate that populations of some marine bird species have recovered from their initial losses (e.g., common murre, black oystercatcher [*Exxon Valdez* Oil Spill Trustee Council 2004]), or are recovering (e.g., marbled murrelet), several species have shown little or no recovery (e.g., common loon, three cormorant species, harlequin duck, pigeon guillemot) or the recovery status is unknown (Kittlitz's murrelet). Although the effect on a bird population that is observed immediately following a spill to have suffered a large mortality is quite obvious, without frequent monitoring of each species following a spill it usually is difficult to be certain whether changes in measured population parameters are the result of lingering spill effects or natural variations that generally occur in all populations over time (Wiens and Parker 1995; Wiens 1996; Wiens et al. 2001). For example, forage fish populations utilized by many marine bird species may have experienced lingering spill effects of severe mortality or interruption of the annual cycle, in turn affecting food availability following the spill and thus influencing the effect of the spill on these bird populations or their recovery from it.

In addition to the birds occupying the open water of bays and inlets, shorebirds numbering in the tens to hundreds of thousands are at risk of oiling where they occupy various shore habitats during their spring passage to northern breeding areas (Gill and Tibbitts 1999). Particularly large numbers would be at risk on the southern Redoubt Bay, Fox River Delta, northern Montague Island, Kachemak Bay, and Copper River Delta, but substantial numbers may be at risk along most shorelines of the region during this season (Gill and Senner 1996; Gill and Tibbitts 1999; Alaska Shorebird Working Group 2000). Based on the experience of the *Exxon Valdez* oil spill, where studies extending 15 years after the event continue to find oil or effects on organisms from exposure to oil, it is highly probable that not all oil spilled would be removed from the environment. Because substantial numbers of birds are present year round in the marine environment of south central Alaska, major effects are expected to result from a spill at any time of year.

Loss or Degradation of Habitat. Marine and coastal birds could be affected by platform construction and removal activities, and pipeline trenching, which could disrupt behaviors of nearby birds. Platforms constructed under the Program would increase the number of offshore platforms present in the inlet by three, and up to 241 km (150 mi) of new offshore pipeline could be constructed. Platform emplacement could disturb birds temporarily; pipeline trenching may also affect birds in nearshore coastal habitats if it occurs in or near foraging, overwintering, or staging areas, or near seabird colonies. About 169 km (105 mi) of new pipeline and one pipeline landfall may be constructed under the Program. The pipelines would likely result in the short- and/or long-term disturbance of a small amount of habitat along the pipeline routes.

While habitat impacts from the construction and operations of onshore facilities could be long term in nature, the areas disturbed would be largely limited to the immediate vicinity of the pipelines and represent a very small portion of habitat available in the Cook Inlet Planning Area. Siting new pipelines and facilities away from coastal areas would reduce the amount of marine or coastal bird habitat that could be affected. Potential habitat impacts could be further reduced by locating the new pipelines within existing utility or transportation rights-of-way, and by locating the new pipeline landfalls away from active colony sites or coastal staging areas of migratory birds. Because there are relatively few nesting colonies in Cook Inlet of Anchor Point (USGS undated), only a few seabird colonies could be affected by onshore construction activities in this area. The disturbance of birds in these colonies could be reduced or avoided by siting new pipelines and facilities away from colony sites, and by scheduling construction activities to avoid nesting periods. Overall, onshore construction activities are expected to affect only a relatively small number of birds and not result in population-level effects.

Only small numbers of nesting birds are likely to be displaced away from the vicinity of onshore pipeline corridors (a few hundred meters) by construction activity and support vessel traffic in the Cook Inlet Planning Area. Onshore habitat alteration is likely to be relatively minor in most of the development support centers. Offshore, disturbance of bottom habitats by platform placement may disrupt small areas of potential diving duck and seabird foraging habitat, but these small removals would be inconsequential.

Construction of landfalls, onshore pads, and roads is not expected to affect the relatively low numbers of loons, waterfowl, and shorebirds nesting in south central Alaska adjacent to likely oil development areas, particularly because construction may take place mainly during the winter season. Like loons and waterfowl that do not migrate out of State, seabirds disperse into nearshore or offshore waters in winter, away from likely development activity.

Disturbance Due to Noise. Noise and human activities (such as normal maintenance) could disturb birds arriving in the area during spring migration and later in the year during nesting, fall molting, and staging periods, causing them to avoid the area and nearby habitats. Because of the small number of new platforms (no more than three), the disturbance of birds in offshore waters by operational noise and human activity would likely be limited to the individuals that might be present around a platform. Potential impacts on colonies could be avoided or mitigated by siting platforms and onshore facilities away from colony sites. Noise from air guns and disturbance from survey vessel traffic could displace foraging seabirds in offshore waters, especially if exploration occurs in high seabird density areas such as the open waters adjacent to the Stevenson and Kennedy Entrances to Cook Inlet and off of the northwestern coast of Kodiak Island (MMS 2003b).

Nesting, staging, migrant, or overwintering loons, waterfowl, and seabirds occurring in areas closer to primary Cook Inlet support facilities on the Kenai Peninsula and vicinity, for example, are more likely to be overflown by aircraft than those in more distant lease areas. This is due to the convergence of routes from offshore sites to the support area, and is expected to be the case in the Gulf of Alaska, Kodiak Island, and Alaska Peninsula areas, where there are few communities capable of adequate support activity. Effects from noise disturbance would be greater in areas where higher concentrations of birds occurred and less where birds were more dispersed and in fewer numbers. The degree of effect is also dependent on whether birds are engaged in critical aspects of their seasonal activity, as well as the intensity and type of disturbance (aircraft overflights, seismic surveys, vessel traffic). In addition, several open-water areas in the vicinity of Kachemak and Kamishak Bays represent important wintering areas (December–April) for the threatened Steller eider (USFWS unpublished data), and disturbance during the winter in these areas has a greater potential to affect this listed species.

Effects on ESA-Listed Species in South Central Alaska. The cumulative effects of OCS and non-OCS program activities on the endangered short-tailed albatross, threatened

Steller's eider, formerly threatened Aleutian Canada goose, and proposed Kittlitz's murrelet are expected to be similar to those noted for nonlisted species over the next 40 years. Continued compliance with ESA regulations and coordination with the USFWS would ensure that lease-specific OCS operations would be conducted in a manner likely to avoid or greatly minimize the potential for affecting these species.

Short-tailed albatrosses occur in waters of south central Alaska, and particularly in continental shelf waters, which places them at considerable oil-spill risk. Although their small population is spread throughout the North Pacific Ocean and few would be expected to be present during any given oil-spill event, the species has a high oil vulnerability index (King and Sanger 1979), and the loss of a few individuals could be detrimental to their small population size (MM 2003b). Because Aleutian Canada geese are not known to occupy marine waters during migration to any great extent, their risk of oil-spill contact in that habitat is considered low. It is unlikely that infrastructure development would occur near the two nesting areas, thus avoiding disturbance and onshore spills that could contact the species.

Factors such as disturbance due to increased boat traffic related to wildlife cruises and offshore oil and gas development, impacts related to oil spills, and a high oil vulnerability index (King and Sanger 1979) make the Kittlitz's murrelet particularly vulnerable to population declines. Although impacts of oil spills have been documented (van Vliet and McAllister 1994; Carter and Kuletz 1995), little is known about potential impacts of disturbance on courtship behavior, foraging ecology and feeding, or energetics (Day et al. 1999). The relatively small population size, limited distribution, apparent periodic breeding failures and low reproductive potential (Beissinger 1995), in conjunction with the above factors, has led to Kittlitz's status as a candidate species (priority 5; 50 CFR Part 17) under the ESA.

Steller's eiders occupying nearshore areas of the eastern Aleutian Islands to Cook Inlet from late fall to early spring could be exposed to the disturbance of air and vessel traffic, seismic surveys, oil-spill cleanup, and pipeline construction. Such activities would be scattered in occurrence, as are the flocks of eiders, or confined to specific corridors in the case of aircraft and vessels, which the flocks are likely to avoid. In general, interactions are expected to result in short-term and localized displacement. Pipeline construction is expected to result in the loss of a small amount of eider nearshore bottom-feeding habitat. Steller's eiders could be killed or injured as a result of collisions with platforms. This is most likely during migration; when visual conditions are reduced, such as in foggy weather; and during movement among habitats on wintering grounds. Because they typically are present throughout the winter, they are at risk for oil-spill contact, particularly in the northern portion of the region including Cook Inlet, where development may first occur, and potentially in the Kodiak Archipelago. However, mortality from a spill is difficult to estimate because of the substantial variation in between-year, seasonal, or even weekly presence and distribution of eiders and uncertainties of where an oil spill might occur. Based on USFWS assumptions, there is greater potential for the majority of individuals affected by factors discussed above to be from the Russian breeding population rather than the ESA-listed Alaska breeding population.

Kittlitz's murrelets typically show a very patchy distribution and are generally found in the vicinity of glaciated fjords of Cook Inlet, Prince William Sound, and southeast Alaska

(Kendall and Agler 1998; Day et al. 1999; Kuletz et al. 2003a). Exploration and development activities are expected to be separated in time, so exposure to disturbing factors such as aircraft and vessel traffic, seismic surveys, and pipeline construction could be infrequent and localized in areas where this species concentrates. There is a greater potential for effects if disturbance occurs in areas where murrelets concentrate and displacement becomes a possibility. In addition, the potential impacts from oil spills vary depending on the timing and location of the spill. For example, oil spills in College or Harrison Fjords during peak breeding or post-breeding would have larger impacts and could cause population-level effects, especially if birds come in contact with spilled oil or larger numbers of breeding age females are impacted. A large spill is likely to spread over a sufficiently large area to contact one or more bays where they may be concentrated during the summer breeding season, or offshore areas where they may be wintering in the Gulf of Alaska. For example, the *Exxon Valdez* oil spill resulted in the loss of an estimated 500 to 1,000 individuals, probably a substantial proportion of the world population, and certainly a major effect on this species.

Conclusion. Marine and coastal birds in Cook Inlet, including those that are ESA-listed, could be adversely affected by activities associated with the Program, as well as those associated with future OCS and non-OCS program activities. Potential impacts include injury or mortality of birds from collisions with platforms associated with OCS and State oil and gas development and other onshore and offshore structures (e.g., radio, television, or cell phone towers), onshore industrial, commercial, and residential development; exposure to discharges from permitted point sources such as sewage treatment discharges and nonpoint sources such as urban runoff, or accidental releases (e.g., oil spills); exposure to emissions from various onshore and offshore sources; ingestion of trash or debris; loss or degradation of habitat due to construction and operations activities; and behavioral disturbance due to the presence of, and noise generated by, equipment and human activity. Other trends such as extensive melting of glaciers (and increasing river discharges) and increased precipitation brought on by global climate change are also expected to adversely affect marine and coastal birds over the next 40 to 50 years. While the cumulative impact of all OCS and non-OCS activities in Cook Inlet could be minor to moderate, the incremental contribution due to routine Program activities would be negligible to medium (see Section 4.4.7.2.2). Compliance with ESA regulations and coordination with the USFWS would ensure that lease-specific OCS operations would be conducted in a manner that is likely to avoid or to greatly minimize the potential for affecting these species.

Marine and coastal birds may also be adversely affected by exposure to oil (via direct contact or through the inhalation or ingestion of oil or tar deposits) that is accidentally released from OCS and non-OCS activities, especially near coastal areas and affecting feeding and nesting areas. The incremental contribution of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on marine and coastal birds would be small to large, depending on the location, timing, duration, and size of the spill; the proximity of the spill to feeding and nesting areas; the timing and nature of spill containment; and the status of the affected birds (see Section 4.4.7.2.2). Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from moderate to major if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to the impacts of spills regardless of size, but their incremental contribution to cumulative impacts is generally expected to be small. A more detailed discussion of the effects of oil spills on marine and coastal birds in Cook Inlet is presented in Section 4.4.7.2.2.

Whether net cumulative impacts are minor or moderate depends on the nature and duration of activities that reduce bird survival and productivity. Losses would be limited in areas occupied by scattered flocks during relatively brief staging and migration periods or scattered nest sites during the brief nesting season; however, in cases for which exposure to localized disturbance is greater, impacts have the potential to rise to the population level.

4.6.4.2.3 Fish. Section 4.4.7.3.2 discusses direct and indirect impacts on fish communities in Cook Inlet resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on these resources result from the incremental impacts of the Program (described in Section 4.4.6.1.1) when added to impacts from ongoing and reasonably foreseeable future actions, including those of future OCS programs and other non-OCS activities. Table 4.6.1-3 presents the exploration and development scenario for the Cook Inlet cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future OCS programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in Cook Inlet are summarized in Table 4.6.1-6 and discussed below, as applicable.

The primary routine OCS activities in the Cook Inlet Planning Area that could result in impacts on fish include seismic surveys, drilling, platform and pipeline placement; releases of permitted discharges from wells; and removal of existing structures. Potential environmental impacts associated with the building and operation of OCS facilities such as platforms and pipelines would increase in conjunction with the increased number of wells. The impacts of routine activities (exploration and site development, production, and decommissioning) on fish communities are discussed in detail in Section 4.4.7.3.2. Overall, routine activities represent up to a minor disturbance, primarily affecting demersal fishes, with the severity of the impacts generally decreasing dramatically with distance from bottom-disturbing activities.

In the Cook Inlet Planning Area, up to three platforms would be constructed, all of which would result from the Program. The addition of new platforms may act as FADs that would attract rockfish and cod-like fishes in Cook Inlet. While some platforms may be allowed to remain as artificial reefs, removal of platforms would reduce available substrate and structures for these fish and some of their prey species. Some fish would be killed in the process of these platform removals although the chance of mortality would be greatly reduced by the fact that explosives would not be used in removal.

Oil and gas exploration and development in State waters could also contribute to cumulative effects on fishery resources in the Cook Inlet. Drilling of wells in State waters could also require construction of platforms and pipelines in waters of Alaska. The effects on fish would be similar to those described above for OCS oil and gas programs (Section 4.4.7.3.2). Other non-OCS activities that could impact fish communities include land use practices, point and non-point source pollution, logging, dredging and disposal of dredging spoils in OCS waters, anchoring, and commercial or sportfishing activities, and commercial shipping (including imported oil). Many of these activities would result in bottom disturbance that would affect bottom-dwelling fishes as well as their food sources in a manner similar to those described for OCS activities (Section 4.4.7.3.2).

Logging could also degrade riverine habitats that are important reproductive and juvenile habitat for migratory fish species. Erosion from areas undergoing commercial logging could increase the silt load in streams and rivers, which could reduce levels of invertebrate prey species and adversely affect spawning success and egg survival. The introduction of fine sediments into spawning gravels may render these habitats unsuitable for salmon spawning. Logging could also remove riparian canopies along some streams, which could increase solar heating of freshwater habitats. Downed timber could physically block salmon migrations. Because of past damage inflicted by commercial logging, improved forestry practices have been initiated, and timber harvests have been curtailed. Continued implementation of effective forest management techniques should help mitigate the adverse effects of logging in the future. Cumulative impacts on migratory species could also occur as a result of activities that obstruct fish movement in marine environments during migration periods.

Commercial fishing practices that are indiscriminate, such as trawling and pots, are responsible for significant amounts of bycatch that can injure or kill juveniles of many fish species (Cooke and Cowx 2006). These types of fishing practices could damage future year classes, reduce available prey species, and damage benthic habitat for many Cook Inlet fish resources. A wide variety of methods are used to target numerous species of fishes and shellfishes, including longlines, seines, setnets, trawls, and traps. Some fisheries target particular fish species returning to their natal stream or river, while other fisheries take place in pelagic waters and target mixed stocks of fishes or shellfishes.

As a consequence of the pressure commercial fishing places on fishery resources, appropriate management is required to reduce the potential for depletion of stocks due to overharvesting. Fisheries in the Cook Inlet Planning Area are managed by State (Alaska Department of Fish and Game) and Federal (North Pacific Fishery Management Council of the National Marine Fisheries Service) agencies. Even with management, the possibility of overfishing still exists. Occasionally fisheries are closed when stocks are considered insufficient to support harvesting, and will sometimes remain closed for multiple seasons before stocks are deemed sufficient.

Although the magnitude of harvests is considerably smaller than for commercial fisheries (Fall et al. 2009), sportfishing also contributes to cumulative effects on the abundance of some fishery resources. Recreational fisheries have a potential to result in overharvest of managed species over the life of the Program. Recreational fishing is subject to harvest limits that reduce the potential for overfishing and recreational fishing methods are less destructive of EFH compared to commercial fisheries.

Subsistence fishing may also contribute to the cumulative effects on the abundance of some fishery resources. Alaska State law defines subsistence as the “noncommercial customary and traditional uses” of fish and wildlife. Subsistence fishing is subject to harvest limits that reduce the potential for overfishing. Also, much of Cook Inlet is defined as a nonsubsistence area and subsistence fishing is therefore not authorized. Consequently, subsistence fishing makes a relatively minor contribution to the reduction in fish stocks compared to commercial fishing (Fall et al. 2009).

Another source of cumulative impacts to fishery resources is the "personal use" fishery which is a legally defined as "the taking, fishing for, or possession of finfish, shellfish, or other fishery resources, by Alaska residents for personal use and not for sale or barter, with gill or dip net, seine, fish wheel, long line, or other means defined by the Board of Fisheries." In the Cook Inlet Planning Area, there are personal use fisheries for salmon, herring, and eulachon. Personal use fisheries are subject to harvest limits that reduce the potential for overfishing. Like subsistence fishing, the personal use fishery is a relatively minor contributor to the reduction in fish stocks compared to commercial fishing.

Climate change may affect fish communities in the Cook Inlet Planning Area and interact with past, present, and future OCS and non-OCS stressors. Physiological and ecosystem-level stressors related to climate change may interact with the non-climate-related anthropogenic stressors such as overfishing, pollution, and habitat loss discussed above. For example, a climate change–related increase in water temperature that results in physiological stress could make individuals more susceptible to stress from pollution or accidental oil spills. Fish respond directly to climate fluctuations, as well as to changes in their biological environment including predators, prey, species interactions, disease, and fishing pressure. Projected changes in hydrology and water temperatures, salinity, and currents could affect the growth, survival, reproduction, and spatial distribution of marine fish species and of the prey, competitors, and predators that influence the dynamics of these species (Watson et al. 1998). Changes in primary production levels in the ocean because of climate change may affect fish stock productivity.

Climate change could potentially affect large-scale ecological processes. Important coastal habitats could be reduced or eliminated by rising sea levels and increased storm damage. For species spawning in low-lying areas or the intertidal zone, or species using coastal estuaries as nursery grounds, rising sea levels could eliminate spawning or juvenile habitat. Anadromous fish and species using nearshore marshes are likely to be most affected. In addition, the current trend of steadily increasing sea surface temperature may favor higher trophic-level fish by increasing their local productivity or by promoting the expansion of large temperate predators into Alaskan waters (Litzow 2006). The establishment of temperate species and non-native fish introduced by human activities could come at the expense of native species, particularly forage fish like herring and capelin. However, given the complexity and compensatory mechanisms of the ecosystem, predictions about the indirect effects of climate change on specific fish species are subject to great uncertainty.

Oil spills could result from OCS and non-OCS activities. The total number of oil spills and the extent of affected areas would likely increase under the Program in conjunction with increased levels of petroleum exploration and production (Table 4.6.1-4). Non-OCS activities, such as oil and gas development in State waters, domestic transportation of oil or refined petroleum products, and commercial shipping, may also result in accidental spills that could potentially impact fish resources within the Cook Inlet Planning Area. While effects on fishery resources would depend on the timing, location, and magnitude of specific oil spills, it is anticipated that most small to medium spills that occur in OCS waters would have limited effects on fishery resources due to the relatively small areas likely to be exposed to high concentrations of hydrocarbons and the short period of time during which potentially toxic concentrations would be present. Most adult fish in marine environments are highly mobile and may avoid high concentrations of hydrocarbons, although they may be subject to sublethal exposures. However, eggs and larvae as well as small obligate benthic species do not have the ability to avoid spills and may therefore suffer lethal or sublethal effects. Oil from a catastrophic spill that reaches shallower, nearshore areas of these planning areas has the potential to be of greatest significance to fish communities. Impacts from such spills could result in long-term, population level impacts on fish communities. The potential impacts of OCS oil spills on fish communities in Cook Inlet are discussed in detail in Section 4.4.7.3.2.

Oil reaching salmon spawning areas, nursery areas, or migration routes has the greatest potential to reduce salmon stocks. However, because of the limited area affected by oil spills relative to the wide pelagic distribution and highly mobile migratory patterns of salmonids, it is anticipated that most impacts would be limited to small fractions of exposed salmon populations. Oil spills occurring at constrictions in migration routes would have an increased potential for adversely affecting salmon. However, the weathering and dispersal of the spilled oil would limit the length of time that an area would be affected. Pacific salmon are also able to detect and avoid oil spills in marine waters (Weber et al. 1981), which would help to reduce the potential for contact. Aggregations of salmon in marine waters typically consist of mixed stocks, so even in the unlikely event of contact with an oil spill, it is anticipated that only a small fraction of any unique spawning population would be adversely affected.

Adverse effects of oil spills on groundfishes of south central Alaska would also be a function of spill magnitude, location, and timing. Adult groundfishes are primarily demersal and would generally be subjected only to the insoluble oil and water-soluble fractions of oil that reach deeper strata. Insoluble oil fractions would sink to the bottom and be distributed diffusely as tar balls over a wide area, and would be unlikely to produce noticeable reductions in the overall numbers of adult fishes. Egg and larval stages would be at a greater risk of exposure to oil spills because spawning aggregations of many groundfish species (e.g., walleye pollock) produce pelagic eggs that could come into contact with surface oil slicks. Herring are also potentially susceptible to oil spills because they spawn in nearshore waters for protracted periods of time.

In addition to effects on individuals and species, impacts to fish can result in ecosystem-level effects if the population impacts are significant. For example, fish can occupy a number of trophic levels ranging from herbivore to top level carnivore. As such, fish are critical to energy flow within nearshore and marine food webs. They are also seasonally important food sources to transient carnivores. Consequently, impacts to fish can propagate throughout the food web, affecting birds and marine mammals. In addition, many Alaskan fishes, particularly salmonids, migrate between and within marine, estuarine, and freshwater habitats. In doing so, they transfer nutrients and carbon over a broad area and connect offshore and freshwater and terrestrial ecosystems (Naiman et al. 2002). Significant impacts to fish populations could reduce this transfer, resulting in local changes in productivity.

Conclusion. Cumulative impacts on fish communities in Cook Inlet as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be moderate to major over the next 40 to 50 years. Non-OCS activities or phenomena affecting these resources include oil and gas development in State waters, sediment dredging and disposal, logging, anchoring, fishing/trawling, commercial shipping, and pollutant inputs from point and non-point sources. Many of these activities would affect fish at various life stages as well as their food sources in a manner similar to OCS activities. The incremental contribution of routine Program activities to these impacts (primarily as a result of displacement, injury or mortality of fish and their food sources) would be negligible to small. Fish could also be affected by the environmental changes predicted to result from climate change.

Fish communities may also be adversely affected by exposure to oil that is accidentally released from OCS and non-OCS activities as well as naturally occurring seeps. The cumulative impacts of past, present, and future oil spills on these resources would be minor to moderate. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on fish would be negligible to medium, depending on the location, timing, duration, and volume of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities. Impacts associated with unexpected large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could range up to moderate if it were to occur. Oil from large spills or a CDE has the greatest potential to contact shoreline areas used for spawning or providing habitat for early life stages of fish and, therefore, could result in large-scale lethal and long-term sublethal effects on fish. Oil is slow to break down in Alaskan waters; therefore, oiling could measurably depress some fish populations for several years. A more detailed discussion of the effects of oil spills on fish in Cook Inlet is presented in Section 4.4.7.3.2.

4.6.4.2.4 Invertebrates and Lower Trophic Levels. Section 4.4.7.5.2 discusses direct and indirect impacts on invertebrates and lower trophic levels in Cook Inlet resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on these resources result from the incremental impacts of the Program (described in Section 4.4.6.1.1) when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS activities. Table 4.6.1-3 presents the exploration and development scenario for the Cook Inlet cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future OCS programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in the GOM are summarized in Table 4.6.1-6 and discussed below, as applicable.

The primary routine OCS activities that could result in impacts on invertebrates include seismic surveys, drilling, platform and pipeline placement; releases of permitted discharges from wells; and removal of existing structures. Potential environmental impacts associated with the building and operation of OCS facilities such as platforms and pipelines would increase in conjunction with the increased number of wells. The impacts of routine activities (exploration and site development, production and decommissioning) on invertebrate communities are discussed in detail in Section 4.4.7.5.2. Overall, routine activities represent up to a moderate disturbance, primarily affecting benthic infaunal invertebrates, with the severity of the impacts generally decreasing dramatically with distance from bottom-disturbing activities.

Up to three platforms could be constructed over the life of the Program, all of which would result from the Program, would allow the colonization of invertebrates requiring hard substrate. While some platforms may be allowed to remain as artificial reefs, removal of platforms will reduce available substrate and structures for invertebrates and injure or kill them during removal.

Oil and gas exploration and development in State waters could also contribute to cumulative effects on invertebrates in the Cook Inlet Planning Area. Drilling of wells in State waters could also require construction of platforms and pipelines in waters of Alaska. The effects on invertebrates would be similar to those described above for OCS oil and gas programs (Section 4.4.7.5.2). Other non-OCS activities that could impact invertebrate communities include land use practices, point and non-point source pollution, logging, dredging and disposal of dredging spoils in OCS waters, anchoring, commercial or sportfishing activities, and commercial shipping (including shipping of imported oil). Many of these activities would affect bottom-dwelling invertebrates at various life stages as well as their food sources in a manner similar to OCS bottom-disturbing activities (Section 4.4.7.5.2). Other non-OCS activities generating pollution and noise may contribute to general habitat degradation (Section 4.6.3.2.2).

Commercial fishing practices that are indiscriminate, such as trawling and pots, are responsible for significant amounts of bycatch that can injure or kill juveniles of many invertebrate species. These types of fishing practices could also damage benthic habitat for many Cook Inlet invertebrate resources.

Physical and chemical changes to invertebrate habitat resulting from climate change could alter the existing distribution, composition, and abundance of invertebrates in Cook Inlet, since physical and chemical parameters are the primary influence on invertebrate communities. For example, the increase in seawater temperature may facilitate a northward expansion of subarctic and temperate invertebrate species. Rising seawater temperatures are also expected to decrease winter ice extent and duration. Currently, ice formation primarily occurs on the western side of Cook Inlet, and changes in benthic invertebrate community structure could result from the reduction in ice scour. In addition, in heavily river influenced systems like Cook Inlet, the predicted hydrologic alterations associated with climate change can rapidly alter existing invertebrate communities in the water column and benthos if the new chemical conditions are not within the physiological tolerance of the existing communities. Another significant source of physiological stress is the expected increase in ocean acidification. Crustaceans, echinoderms, foraminiferans, and mollusks could have greater difficulty in forming shells, which could result in a reduction in their fitness, abundance, and distribution (Fabry et al. 2008).

Oil spills could result from OCS and non-OCS activities. The total number of oil spills and the extent of affected areas would likely increase under the Program in conjunction with increased levels of petroleum exploration and production (Table 4.6.1-3). Non-OCS activities, such as oil and gas development in State waters, domestic transportation of oil or refined petroleum products, and commercial shipping, may also result in accidental spills that could potentially impact invertebrate resources within the Cook Inlet Planning Area. While effects on invertebrate resources would depend on the timing, location, and magnitude of specific oil spills, it is anticipated that most small to medium spills that occur in OCS waters would have limited effects due to the relatively small areas likely to be exposed to high concentrations of hydrocarbons and the short period of time during which potentially toxic concentrations would be present. Large water column and benthic invertebrates are mobile and therefore have the potential to avoid high concentrations of hydrocarbons although they may be subject to sublethal exposures. However, zooplankton and infauna do not typically have the ability to avoid spills and may therefore suffer lethal or sublethal effects. Oil from catastrophic spills that reaches shallower, nearshore areas of the Cook Inlet Planning Area has the potential to be of greatest significance to invertebrate communities. Impacts from such spills could result in long-term, population-level impacts on intertidal invertebrate communities. Benthic and pelagic invertebrates are important trophic links that connect primary producers to higher-trophic-level organisms. Consequently, oil spill contamination on a large scale could result in contaminant transfer to higher trophic levels and/or in reduced food availability to higher trophic levels if invertebrate populations were severely depressed by a CDE. The potential impacts of OCS oil spills on invertebrate communities in Cook Inlet are discussed in detail in Section 4.4.7.5.2.

Commercial shellfish stocks (such as tanner, snow, and red king crab) are unlikely to be exposed to surface oil. Although soluble and insoluble hydrocarbon fractions could reach deeper strata, these fractions would be distributed diffusely over wide areas and would likely not constitute a threat to shellfish stocks. Pelagic crab larvae could be affected if a large surface oil spill occurred during the spring spawning season. However, because the area affected by most spills would be expected to be small relative to overall distributions of crab larvae, overall population levels are unlikely to be noticeably affected.

Conclusion. Cumulative impacts on invertebrate communities in the Cook Inlet Planning Area as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be moderate to major over the next 40 to 50 years. Non-OCS activities or phenomena affecting these resources include oil and gas production in State waters, sediment dredging and disposal, logging, anchoring, fishing/trawling, commercial shipping, and pollutant inputs from point and non-point sources. The incremental contribution of routine Program activities to these impacts (mainly due to bottom-disturbing activities) would be negligible to medium, with the severity of impacts generally decreasing with distance from the disturbance. Several major classes of invertebrates could also be affected by naturally occurring oil seeps and the environmental changes predicted to result from climate change. Invertebrate communities may also be adversely affected by exposure to oil that is accidentally released from OCS and non-OCS activities as well as naturally occurring seeps. The cumulative impacts of past, present, and future oil spills on these resources would be minor to moderate. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on invertebrates would be negligible to small, depending on the location, timing, duration, and size of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could range up to moderate if it were to occur. Spills in deeper water, whether from OCS or non-OCS sources, are unlikely to have overall population-level effects on invertebrate resources because of the relatively small proportion of similar available habitats that would come in contact with released oil at concentrations great enough to elicit toxic effects. A CDE could also contaminate or reduce the abundance of seasonally abundant copepods, which may in turn impact higher trophic levels. A more detailed discussion of the effects of oil spills on invertebrates in Cook Inlet is presented in Section 4.4.7.5.2.

4.6.4.3 Alaska Region – Arctic

4.6.4.3.1 Mammals.

Marine Mammals. The cumulative analysis considers past, ongoing, and foreseeable future human and natural activities that may occur and adversely affect marine mammals in the Arctic Planning Areas. These activities include effects of the OCS Program (Programs and prior and future OCS sales), oil and gas activities in State waters, shipping, commercial fishing, recreational fishing, subsistence fishing, personal-use fishing, and boating activities, military operations, scientific research, and natural phenomena. Specific types of impact-producing factors considered include noise from numerous sources, pollution, ingestion and entanglement in marine debris, vessel strikes, habitat degradation, subsistence harvests, military activities, industrial development, community development, climate change, and natural catastrophes. Section 4.4.7.1.3 provides the major impact-producing factors related to the Program in Cook Inlet.

Routine Activities.

OCS Activities. Marine mammals and their habitats in the Arctic Planning Areas could be affected by a variety of exploration, development and production activities as a result of the proposed and future OCS leasing actions (see Section 4.4.7.1.3). These activities include seismic exploration, offshore and onshore infrastructure construction, the discharge of operational wastes, and vessel and aircraft traffic. Impacts to marine mammals from these activities may include physical injury or death; behavioral disturbances; lethal or sublethal toxic effects; and loss of reproductive, nursery, feeding, and resting habitats. The degree of impact at the population level depends greatly on the status of the population (reflected in its listing under the ESA) and the degree of disturbance or harm from OCS-related activities in areas important to species survival (i.e., feeding, breeding, molting, rookery or haulout areas).

Potential impacts (primarily behavioral disturbance) to marine mammals from OCS-related seismic activity would be short-term and temporary, and not expected to result in population level impacts for any affected species if appropriate mitigation measures are implemented.

Impacts from OCS construction and operation activities could include the temporary disturbance and displacement of individuals or groups by construction equipment and long-term disturbance of some individuals from operational noise. No long-term, population-level effects would be expected because individuals most affected by these impacts would be only those in the immediate vicinity of the construction site or operational platform and disturbance of individuals during construction would be largely temporary. In addition, appropriate mitigation measures could lessen the potential for impacts.

Operational and waste discharges (e.g., produced water, drilling muds, and drill cuttings) would be disposed of through downhole injection into NPDES-permitted disposal wells, and thus would not be expected to result in any incremental impacts to marine mammals. Liquid wastes (such as bilge water) may also be generated by OCS support vessels and on production platforms. While these wastes may be discharged (if permitted) into surface waters, they would be rapidly diluted and dispersed, and would not be expected to result in any incremental impacts to marine mammals from exposure to these wastes. Drilling and production wastes may contain materials such as metals and hydrocarbons, which can bioaccumulate through the food chain into the tissues of marine mammals. Although the bioaccumulation of anthropogenic chemicals has been reported for a variety of marine mammals, adverse impacts or population-level effects resulting from such bioaccumulation have not been demonstrated (Norstrom and Muir 1994; Muir et al. 1999).

Marine mammals could be temporarily disturbed by OCS vessel traffic (all species) or incur injury or death from collisions with support vessels (primarily larger, slower moving cetaceans). The low level of OCS vessel trips in the Arctic Planning Areas under the Program would likely limit potential cumulative impacts to a few individuals, be largely short-term in nature, and not result in population-level effects. Noise from helicopter overflights would be transient in nature. Impacts to marine mammals would be behavioral in nature, primarily resulting in short-term disturbance in normal activities, and would not be expected to result in population-level effects. Overflights and vessels could disturb pinnipeds on rookeries and haul-outs. In particular, disturbance of walruses can cause stampedes, where younger animals and calves can be killed, possibly causing population-level impacts to some species. Appropriate mitigation measures such as overflight restrictions and flightline selection to avoid rookeries and haul-outs would limit the potential for adversely affecting animals at these locations.

No platforms would be removed under the Program for the Arctic Planning Areas.

Non-OCS Activities. A number of non-OCS activities such as oil and gas exploration and development in State waters, subsistence harvests, vessel traffic, and climate change could also affect marine mammals in the Arctic Planning Areas. Many of the effects of these activities on marine mammals would be similar in nature to those resulting from OCS-related activities, namely, behavioral disturbance, habitat disturbance, injury, or mortality, and exposure to toxic substances. Marine mammals may also be adversely affected by climate change.

<u>Oil and Gas Exploration and Development in State Waters.</u> The State of Alaska has made nearshore State lands available for leasing along the Beaufort Sea coast. The exploration activities (and associated impacts to marine mammals) that could result with State oil and gas lease sales may greatly outnumber exploration activities (and potential impacts to marine mammals) that could occur under the OCS Program.

Exploration, construction, and operation activities associated with State leases would occur in nearshore and coastal areas, while OCS platforms and pipelines would be located away from coastal areas (with the exception of relatively few pipeline landfalls and onshore bases and processing facilities). Thus, State oil and gas leasing activities may be expected to have a greater potential for affecting marine mammals in coastal habitats than would the proposed OCS actions.

Subsistence Harvesting. Subsistence harvesting has been identified as impacting marine mammals in Alaskan waters (Allen and Angliss 2011). However, annual mortality from subsistence harvests is considered to have little adverse effect on most marine mammal populations or stocks. The following are the reported estimated annual Alaska-wide subsistence harvests for marine mammals that occur in the Beaufort and/or Chukchi Seas (Allen and Angliss 2011):

- The best estimate of annual subsistence harvest of spotted seals is 5,265 animals.

- The best estimate of annual subsistence harvest of bearded seals is 6,788 animals.

- The best estimate of annual subsistence harvest of ringed seals is 9,567 animals.

- The best estimate of annual subsistence harvest of ribbon seals is 193 animals.

- The best estimate of annual subsistence harvest for the Beaufort Sea beluga whale stock is 139 animals, which includes 25 individuals in Alaska and 114 individuals in Canada.

- The best estimate of annual subsistence harvest for the Eastern Chukchi Sea beluga whale stock is 59 animals.

- There are known subsistence harvests of narwhals by Alaska Natives.

- There are no known subsistence harvests of the Bering Sea stock of harbor porpoises by Alaska Natives. However, Suydam and George (1992) noted that individuals from this stock have been entangled in subsistence nets.

- Annual subsistence take of grey whales averaged 121 individuals between 2003 to 2007. Russian Chukotka people take most of the gray whales. The U.S. Makah Indian Tribe has a yearly average quota of 4 whales. In 2005, an unlawful subsistence hunt and kill of a gray whale occurred in Alaska.

- No subsistence takes of the Northeast Pacific stock of fin whales are reported from Alaska or Russia.

- Subsistence take of minke whales by Alaska Natives is rare (e.g., only nine between 1930 and 1995).

- Alaska Native subsistence hunters take 14 to 72 bowhead whales per year (0.1 to 0.5% of the population). Russian and Canadian subsistence hunters also take a few bowhead whales. The annual subsistence take from 2004 to 2008 for Alaska, Russian, and Canadian Natives averaged 41.2 bowhead whales. Several cases of fishing rope or net entanglement have been reported from whales taken in subsistence hunts.

- The 1925 to 1953 estimated annual Alaska harvests of polar bears for subsistence, handicrafts, and recreation was 120 animals. Recreational harvests by non-Native sports hunters using aircraft averaged 150 annually from 1951 to 1960 and 260 annually from 1960 to 1972. A prohibition on non-Native hunting became effective in 1973. The annual subsistence harvests for the Chukchi/Bering Seas stock was 92/year in the 1980s, 49/year in the 1990s, and 43/year in the 2000s.

- The annual harvests for the Southern Beaufort Sea polar bear stock was 39/year in the 1980s, 33/year in the 1990s, and 32/year in the 2000s.

- The estimated annual subsistence harvest mortalities for the Pacific walrus from 2003 to 2007 averaged from 4,960 to 5,457 animals/year. This includes 1,630 to 1,918 harvested in the United States; 1,247 harvested in Russia; and 2,083 to 2,292 struck and lost.

<u>Climate Change.</u> A concern regarding marine mammals in polar regions is the potential for climate change and associated loss in the extent of sea ice in some Arctic and subarctic waters. Some species, such as the bearded seal and polar bear, are dependent on sea ice for at least part of their life history, and may be more sensitive to changes in Arctic weather, sea-surface temperatures, or extent of ice cover (Allen and Angliss 2011). Ice edges are biologically productive systems where ice algae form the base of the food chain. The ice algae are crucial to Arctic cod, which is a pivotal species in the Arctic food web. As ice melts, there is concern that there will be loss of prey species of marine mammals, such as Arctic cod and amphipods, that are associated with ice edges (MMS 2004a). Changes in the extent, concentration, and thickness of the sea ice in the Arctic may alter the distribution, geographic ranges, migration patterns, nutritional status, reproductive success, and, ultimately, the abundance of ringed seals and other ice-dependent pinnipeds that rely on the ice platform for pupping, resting, and molting (MMS 2004a). Reductions in sea ice coverage would adversely affect the availability of pinnipeds as prey for polar bears. More polar bears may stay onshore during the summer (MMS 2004a). If the Arctic climate continues to warm and early spring rains become more widespread, ringed seal lairs might collapse prematurely, exposing ringed seal pups to increased predation by polar bears and Arctic foxes, negatively impacting the ringed seal population and, therefore, eventually the polar bear population (MMS 2004a).

The loss of sea ice could have several potential effects on bowhead whales. These would include increased noise and disturbance related to increased shipping, increased interactions with commercial fisheries, including noise and disturbance, incidental intake, and gear entanglement; changes in prey species concentrations and distribution; changes in subsistence-hunting practices; increased predation from expanding killer whale range; and competition from expanding fin, humpback, and other baleen whale ranges. Bowhead whale seasonal distribution may change with changes in seasonal ice distribution as well.

<u>Other Impacting Factors.</u> Marine mammals may also be impacted by other factors such as UMEs and invasive species. A UME is an unexpected stranding that involves a significant die-off of any marine mammal population, and demands immediate response (NMFS 2011b). Causes of UMEs include infections, biotoxins, human interactions, and malnutrition (NMFS 2011b). Since establishment of the UME program in 1991, there have been 55 formally recognized UMEs in the U.S., one of the ongoing UMEs involving pinnipeds includes the Arctic (NMFS 2011b). Section 3.8.1.3.1 discusses this UME. Invasive species could affect some marine mammals by disrupting local species and ecosystems, affecting the prey base for some marine mammals. Currently, invasive species are not a major factor in the Arctic Planning Areas. However, as climate change continues to warm Alaskan waters, the Arctic Planning Areas may become more susceptible to invasive species (e.g., from ballast discharges associated with increased vessel traffic).

Accidents. Marine mammals could be exposed to oil accidentally released from platforms, pipelines, and vessels from the Program (Table 4.4.2-1). Potential non-OCS sources of oil spills include the domestic transportation of oil, oil and gas development in State waters, and natural sources such as seeps. Accidental oil releases could expose marine mammals to oil by direct contact or through the inhalation or ingestion of oil or tar deposits. The magnitude and duration of exposure will be a function of the location, timing, duration, and size of the spill; the proximity of the spill to feeding and other important habitats; the timing and nature of spill containment; and the status of the affected animals. Most expected small to medium spills (less than 1,000 bbl) would have limited effects on marine mammals due to the relatively small areas likely to incur high concentrations of hydrocarbons and the short period of time during which potentially toxic concentrations would be present. The magnitude of impact would be expected to increase should a spill occur in habitats important to marine mammals or affect a number of individuals from a population listed under the ESA. Some spills from OCS activity may locally represent the principal source of oil exposure for some species, especially for spills contacting important coastal and island habitats or collecting along ice leads.

Conclusion. Cumulative impacts on marine mammals in the Beaufort and Chukchi Sea Planning Areas as a result of future OCS program and ongoing and future non-OCS program activities could be minor to moderate over the next 40 to 50 years. Non-OCS program activities or phenomena that may affect populations of marine mammals include climate change, contaminant releases, vessel traffic, subsistence harvests, and invasive species. The incremental contribution of routine Program activities to these impacts would be negligible to small (see Section 4.4.7.1.3).

Marine mammals may also be adversely affected by exposure to oil that is accidentally released from OCS and non-OCS activities. The cumulative impacts of past, present, and future oil spills on marine mammals would be minor to moderate. The incremental impacts of expected accidental spills associated with the Program on marine mammals would be negligible to large, depending on the location, timing, and volume of the spills; the environmental settings of the spills; and the species (and number of individuals) exposed to the spills (Section 4.4.7.1.3). Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from minor to major if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to the impacts of spills regardless of size, but their incremental contribution to cumulative impacts is generally expected to be small. A more detailed discussion of the effects of oil spills on marine mammals in the Arctic is presented in Section 4.4.7.1.3.

Terrestrial Mammals. Terrestrial mammals and their habitats could be affected by a variety of activities associated with the proposed OCS actions (Section 4.4.7.1.3). These activities include construction and operation of onshore pipelines and vehicle and aircraft traffic. Impacts to terrestrial mammals from these activities may include physical injury or death; behavioral disturbances; lethal or sublethal toxic effects; and loss of reproductive, nursery, feeding, and resting habitats. In the Arctic Planning Areas, these impacts would be in addition to similar (in nature) impacts resulting from ongoing and planned OCS lease sales under previously approved 5-year programs.

Impacts from OCS construction and operation activities could include the injury or death of smaller mammals (such as mice and voles) and the disturbance and displacement of individuals or groups of larger species (such as caribou, muskoxen, and brown bear). Because of the limited areal extent of new pipeline under the Program, disturbance (primarily behavioral in nature) of most of these species during construction would be largely temporary, and no long-term population level effects would be expected. However, construction activities in the Arctic could disturb caribou in calving, foraging, or insect avoidance habitats, which could affect adult and calf survival. However, the potential for such impacts could be minimized by careful siting of new pipelines to avoid important habitats.

Species such as the Arctic fox that habituate to human activity and facilities could experience local increases in density, while bears may experience increases in mortality associated with defense of life and property killings. In the Arctic, pipelines and roads associated with the Program have the potential to incrementally affect local and seasonal movements of caribou.

Under the Program, vehicle traffic associated with normal operations and maintenance of onshore pipelines could disturb wildlife. Vehicle traffic could disturb wildlife foraging along pipelines or access roads, causing affected wildlife to temporarily stop normal activities (e.g., foraging, resting) or leave the area, while collision with vehicles could injure or kill some individuals. Because vehicle traffic would be infrequent, vehicle-related impacts associated with the Program would result in little incremental increase in vehicle-related impacts from current or ongoing OCS activities in the Arctic.

Up to 27 weekly helicopter trips would occur to platforms in the Arctic Planning Areas. Impacts to terrestrial mammals from helicopter overflights would be behavioral in nature, primarily resulting in short-term disturbance in normal activities, and would not be expected to result in population-level effects. Overflights disturbing active calving and overwintering sites could result in decreased survival of young or adults, and potentially result in population level impacts to some species. Selection of flight lines to avoid overflights of important habitats would greatly limit the potential for adversely affecting calving or overwintering animals.

Terrestrial mammals in the Arctic Planning Area could also be affected by a number of non-OCS activities, including oil and gas exploration and development in State waters, and coastal and community development, and climate change. Many of the effects of these activities on terrestrial mammals would be similar in nature to those resulting from OCS-related activities, namely behavioral disturbance, habitat disturbance, and injury or mortality. The State of Alaska has made leases of State waters available along much of the Beaufort Sea coast. Because these leases are closer to shore than those for the Program, impacts on terrestrial mammals may exceed the potential impacts that could occur under the OCS Program. Implementation of the Program could increase coastal and community development, indirectly adding to impacts to terrestrial mammals and their habitats. Terrestrial mammals could be adversely affected by the accidental release of oil from an onshore pipeline, or by offshore spills contacting beaches and shorelines utilized by terrestrial mammals (such as caribou or brown bears). Impacts to terrestrial mammals from an oil spill would depend on such factors as the time of year and volume of the spill, type and extent of habitat affected, and home range or density of the species. Spills contacting high-use areas (such as caribou calving areas) could locally affect a relatively large number of animals. It is anticipated that most of the spills would have limited effects on terrestrial mammals, due to the relatively small areas likely to be directly exposed to the spills, and the small number and size of spills projected for the Program and for current and planned OCS oil and gas developments. However, some spills may locally represent the principal source of oil exposure for some species, especially for spills contacting important calving or overwintering habitats.

Conclusion. Cumulative impacts on terrestrial mammals in the Beaufort and Chukchi Sea Planning Areas as a result of future OCS program and ongoing and future non-OCS activities could be minor to moderate over the next 40 to 50 years. Non-OCS activities or phenomena that may affect populations of terrestrial mammals include climate change, natural catastrophes, contaminant releases, and vehicle traffic. The incremental contribution of routine Program activities to these impacts would be negligible to small (see Section 4.4.7.1.3).

Terrestrial mammals may also be adversely affected by exposure to oil that is accidentally released from onshore (e.g., Prudhoe Bay) and State offshore oil and gas activities. The cumulative impacts of past, present, and future oil spills on terrestrial mammals would be minor to moderate. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on terrestrial mammals would be negligible to large, depending on the location, timing, duration, and size of the spill; the proximity of the spill to feeding and other important habitats; the timing and nature of spill containment; and the status of the affected animals (see Section 4.4.7.1.3).

An unexpected, low-probability CDE has a greater potential to affect terrestrial habitats; therefore, impacts could range from minor to major if one were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to the impacts of spills regardless of size, but their incremental contribution to cumulative impacts is generally expected to be small. A more detailed discussion of the effects of oil spills on terrestrial mammals in the Arctic region is presented in Section 4.4.7.1.3.

4.6.4.3.2 Marine and Coastal Birds. Section 4.4.7.2.3 discusses impacts to marine and coastal birds in the Arctic region resulting from the Program (OCS program activities from 2012 to 2017). Cumulative impacts on marine and coastal birds result from the incremental impacts of the Program when added to impacts from existing and reasonably foreseeable future OCS program activities (that are not part of the Program) and other non-OCS program activities. Table 4.6.1-2 presents the exploration and development scenario for the Beaufort and Chukchi Seas cumulative cases (encompassing the Program and other OCS program activities) over the next 50 years. A number of OCS program activities could affect Arctic marine or terrestrial birds or their habitats; these include offshore exploration, construction of offshore platforms and pipelines, construction of onshore pipelines, operations of offshore platforms, operational discharges and wastes, and OCS-related marine vessel and aircraft traffic. Potential impacts on marine and coastal birds from OCS program activities include injury or mortality of birds from collisions with platforms, vessels, and aircraft; exposure to operational discharges; ingestion of trash or debris; loss or degradation of habitat due to construction; and behavioral disturbance due to the presence of, and noise generated by, equipment and human activity.

Non-OCS program activities affecting marine and coastal birds in the Beaufort Sea and Chukchi Sea Planning Areas include dredging and marine disposal; coastal and community development; onshore and offshore construction and operations of facilities associated with State oil and gas development (mainly Prudhoe Bay); commercial and recreational boating; and small aircraft traffic. Potential impacts on marine and coastal birds from these activities are similar to those under the OCS program and include injury or mortality of birds from collisions with platforms associated with State oil and gas development and other onshore and offshore structures (e.g., radio, television, or cell phone towers); onshore industrial, commercial, and residential development; exposure to discharges from permitted point sources such as sewage treatment discharges and nonpoint sources such as snowmelt and stormwater runoff; or accidental releases (e.g., oil spills), as described in Section 4.6.2.1.3 and Table 4.6.2-4; exposure to emissions from various onshore and offshore sources (e.g., power generating stations and marine vessels), as described in Section 4.6.2.1.3; ingestion of trash or debris; loss or degradation of habitat due to construction and operations activities; and behavioral disturbance due to the presence of, and noise generated by, equipment and human activity. Other trends such as extensive melting of glaciers (and increasing river discharges), thawing of permafrost, and increased precipitation brought on by global climate change are also expected to adversely affect marine and coastal birds over the next 50 years.

Injury or Mortality from Collisions. Under the cumulative scenario, annual collision injury or mortality in the Beaufort and Chukchi Sea Planning Areas could increase in the near term as platforms are built under the Program. Such impacts would be minor relative to those that currently involve non-OCS structures. Over time, the injury or mortality impacts from collisions could decrease as oil and gas production in the inlet declines.

Exposure to Wastewater Discharges and Air Emissions. The discharge of operational wastes and air emissions from current non-OCS related vessel traffic and platform operations in the Beaufort and Chukchi Seas is strongly regulated and would continue to be so regulated over the next 50 years. Many wastes (such as produced water, drilling muds, and drill cuttings) would be disposed of through onsite injection into NPDES-permitted disposal wells. However, such wastes and emissions would still expose marine and coastal birds to potentially toxic materials or to solid debris that could be ingested or result in entanglement. These facilities and activities include sewage treatment plants, industrial manufacturing or processing facilities, electric generating plants, dredging and marine disposal, and vessel traffic (e.g., cargo and tanker ships and military and research vessels). Operational wastewater discharges and air emissions associated with the Program would contribute to the overall cumulative risk of toxic exposure and debris ingestion or entanglement of existing non-OCS wastewater discharges and air emissions in the inlet, but the incremental increase in impact is expected to be small relative to these other activities.

Under the Program, marine and coastal birds could be exposed to oil accidentally released from platforms, pipelines, and vessels, and would be most susceptible to adverse impacts from spills occurring in coastal areas and affecting feeding and nesting areas. Most of the oil released to Arctic waters is from leaks related to the oil industry (Section 4.6.2.3.1). Oil releases from all sources may expose marine and coastal birds via direct contact or through the inhalation or ingestion of oil or tar deposits (see Section 4.4.7.3.1).

Marine and coastal birds may become entangled in, or ingest, floating, submerged, and beached debris (Heneman and the Center for Environmental Education 1988; Ryan 1987, 1990). Entanglement may result in strangulation, injury or loss of limbs, entrapment, or the prevention or hindrance of the ability to fly or swim; all of these effects may be considered lethal. Ingestion of debris may irritate, block, or perforate the digestive tract, suppress appetite, impair digestion of food, reduce growth, or release toxic chemicals (Fry et al. 1985; Dickerman and Goelet 1987; Ryan 1988; Derraik 2002). Because the discharge or disposal of solid debris into offshore waters from OCS structures and vessels is prohibited by BOEM (30 CFR 250.40) and the USCG (MARPOL, Annex V, Public Law 100 220 [101 Statute 1458]), entanglement in or ingestion of OCS-related trash and debris by marine and coastal birds would not be expected under normal operations.

Oil Spills and Cleanup Activities. Oil spills under the cumulative scenario are shown in Table 4.6.1-3. No more than six large spills (between 1,000 and 5,300 bbl from either a platform or a pipeline) and 530 small spills (less than 1,000 bbl) would be expected as a result of the Beaufort Sea and Chukchi Sea Planning Areas OCS program over the next 50 years.

Loons, waterfowl, and shorebirds in onshore habitats are generally at low risk of contacting a spill while nesting, but risk of exposure increases as they leave the mainland nesting areas and concentrate in coastal or marine habitats for brood rearing, molting, or staging prior to southward migration. In addition, some species (e.g., red-throated loons) forage almost exclusively offshore and bring food back to their nestlings or young, so impacts of oil spills may be greater on these species (Eberl and Picman 1993). Likewise, species nesting on barrier islands, such as common eider, gulls, and terns, are at risk when post-nesting individuals join other species in lagoons and other nearshore habitats. Substantial numbers occupy Simpson and other Beaufort Sea lagoons, Harrison and Smith Bays, Kasegaluk Lagoon, and Peard and Ledyard Bays in the Chukchi Sea at this time. For example, tens of thousands of long-tailed ducks molting in Beaufort Sea lagoons, far outnumbering other species, are at risk in July and August, and in late August and early September, a large proportion of the Pacific flyway brant population could be exposed to a spill that enters Kasegaluk Lagoon. Substantial numbers of non-breeding, foraging, or staging birds that occupy offshore areas in both the Beaufort and Chukchi Seas, when open water beyond the barrier islands is available, could be exposed to an oil spill. Most brood rearing of loons, swans, and geese occurs on large lakes or coastal saltmarsh. Risk of oil spill contact is much greater for those using the latter habitat. The most important molting area for brant and several other species of geese (and to a lesser extent ducks) is the Teshekpuk Lake Special Area (Derksen et al. 1979, 1982). Beached oil along these coastlines could expose hundreds to low thousands or possibly greater numbers of shorebirds that pause along the coast during migration (Connors et al. 1979; Smith and Connors 1993; Andres 1994). In the southeastern Chukchi Sea, large numbers of murres and kittiwakes nesting in seabird colonies at Capes Lisburne and Thompson, together with nonbreeding individuals, form foraging flocks containing tens to hundreds of individuals that also could be exposed to an oil spill. Major effects on bird populations during the open water season are expected to follow a spill. A spill occurring in winter, when birds are virtually absent, still may have serious impacts if substantial quantities of oil are entrained in the ice and then released during the following breeding season.

Large flocks of long-tailed ducks molting in Beaufort Sea lagoons and common eiders occupying barrier islands or lagoons are particularly susceptible to oil spill impacts if they are nesting, brood rearing, or flightless. Likewise, brant staging in Kasegaluk Lagoon in the Chukchi Sea would be particularly vulnerable. For all species, the degree of impact depends heavily on the location of the spill and its timing with respect to critical natural behaviors (e.g., breeding, molting, feeding). Survival and fitness of individuals may be affected, but in many cases, this infrequent disturbance is not expected to result in significant population losses. However, effects may be greater if a spill and cleanup were to occur in the spring when large numbers of king and common eiders, long-tailed ducks, and other waterfowl, seabirds, and shorebirds are present following spring ice-lead systems. In addition, it is unlikely that all spilled oil would be removed from the environment, especially in winter; thus the remaining accumulations could move under the ice and into leads.

In addition to the potential impacts from spilled oil, the oil spill cleanup process may also affect marine and coastal birds in the Arctic region. The presence of large numbers of workers, boats, and additional aircraft during the breeding season following a spill is expected to displace waterfowl or other seabirds occupying affected offshore or nearshore waters, and shorebirds in coastal habitats for one to several seasons. Cleanup in coastal areas late in the breeding season may disturb brood-rearing, juvenile, or staging birds. Cleanup and the presence of oil can dramatically influence avian species composition and distribution (Piatt et al. 1990). It is extremely difficult to separate the effects of oiling and disturbance from cleanup activities, but either separately or together they have the potential to influence habitat use by birds (Wiens 1996). Survival and fitness of individuals may be affected to some extent, but this infrequent disturbance is not expected to result in significant population losses.

Loss or Degradation of Habitat. Marine and coastal birds could be affected by platform construction and removal activities, and pipeline trenching, which could disrupt behaviors of nearby birds. The Program would include the placement of up to 36 exploration and development wells and 9 offshore platforms; up to 652 km (405 mi) of new offshore pipeline and 129 km (80 mi) (0 in the Chukchi Sea) of onshore pipeline could be constructed (Table 4.4.1.1-4). Platform emplacement could disturb birds temporarily; pipeline trenching may also affect birds in nearshore coastal habitats if it occurs in or near foraging, overwintering, or staging areas, or near seabird colonies. No pipeline landfalls would be constructed under the Program. Depending on where they are sited, new offshore pipelines would likely result in the permanent elimination of a small amount of habitat along pipeline routes.

Any construction activities that take place in summer (one season) (e.g., platform installation for field development) could displace birds from within about 1 km (0.62 mi) of the construction site. However, localized burial of potential prey and destruction of a few square kilometers of foraging habitat as a result of pipeline trenching or island construction are not expected to cause a significant decline in prey availability. It is likely that much construction, particularly of gravel islands, roads, pads, and pipelines, would take place during winter when most birds are absent. Several studies speculate that increased predator populations sustained by scavenging opportunities around human habitation may indirectly contribute to long-term declines of common eiders and long-tailed duck populations currently in evidence (Day 1998; Johnson 2000; Troy 2000). The effect of any habitat loss on the species' productivity would likely be localized to these areas but may persist over the life of any offshore field and beyond. The potential exists for long-term adverse effects to occur (e.g., fecundity reduced after location to suboptimal habitat due to disturbance).

Gravel placement (for artificial islands) results in nesting and foraging habitat loss for most shorebirds (Troy 2000). On the North Slope, gravel is generally extracted from the floodplains of large rivers (Pamplin 1979; BLM 2002). The effects of gravel extraction/ placement would be reduced if areas where particular species seasonally concentrate are avoided.

Winter construction would also utilize ice roads to build and access gravel island construction sites. Ice roads may be constructed over both tundra habitats and frozen ocean habitats. Ice roads constructed in tundra habitats may delay ice-off and snow melt (NRC, 2003b), potentially reducing the availability of such areas for early nesting species. Ice roads could also flatten underlying vegetation, which may discourage use of the area by tundra-nesting birds (Walker et al., 1987a, b). Water removal from lakes and ponds for ice road construction may reduce the quality or quantity of aquatic habitats important for breeding and postmolting for some species. In each of these cases, the impacts to potential nesting habitat would be temporary and localized, and birds would likely respond by selecting other areas for nesting or postmolting.

Construction camps to support onshore construction activities would temporarily remove some areas from potential use by birds, and this loss may be short- or long-term depending on the nature and effectiveness of camp abandonment following completion of construction activities. Regardless of the duration of the effect, the amount of habitat that would be disturbed would be relatively small and not be expected to affect more than a few birds.

The construction and operation of up to 320 km (200 mi) of new overland pipelines would be expected to affect bird populations in a manner similar to that identified for the construction and operation of new onshore processing facilities and associated infrastructure (especially access roads). Potential nesting or post-molting habitat would be permanently lost within the footprint of the new pipelines, causing birds to select habitats in other locations.

Although pipeline trenching would also be carried out in winter when most seabird and waterfowl species are not present, seafloor trenching could locally disrupt benthic invertebrate communities that may serve as food sources for waterfowl during other seasons. The extent to which benthic food sources could be affected and the subsequent impact to waterfowl will depend on the type and amount of benthic habitat that would be permanently disturbed by trenching, the importance of the specific habitats in providing food resources to waterfowl, and the number of waterfowl that could be affected. Because no more than three new pipelines would be built under the Program within the entire Arctic region, relatively little benthic habitat would be disturbed (no more than 120 ha [297 ac] within the entire region). In addition, portions of the new pipelines would be in water depths down to 60 m (200 ft) and potentially unavailable for many marine birds and waterfowl. Thus, any impacts to food sources from pipeline trenching would be very localized and short-term, and not expected to result in population-level impacts to local waterfowl populations.

The construction of new facilities and pipelines would permanently eliminate potential bird habitat at the construction sites. While this habitat loss would be long-term, the areas disturbed would represent a small portion of the habitat present in the Arctic region. Careful siting of any new facilities to avoid important nesting or post-molting habitat would further reduce the magnitude of any potential effects on local bird populations.

Helicopter or fixed-wing aircraft overflights are generally conducted at low altitudes and could disturb birds in onshore and offshore locations (Ward and Stein 1989; Ward et al. 1994; Miller 1994; Miller et al. 1994). Helicopter and aircraft overflights during spring breakup of pack ice may disturb marine species feeding in open waters and waterfowl in coastal waters, causing birds to leave the area. Similarly, overflights in summer could displace waterfowl and seabirds from preferred foraging areas and waterfowl from coastal nesting or brood-rearing areas such as the lagoon systems of the Beaufort and Chukchi Seas. Molting and staging waterfowl may temporarily leave an area experiencing helicopter overflights (Derksen et al. 1992), while geese have been reported to exhibit alert behavior and flight in response to helicopter overflights (Ward and Stein 1989; Ward et al. 1994). The type of response elicited by the birds and the potential effect on the birds will depend in large part on the time of year for the overflights and the species disturbed. Birds experiencing frequent overflights may permanently relocate to less favorable habitats (MMS 2002b). In addition, the temporary absence of adult birds may increase the potential for predation of unguarded nests and young (NRC 2003b).

Marine vessel trips could disturb seabirds and waterfowl in preferred foraging, molting, and staging areas, causing them to leave the area and move to potentially less favorable habitats. Vessel traffic that displaces nesting seabirds or waterfowl may result in an increased predation rate on eggs and young, especially in areas near gull colonies (Day 1998; Johnson 2000; Noel et al. 2005). However, the amount of vessel and aircraft traffic that could occur under the Program would be relatively limited. Which birds could be affected, the nature of their response, and the potential consequences of the disturbance will be a function of a variety of factors, including the specific routes, the number of trips per day, the seasonal habitats along the routes, the species using the habitats and the level of their use, and the sensitivity of the birds to vessel traffic. Traffic over heavily used feeding or nesting habitats of sensitive species could result in population-level effects, while impacts from traffic over other areas with less sensitive species would largely be limited to a few individuals and not result in population-level effects.

Marine and coastal birds could be affected by accidental oil spills from offshore platforms and pipelines, as well as from onshore processing facilities and pipelines. In general, loons, waterfowl, seabirds, and shorebirds are not expected to survive moderate to heavy oil contact. Oiled feathers lose their insulative and water repellent characteristics, and birds die of hypothermia (Albers and Gay 1982). Swallowed oil is toxic and causes impaired physiological function and production of fewer young. Oiled eggs have significantly reduced hatching success (Albers 1980). Vulnerability of bird populations to an oil spill is highly variable because of their seasonally patchy distribution in areas where the probability of spill contact also is variable and depends on location, oceanography, weather patterns, and habitats typically occupied by and habits of, the particular species. Because they are unable to fly, molting birds probably are the most vulnerable. For all species, the degree of impact depends heavily on the location of the spill and its timing with respect to critical natural behaviors (e.g., breeding, molting, feeding).

If losses are substantial in a species with a low reproductive rate, including most marine species, recovery may take many years, or populations may not recover to their prespill size. Rate of recovery from oil spill mortality depends both on the numbers lost from a particular species population and its prevailing population trend, which in turn are determined by reproductive rate and survival rate. Population dynamics of wildlife recovering from an oil spill may be influenced by multiple factors including predation, prey availability, immigration of new individuals into the recovering population, and competition for resources (depends on the impact of the oil spill on competition within a species and among species) (Bodkin et al. 2002; Gilfillan et al. 1995; Golet et al. 2002). Oil contamination of food resources may influence recovery of a local population by affecting reproductive success and survival, with the degree of impact largely dependent on the patterns of prey distribution (Trust et al. 2000; Golet et al. 2002). Species dependent on widely dispersed prey would have more limited effects. However, seabirds, in particular, are attracted to patchy prey sources found on oceanic fronts (Piatt and Springer 2003) and would experience greater effects from prey reduction. In addition, nonbreeding individuals and those that have completed annual parental activities are better able to search for prey in uncontaminated areas. However, those individuals actively feeding young and dependent upon nearby food resources would be unable to seek uncontaminated prey elsewhere. If a leak in an onshore pipeline were to occur on a pad, the extent of the spill likely would be restricted by containment berms. If the spill occurred along the off-pad portion of the pipeline, the area covered may include several acres; if the spill were to enter streams or lakes, a larger area could be affected as the oil spreads over a water surface or is carried down a watercourse. From mid- to late summer, such an occurrence could contact broodrearing females and their young, as well as potentially large flocks of nonbreeding and postbreeding individuals undergoing wing molt.

Most bird species are absent from the Arctic region from late October to at least early April. During spring migration, substantial numbers of migrants moving north along the spring lead system in the Chukchi Sea are at risk if oil enters this habitat, since there are few alternatives until open water off river deltas is available as the ice breaks up in late spring. The most numerous species include king eider, common eider, long-tailed duck, brant, and murres. Likewise, a similar rather restricted open water situation exists in both the Beaufort and Chukchi Seas for migrants that pause awaiting further melting to the north or east, and for birds occupying delta waters and nearshore areas that have melted prior to general ice breakup and awaiting the availability of onshore habitats.

Disturbance Due to Noise. Noise and human activities (such as normal maintenance) could disturb birds. Operational facilities may provide additional nesting and feeding opportunities for some species. Unexpected noise can startle birds and potentially affect feeding, resting, or nesting behavior, and often causes flocks of birds to abandon the immediate area. Some species may react by avoiding nearby habitats, while other species may show little response or become habituated. Because of the small number of new onshore facilities (no more than four in the entire Arctic region), the disturbance of birds by operational noise and activity would likely be limited to relatively few individuals and would not be expected to result in population-level effects. Prolonged or repeated periods of maintenance activities could have a greater impact on nesting birds by increasing cooling periods of eggs, and on brood-rearing birds by increasing the time that young and adult birds are separated.

Effects on ESA-Listed Species in the Arctic Region. The cumulative effects of OCS and non-OCS program activities on ESA-listed species in the Arctic region, including the spectacled eiders and Steller’s eider, are expected to be similar to those noted for nonlisted species over the next 50 years. Continued compliance with ESA regulations and coordination with the USFWS would ensure that lease-specific OCS operations would be conducted in a manner likely to avoid or greatly minimize the potential for impacting these species.

The risk of oil contact to spectacled eiders using the spring lead system to move north into the Chukchi Sea during spring migration could be high if a spill entered the area of the leads. Since most spectacled eiders probably use overland routes from the Chukchi to complete their spring migration to nesting areas on the ACP, they are not likely to be contacted by an oil spill during migration. During the broodrearing period, when the young are led to watercourses and ultimately to nearshore marine environments for further development, staging, and fall migration, the risk of oil contact is much greater. Males could be exposed to an oil spill in any of the several bays and lagoons occupied for molting and staging in both the Beaufort and Chukchi Seas (Petersen et al. 1999). The period of highest exposure risk for a given individual migrating across the Beaufort is about 3–5 days. Females and young are at risk of contact primarily when they occupy Smith Bay in the Beaufort (Troy 2003) and Ledyard and Peard Bay (Laing and Platte 1994) in the Chukchi (this area is used by nonbreeding, failed breeding, and successful breeders, as well as both sexes) for the molt prior to fall migration (Petersen et al. 1999).

Ledyard Bay has been defined as critical habitat for spectacled eiders. Since most, if not all, of the successfully breeding females (and their young) from the ACP could be concentrated in Ledyard Bay critical habitat area during the molt period, a spill affecting this group in this location could have a long-term population-level effect.

The small ACP population of Steller's eider is not likely to be exposed to an oil spill during nesting or postnesting periods, since most presumably move to the Russian side of the Chukchi prior to migrating south to molting areas. However, there is some evidence to suggest use of Peard Bay by postbreeding Steller's eiders (Martin unpubl. data; Dau and Larned 2004, 2005).

Climate Change. Climate change could have dramatic impacts on the Beaufort Sea and Chukchi Sea Planning Areas. The expected changes in air temperature would have the most immediate effect on the distribution and biology of Arctic seabirds and the seabird species most dependent on the presence of ice and snow would be expected to be among the first affected. If temperature increases in the Arctic region are as high as predicted, the Beaufort Sea pack ice could retreat more than 100 km (62 mi) from mainland Alaska (Meehan et al. 1998). This sea ice retreat could have major adverse effects on seabirds that rely on prey associated with ice edges.

Conclusion. Marine and coastal birds in the Beaufort and Chukchi Sea Planning Areas, including those that are ESA-listed, could be adversely affected by activities associated with the Program as well as those associated with future OCS and non-OCS program activities. Potential impacts include injury or mortality of birds from collisions with platforms associated with OCS and State oil and gas development and other onshore and offshore structures (e.g., radio, television, or cell phone towers), onshore industrial, commercial, and residential development; exposure to discharges from permitted point sources such as sewage treatment discharges and nonpoint sources such as urban runoff, or accidental releases (e.g., oil spills); exposure to emissions from various onshore and offshore sources; ingestion of trash or debris; loss or degradation of habitat due to construction and operations activities; and behavioral disturbance due to the presence of, and noise generated by, equipment and human activity. Other trends such as extensive melting of glaciers (and increasing river discharges) and increased precipitation brought on by global climate change is also expected to adversely affect marine and coastal birds over the next 40 to 50 years. While the cumulative impact of all OCS and non-OCS activities in the Beaufort and Chukchi Seas could be minor to moderate, the incremental contribution due to the Program would be negligible to medium (see Section 4.4.7.2.3). Compliance with ESA regulations and coordination with the USFWS would ensure that lease-specific OCS operations would be conducted in a manner that is likely to avoid or to greatly minimize the potential for impacting ESA species.

Marine and coastal birds may also be adversely affected by exposure to oil (via direct contact or through the inhalation or ingestion of oil or tar deposits) that is accidentally released from OCS and non-OCS activities, especially near coastal areas and affecting feeding and nesting areas. The incremental contribution of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on marine and coastal birds would be small to large, depending on the location, timing, duration, and size of the spill; the proximity of the spill to feeding and nesting areas; the timing and nature of spill containment; and the status of the affected birds (see Section 4.4.7.2.3). Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from moderate to major if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to the impacts of spills regardless of size, but their incremental contribution to cumulative impacts is generally expected to be small. A more detailed discussion of the effects of oil spills on marine and coastal in the Arctic region is presented in Section 4.4.7.2.3.

Whether net cumulative impacts are minor or moderate depends on the nature and duration of activities that reduce bird survival and productivity. Losses would be limited in areas occupied by scattered flocks during relatively brief staging and migration periods or scattered nest sites during the brief nesting season; however, in cases where exposure to localized disturbance is greater, impacts have the potential to rise to the population level. Population-level effects could be incurred due to the tendency for large numbers of individuals of some bird species to concentrate in certain coastal Arctic locations.

4.6.4.3.3 Fish. Section 4.4.7.3.3 discusses direct and indirect impacts on fish communities in the Beaufort Sea and Chukchi Sea Planning Areas resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on these resources result from the incremental impacts of the Program (described in Section 4.4.6.1.1) when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS activities. Table 4.6.1-3 presents the exploration and development scenario for the Arctic region cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future OCS programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in the Arctic are summarized in Table 4.6.1-7 and discussed below, as applicable.

The primary routine OCS activities that could result in impacts on fish include seismic surveys; construction of artificial islands, ice roads, drilling, platforms and pipeline placement; releases of permitted discharges from wells; and removal of existing structures. Potential environmental impacts associated with the building and operation of OCS facilities such as subsea production wells, platforms, artificial islands, and pipelines would increase in conjunction with the increased number of wells. Although all of these activities would disturb bottom habitats to some degree, artificial islands result in a more complete loss of benthic habitat due to larger footprints (approximately 9 ha for artificial islands versus less than 1.5 ha for platforms) and due to complete burial of existing substrate during construction. The impacts of routine activities (exploration and site development, production and decommissioning) on fish communities are discussed in detail in Section 4.4.7.3.3. Overall, routine activities represent up to a minor disturbance, primarily affecting demersal fishes, with the severity of the impacts generally decreasing with distance from bottom-disturbing activities.

Oil and gas exploration and development in State waters could also contribute to cumulative effects on fishery resources in the Beaufort and Chukchi Planning Areas. Drilling of wells in State waters could also require construction of platforms and pipelines in waters of Alaska. The effects on fish would be similar to those described above for OCS oil and gas programs (Section 4.4.7.3.2). Other non-OCS activities that could impact fish communities include subsistence fishing, hardrock mining, sediment dredging and disposal of dredging spoils in OCS waters, and commercial shipping (tanker vessels) and anchoring. Many of these activities would result in bottom disturbance that would affect bottom dwelling fishes as well as their food sources in a manner similar to those described for OCS activities (MMS 2008b; ADEC 2007a; Section 4.4.7.3.3). Commercial fishing does not occur in the Beaufort and Chukchi Sea Planning Areas, and sportfishing is minor in the Arctic but could increase if regulations change and if warming temperatures allow an increase in vessel traffic. Effects on fish resources from non-OCS dredging and marine disposal activities are expected to be similar to those described for OCS bottom disturbing activities (Section 4.4.7.3.3). Due to the small number and limited use of disposal sites in the vicinity of the Beaufort and Chukchi Sea Planning Areas, these activities are not expected to noticeably alter fish populations.

The Beaufort and Chukchi Seas fall in the Kotzebue Sound and Northern Subsistence fishing areas. Subsistence fishing may contribute to the cumulative effects on the abundance of some fishery resources. Alaska State law defines subsistence as the "noncommercial customary and traditional uses" of fish and wildlife. The Alaska Department of Fish and Game defines subsistence fishing to include "the taking of, fishing for, or possession of fish, shellfish, or other fisheries resources by a resident of the state for subsistence uses with gill net, seine, fish wheel, long line, or other means defined by the Board of Fisheries." These fishing methods have more limited impacts on fish and fish habitat compared to commercial fishing methods. In addition, subsistence fishing is subject to harvest limits that reduce the potential for overfishing. Consequently, subsistence fishing makes a relatively minor contribution to the reduction in fish stocks.

Cumulative impacts on diadromous species could also occur as a result of activities that obstruct fish movement in marine environments during migration periods. For example, some structures along the Beaufort Sea mainland (e.g., the West Dock) have been shown to block the movements of diadromous fishes, particularly juveniles, under certain meteorological conditions (Fechhelm 1999; Fechelm et al. 1999). Causeways such as the 40 m wide and 60 m long structure associated with the Red Dog Mine may impede coastal movement either by directly blocking fish or by modifying nearshore water conditions to the point where they might become too cold and saline for some species (Fechhelm et al. 1999). Although the presence of causeways has been an issue associated with oil development activities in the Beaufort Sea, the small size of the Red Dog causeway would likely have little effect on the coastal movements and distributions of Chukchi Sea fishes and shellfishes. However, it is anticipated that proper placement and design considerations for future causeway construction along the North Slope would alleviate the potential for such effects on fish movement.

There are several contaminant sources in the Beaufort and Chukchi Sea Planning Areas. The Red Dog Mine in Alaska is the largest lead and zinc mine in the world, and is presently the only base-metal lode mine operating in northwest Alaska. A study for the National Park Service (Hasselbach et al. 2004) showed extensive airborne transport of cadmium and lead from Red Dog Mine; although the study was focused only on the limits of the Cape Krusenstern National Monument, these contaminants are probably carried out into the Chukchi Sea. There are also natural sources of metals and hydrocarbons. Sediments, peats, and soils from the Sagavanirktok, Kuparuk and Colville Rivers are the largest source of dissolved and particulate metals and saturated and polycyclic aromatic hydrocarbons in the development area. However, concentrations of metals and organics in fish sampled in the Arctic Planning Areas are typically at background levels (Neff & Associates, LLC 2010).

Climate change may affect fish communities in the Beaufort and Chukchi Sea Planning Areas and interact with past, present, and future OCS and non-OCS stressors. Physiological and ecosystem level stressors related to climate change may interact with the non-climate-related anthropogenic stressors such as overfishing, pollution, and habitat loss discussed above. For example, a climate change–related increase in water temperature that results in physiological stress could make individuals more susceptible to stress from pollution or accidental oil spills. Climate would only be one of several factors that regulate fish abundance and distribution. Many fish populations are already subject to stresses, and global climate change may aggravate the impacts of ongoing and future human use of the coastal zone. Fish respond directly to climate fluctuations, as well as to changes in their biological environment including predators, prey, species interactions, and disease. Projected changes in hydrology and water temperatures, salinity, and currents can affect the growth, survival, reproduction, and spatial distribution of marine fish species and of the prey, competitors, and predators that influence the dynamics of these species (Watson et al. 1998). Changes in primary production levels in the ocean because of climate change may affect fish stock productivity. Climate change may have a number of effects on fish communities, including:

- Changes in the timing of seasonal fish migrations;

- Increased storm damage to nearshore areas as the amount of open water increases and their reduction or elimination by rising sea levels;

- Reduction in habitat for sea ice dependent species; and

- Replacement of true Arctic species such as Arctic cod and capelin by the range expansions of subarctic species.

Large-scale changes in oceanographic and ecosystem processes resulting from climate change could indirectly affect fish populations in the Arctic in several ways. For example, under the existing temperature regime, the Chukchi Sea has a food web dominated by benthic consumers and cryopelagic (sea ice-associated) fishes. The loss of sea ice and the increased surface water temperature may promote a shift to a pelagic-based food web with high phytoplankton and zooplankton productivity and greater numbers of predatory fish (Loeng 2005; Hopcroft et al. 2008). Ultimately, however, predictions about the indirect and cascading ecological impacts of climate change on specific species are subject to great uncertainty, given the complexity of the ecosystem.

Oil spills could result from OCS and non-OCS activities. The total number of oil spills and the extent of affected areas would likely increase under the Program in conjunction with increased levels of petroleum exploration and production. The potential impacts of OCS oil spills on fish communities in the Beaufort and Chukchi Sea are discussed in detail in

Section 4.4.7.3.3. Non-OCS activities, such as oil and gas development in State waters, domestic transportation of oil or refined petroleum products, and commercial shipping (including tankering), may also result in accidental spills that could potentially impact fish resources within the Beaufort and Chukchi Sea Planning Areas. While effects to fishery resources would depend on the timing, location, and magnitude of specific oil spills, it is anticipated that most small to medium spills that occur in OCS waters would have limited effects on fishery resources due to the relatively small areas likely to be exposed to high concentrations of hydrocarbons and the short period of time during which potentially toxic concentrations would be present. In general, adult fish in marine environments are highly mobile and capable of avoiding high concentrations of hydrocarbons although they may be subject to sublethal exposures. However, fish eggs and larvae as well as small benthic obligate fish species do not typically have the ability to avoid spills and may therefore suffer lethal or sublethal effects. Oil from large and catastrophic spills that reaches shallower, nearshore areas of these planning areas has the potential to be of greatest significance to fish communities. The potential impacts of OCS oil spills on fish communities in the Beaufort and Chukchi Sea Planning Areas are discussed in detail in Section 4.4.7.3.3.

Some diadromous species of the Beaufort and Chukchi Sea Planning Areas could be at greater risk from oil spills because of their unique life-history cycles. Oil spills occurring at constrictions in migration routes, nursery areas, and spawning areas would have an increased potential for adversely affecting diadromous fishes, and catastrophic spills could result in long-term, population-level impacts on diadromous fish communities. Pacific salmon are also able to detect and avoid oil spills in marine waters (see Section 4.4.7.3.2), which would help to reduce the potential for contact. Aggregations of salmon in marine waters typically consist of mixed stocks, so even in the unlikely event of contact with an oil spill, it is anticipated that only a small fraction of any unique spawning population would be adversely affected. Juveniles of some species of whitefish (including broad whitefish, humpback whitefish, and least cisco) are intolerant of highly saline marine conditions. During their summer feeding dispersals in the Beaufort Sea, these species tend to remain within a narrow band of warm, low-salinity water along the coast. Thus, unlike most subarctic fishes, North Slope whitefish have a reduced capacity to bypass localized disruptions to their migration corridor by moving offshore and around the impasses. An oil spill, even one of limited area, could block the narrow nearshore corridor and prevent fishes from either dispersing along the coast to feed or returning to their overwintering grounds in North Slope rivers.

In addition to effects on individuals and species, impacts to fish can result in ecosystem-level effects if the population impacts are significant. For example, fish can occupy a number of trophic levels ranging from herbivore to top level carnivore. As such, fish are critical to energy flow within nearshore and marine food webs. They are also seasonally important food sources to transient carnivores. Consequently, impacts to fish can propagate throughout the food web, affecting sea turtles, birds and marine mammals. In addition, many Alaskan fishes, particularly salmonids, migrate between and within marine, estuarine, and freshwater habitats. In doing so, they transfer nutrients and carbon over a broad area and connect offshore and coastal ecosystems (Naiman et al. 2002). Therefore, significant impacts to fish populations could reduce this transfer resulting in local changes in productivity.

Conclusion. Cumulative impacts on fish communities in the Beaufort Sea and Chukchi Sea Planning Areas as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be moderate to major over the next 40 to 50 years. Non-OCS activities or phenomena affecting these resources include oil and gas development in State waters, domestic transportation of oil or refined petroleum products, commercial shipping, and pollutant inputs from point and non-point sources. Many of these activities would affect bottom-dwelling fish at various life stages as well as their food sources in a manner similar to OCS bottom-disturbing activities. The incremental contribution of routine Program activities to these impacts (primarily as a result of disturbance affecting demersal fishes) would be negligible to small, with the severity of impacts generally decreasing with distance from the disturbance. Fish could also be affected by the environmental changes predicted to result from climate change.

Fish communities may also be adversely affected by exposure to oil that is accidentally released from OCS and non-OCS activities as well as naturally occurring seeps. The cumulative impacts of past, present, and future oil spills on these resources would be minor to moderate. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on fish would be negligible to medium, depending on the location, timing, duration, and volume of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDEs would also depend on these factors, and could range up to moderate if they were to occur. Oil from large spills or a CDE has the greatest potential to contact shoreline areas used for spawning or providing habitat for early life stages of fish and, therefore, could result in large-scale lethal and long-term sublethal effects on fish. A more detailed discussion of the effects of oil spills on fish in Arctic waters is presented in Section 4.4.7.3.3.

4.6.4.3.4 Invertebrates and Lower Trophic Levels. Section 4.4.7.5.3 discusses direct and indirect impacts on invertebrates and lower trophic levels in the Beaufort Sea and Chukchi Sea Planning Areas resulting from the 2012-2017 Program under the proposed action (Alternative 1). Cumulative impacts on these resources result from the incremental impacts of the Program (described in Section 4.4.6.1.1) when added to impacts from ongoing and reasonably foreseeable future actions, including those of ongoing and future OCS programs and other non-OCS activities. Table 4.6.1-3 presents the exploration and development scenario for the Arctic region cumulative case, which takes into account activities associated with the Program in combination with those from ongoing and future OCS programs. Other ongoing and reasonably foreseeable future actions contributing to cumulative impacts in Arctic waters are summarized in Table 4.6.1-8 and discussed below, as applicable.

The primary routine OCS activities that could result in impacts on invertebrates include seismic surveys, drilling, the placement of subsea wells, platforms, and pipelines; releases of permitted discharges from wells; and removal of existing structures. Potential environmental impacts associated with the building and operation of OCS facilities such as platforms, and pipelines would increase in conjunction with the increased number of wells. The impacts of routine activities (exploration and site development, production and decommissioning) on invertebrate communities are discussed in detail in Section 4.4.7.5.3. Overall, routine activities represent up to a moderate disturbance, primarily affecting benthic infaunal invertebrates, with the severity of the impacts generally decreasing dramatically with distance from bottom-disturbing activities.

The placement of new platforms over the life of the Program would allow the colonization of invertebrates requiring hard substrate. While some platforms may be allowed to remain as artificial reefs, removal of platforms will reduce available substrate and structures for invertebrates and injure or kill them during removal.

Oil and gas exploration and development in State waters could also contribute to cumulative effects on invertebrates in the Beaufort and Chukchi Sea Planning Areas. Drilling of wells in State waters could also require construction of platforms and pipelines in waters of Alaska. The effects on invertebrates would be similar to those described above for OCS oil and gas programs (Section 4.4.7.5.3). Other non-OCS activities that could impact invertebrate communities include land use practices, point and non-point source pollution, logging, dredging/ and disposal of dredging spoils in OCS waters, and anchoring. Commercial fishing does not occur in the Arctic and therefore is not expected to add to cumulative impacts on invertebrate communities. However, this could change if regulations change and if warming temperatures allow an increase in vessel traffic. Effects on invertebrates from non-OCS dredging and marine disposal activities are expected to be similar to those described for OCS bottom disturbing activities (Section 4.4.7.5.3). Recovery of benthic invertebrates at the dredge and disposal sites to their pre-disturbance composition would likely take multiple years. Many of these activities would affect bottom dwelling invertebrates at various life stages as well as their food sources in a manner similar to OCS bottom disturbing activities (Section 4.4.7.5.1). Other non-OCS activities generating pollution and noise may contribute to general habitat degradation (Section 4.6.3.2.2).

There are several contaminant sources in the Beaufort and Chukchi Sea Planning Areas. The Red Dog Mine in Alaska is the largest lead and zinc mine in the world, and is presently the only base-metal lode mine operating in northwest Alaska. A study for the National Park Service (Hasselbach et al. 2004) showed extensive airborne transport of cadmium and lead from Red Dog Mine; although the study was focused only on the limits of the Cape Krusenstern National Monument, these contaminants are probably carried out into the Chukchi Sea. There are also natural sources of contaminants. Sediments, peats, and soils from the Sagavanirktok, Kuparuk and Colville Rivers are the largest sources of dissolved and particulate metals and saturated and polycyclic aromatic hydrocarbons in the development area. However, contaminant concentrations in the benthic invertebrates collected in the Beaufort and Chukchi Sea Planning Areas are typically at background levels (Neff & Associates, LLC 2010).

It is predicted that physical and chemical changes to Arctic and subarctic invertebrate habitat could result from climate change (Section 3.3). These changes could alter the existing distribution, composition, and abundance of invertebrates, since physical and chemical parameters are the primary influence on invertebrate communities. In general, the increase in seawater temperature will facilitate a northward expansion of subarctic invertebrate species from the Bering Sea. Weslawski et al. (2011) identified the Bering Strait as a major corridor through which new invertebrate species will expand their range northward. Such expansion will likely increase overall invertebrate species diversity in the Arctic, but the new species may displace existing species or alter existing inter-specific species interactions. The change in species composition may be greatest in the eastern Beaufort Sea where Arctic species currently predominate. It is predicted that a decrease in sea ice habitat would result from increasing water temperature. This may have several impacts on invertebrate communities in the Arctic including:

- Loss of habitat for invertebrates specialized to inhabit sea ice;
- An increase in the productivity of water column invertebrates with increasing temperature and open water;
- An increase in the abundance of benthic invertebrates in nearshore areas with the reduction in ice scour extent and duration (Weslawski et al. 2011); and
- An increase in benthic disturbance from severe weather as the amount of open water increases.

Changes in the magnitude, frequency, and timing of river discharge into the Beaufort/Chukchi Shelf Ecoregion are expected to result from climate change (Arctic Council and IASC 2005). Invertebrates in marine ecoregions with strong riverine inputs — like the Beaufort Neritic Ecoregion — would likely be affected by alterations in the salinity, temperature, and sediment delivery regime. Hydrologic change can rapidly alter existing invertebrate communities in the water column and benthos, if the new chemical conditions are not within the physiological tolerance of the existing communities. The greater variability in hydrologic conditions could favor tolerant and opportunistic species, thereby homogenizing invertebrate species composition and decreasing overall species diversity in the Beaufort and Chukchi Seas (Weslawski et al. 20011).

The expected increase in ocean acidification is considered to be another significant source of physiological stress. Crustaceans, echinoderms, foraminiferans, and mollusks could have greater difficulty in forming shells, which could reduce their fitness, abundance, and distribution (Fabry et al. 2008).

Oil spills could result from OCS and non-OCS activities. The total number of oil spills and the extent of affected areas would likely increase under the Program in conjunction with increased levels of petroleum exploration and production (Table 4.6.1-3). The potential impacts of OCS oil spills on invertebrate communities in the Beaufort and Chukchi Sea are discussed in detail in Section 4.4.7.5.3. Non-OCS activities, such as oil and gas development in State waters, domestic transportation of oil or refined petroleum products, and commercial shipping, may also result in accidental spills that could potentially impact invertebrate resources within the Beaufort and Chukchi Sea Planning Areas. While effects to invertebrates would depend on the timing, location, and magnitude of specific oil spills, it is anticipated that most small to medium spills that occur in OCS waters would have limited effects due to the relatively small areas likely to be exposed to high concentrations of hydrocarbons.

Oil from catastrophic spills that reaches shallower, nearshore areas of these planning areas has the potential to be of greatest significance to invertebrate communities. Large, mobile epifaunal invertebrates are capable of avoiding high concentrations of hydrocarbons although they may be subject to sublethal exposures. However, infauna and invertebrate eggs and larvae do not typically have the ability to avoid spills and may therefore suffer lethal or sublethal effects. Catastrophic spills could result in long-term alterations in the abundance of intertidal and shallow subtidal invertebrate communities. Benthic and pelagic invertebrates are important trophic links connecting primary producers to higher-trophic-level organisms. Consequently, oil spill contamination on a large scale could result in contaminant transfer to higher trophic levels and/or reduce food availability to higher trophic levels if invertebrate populations were severely depressed by a CDE. The potential impacts of OCS oil spills on invertebrate communities in the Arctic planning areas are discussed in detail in Section 4.4.7.5.3.

Conclusion. Cumulative impacts on invertebrate communities in the Beaufort Sea and Chukchi Sea Planning Areas as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be moderate to major over the next 40 to 50 years. Non-OCS activities or phenomena offshore marine transportation and pollutant inputs from point and non-point sources. The incremental contribution of routine Program activities to these impacts (mainly due to bottom-disturbing activities) would be negligible to medium, with the severity of the impacts generally decreasing with distance from bottom-disturbing activities. Several major classes of invertebrates could also be affected by the environmental changes predicted to result from climate change.

Invertebrate communities may also be adversely affected by exposure to oil that is accidentally released from OCS and non-OCS activities. The cumulative impacts of past, present, and future oil spills on these resources would be minor to moderate. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on invertebrates would be negligible to small, depending on the location of the spill and the season in which the spill occurred. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could range up to moderate if it were to occur. Spills in deeper water, whether from OCS or non-OCS sources, are unlikely to have overall population-level effects on invertebrate resources because of the relatively small proportion of similar available habitats that would come in contact with released oil at concentrations great enough to elicit toxic effects. A CDE could also contaminate or reduce the abundance of seasonally abundant copepods and euphausiids, which may in turn impact higher trophic levels. Oil from a CDE occurring under ice is more difficult to locate and clean than surface spills and may have more persistent effects on water column and sea ice-associated invertebrates. A more detailed discussion of the effects of oil spills on marine mammals in the Arctic region is presented in Section 4.4.7.5.3.

4.6.4.4 Summary for Gulf of Mexico Region

4.6.4.4.1 Marine Mammals. All marine mammals in U.S. waters are protected under the Marine Mammal Protection Act of 1972. The marine mammals in the GOM are diverse and widely distributed throughout the northern GOM. Their distribution and abundance are influenced by oceanographic circulation patterns (which are largely wind-driven, but affected locally by freshwater discharge). There are 21 species of cetaceans (whales) and one species of Sirenian (manatees), several of which are listed as federally endangered under the ESA. Ongoing and future activities or phenomena that affect marine mammals in the GOM include onshore and offshore oil and gas development (and infrastructure), natural phenomena (e.g., hurricanes and diseases), marine vessel traffic, commercial fishing, pollution, military operations, catastrophes, climate change, and invasive species. Cumulative impacts on marine mammals in the GOM region are considered to be minor to moderate.

Routine oil and gas-related activities (e.g., seismic surveys, facility construction, normal operations, and, eventually, decommissioning) would result in minor to moderate impacts on marine mammals. Impacts on marine mammals from these activities could include physical injury or death; behavioral disturbances; lethal or sublethal toxic effects; and loss of reproductive, nursery, feeding, and resting habitats. The contribution of Program activities to cumulative impacts on marine mammals would be negligible to medium. The incremental impacts of expected accidental oil spills (most of which are less than 1,000 bbl) would be small to large, depending on the location, timing, and volume of the spills; the environmental settings of the spills; and the species exposed to the spills. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from moderate to major if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to these impacts.

4.6.4.4.2 Terrestrial Mammals. The terrestrial mammals considered in this report are those likely to be present in coastal habitats of the northern GOM. These include the federally endangered GOM coast beach mouse subspecies, which lives in mature coastal barrier sand dunes, and the federally endangered Florida salt marsh vole, which lives in areas vegetated by saltgrass, especially in Dixie and Levy Counties. Ongoing and future activities or phenomena that affect terrestrial mammals include onshore and offshore oil and gas development (and infrastructure), natural phenomena (e.g., hurricanes and tropical storms), industrial and residential development, vehicle traffic, recreation, trash and debris, artificial lighting, climate change (including sea level rise), and invasive and feral species. Present beach mice habitat is no longer of optimal quality because of historical beach erosion, habitat loss and fragmentation from beach front development, and tropical storm damage. The Florida salt marsh vole is rare and has a very restricted range, so catastrophic events could result in its extinction. Cumulative impacts on terrestrial mammals in the GOM region are considered to be minor to moderate.

Routine oil and gas-related activities (e.g., facility construction, normal operations, and, eventually, decommissioning) are not expected to significantly affect the four federally endangered beach mouse subspecies and the federally endangered Florida salt marsh vole. Negligible to minor impacts may result from consumption of or entanglement in beach trash and debris originating from Program activities. The contribution of the Program activities to cumulative impacts therefore would be negligible to medium. The effects of expected accidental oil spills (most of which are less than 1,000 bbl) on these terrestrial mammals would be small to large, depending on the location, timing, duration, and size of the spill; the proximity of the spill to feeding and other important habitats; the timing and nature of spill containment; and the status of the affected animals. An unexpected, low-probability CDE has a greater potential to affect the habitats of beach mice and the Florida salt marsh vole; therefore, impacts would range from moderate to major if one were to occur. Oil impacts on beach mice would be more likely if a storm surge transports the oil over foredunes.

4.6.4.4.3 Marine and Coastal Birds. The GOM is an important pathway for migratory birds. Most migrant birds either directly cross the GOM or move north or south by traversing the GOM or the Florida peninsula. A diverse range of habitats support migratory and resident bird species along the northern GOM coast. Cumulative impacts on migratory and resident bird species result from direct injury or mortality of marine and coastal birds due to collisions with onshore and offshore structures, ingestion of trash or debris, or exposure to discharges or emissions; loss or degradation of habitat due to coastal development, climate change, or construction and operations activities; and behavioral disturbance due to commercial and recreational boating and small aircraft traffic. Many bird species are currently experiencing a loss or degradation of habitat due to land development and climate change, and these impacts are expected to continue into the foreseeable future. Ongoing and future actions/trends that affect marine and coastal birds in the GOM region include those related to oil and gas development (and infrastructure), coastal development, marine vessel traffic, dredging operations, and climate change. Cumulative impacts on marine and coastal birds in the GOM region are considered to be moderate.

Routine operations may result in localized short-term impacts due to infrastructure construction and marine vessel and aircraft traffic. The contribution of Program activities to cumulative impacts on marine and coastal birds therefore would be negligible to medium. Birds may also be adversely affected by exposure to oil, especially near coastal areas and affecting feeding and nesting areas. The incremental contribution of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on marine and coastal birds would be small to large, depending on the location, timing, duration, and size of the spill; the proximity of the spill to feeding and nesting areas; the timing and nature of spill containment; and the status of the affected birds. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from moderate to major if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to these impacts.

4.6.4.4.4 Fish. Fish in the northern GOM live in the water column (pelagic) and on the seafloor or near bottom waters (demersal) along the gradient from the continental shelf to the abyssal plain. Demersal species are much more abundant and diverse in the hard-bottom habitats found in the eastern GOM. Some fish migrate between saltwater and freshwater habitats. For example, anadromous species (such as the Gulf sturgeon and striped bass) spend most of their adulthood in saltwater but spawn in freshwater; catadromous species (such as the American eel) live primarily in freshwater and spawn in saltwater. Cumulative impacts on fish result from activities that generate lethal or sublethal impacts on individuals as well as habitat loss or degradation. Ongoing and future actions/trends that affect fish in the GOM include oil and gas development, commercial and recreational fishing, noise, dredging and trawling operations, explosive platform removal, land loss, and coastal hypoxia. Climate change is also expected to affect fish habitat, productivity, and community structure. Cumulative impacts on fish in the GOM are considered to be moderate to major. The incremental contribution of routine Program activities to these impacts (primarily as a result of disturbance affecting demersal fishes) would be negligible to small, with the severity of impacts generally decreasing with distance from the disturbance.

Fish communities may also be adversely affected by exposure to oil that is accidentally released from OCS and non-OCS activities as well as naturally occurring seeps. The cumulative impacts of past, present, and future oil spills on these resources would be minor to moderate. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on fish would be negligible to medium, depending on the location, timing, duration, and volume of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could range up to moderate if it were to occur.

4.6.4.4.5 Reptiles. Five species of sea turtles are known to inhabit the GOM. The federally protected American crocodile also lives in the eastern GOM, along Florida's southern coast (in mangrove swamps, brackish bays, and inshore freshwater habitats). Hurricanes in 2005 adversely affected sea turtle nesting sites, and the DWH event caused sea turtle mortality and fouling of habitats. Cumulative impacts on sea turtles result from activities that generate lethal and sublethal impacts, or that alter or eliminate habitat required for reproduction, feeding, and early life stage development. Ongoing and future actions/trends that affect sea turtles and crocodiles in the GOM include climate change, oil and gas development, marine vessel traffic, coastal development, dredging, commercial fishing, and land loss. Cumulative impacts on reptiles in the GOM are considered to be moderate to major. The incremental contribution of routine Program activities to these impacts would be small to medium.

Expected accidental oil spills under the Program (most of which are less than 1,000 bbl) would result in a comparatively negligible to medium incremental increase in the overall impact of exposure to oil from other anthropogenic activities (such as spills from foreign tankers) because such spills are relatively easy to contain and would only affect small areas of habitat (and few individuals). However, large spills (1,000 bbl or greater) or an unexpected CDE could potentially result in population-level effects. Although such spills are rare events, impacts would be major and long-term if multiple individuals and their habitat (especially nesting habitat) are exposed to oil.

4.6.4.4.6 Invertebrates and Lower Trophic Levels. Invertebrates (animals without a backbone) occupy multiple habitat types from the intertidal zone to the deep sea. Benthic invertebrates burrow into bottom sediments or move along the sediment surface; pelagic invertebrates either drift with the current or actively swim. In the GOM, invertebrates and lower trophic level organisms include prokaryotes, viruses, protozoa, sponges, jellyfish, worms, mollusks (bivalves, squid, octopi), echinoderms (sea urchins and sea star), and crustaceans (barnacles, crabs, shrimp) among others. Cumulative impacts on invertebrates and lower trophic organisms result from activities that generate lethal or sublethal impacts on individuals as well as habitat loss or degradation. Ongoing and future actions/trends that affect invertebrates and lower trophic organisms in the GOM include oil and gas development, dredging, trawling, land loss, coastal hypoxia, and climate change (especially in terms of ocean acidification). Cumulative impacts on invertebrates and lower trophic organisms in the GOM are considered to be moderate to major.

Routine operations would result in minor to moderate localized impacts primarily due to bottom-disturbing activities and platform placement and removal. The contribution of the Program to cumulative impacts (mainly due to bottom-disturbing activities) would be negligible to medium, with the severity of the impacts generally decreasing with distance from bottom-disturbing activities. Invertebrate communities may also be adversely affected by exposure to oil that is accidentally released from OCS and non-OCS activities as well as naturally occurring seeps. The cumulative impacts of past, present, and future oil spills on these resources would be minor to moderate. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on invertebrates would be negligible to small, depending on the location, timing, duration, and size of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could range up to moderate if they were to occur.

4.6.4.5 Summary for Alaska – Cook Inlet

4.6.4.5.1 Marine Mammals. All marine mammals in U.S. waters are protected under the Marine Mammal Protection Act of 1972. Currently, there are 17 marine mammal species in Cook Inlet or nearby waters of the Gulf of Alaska, including whales, sea lions, sea otters, harbor porpoises, and harbor seals; nine of these species are listed as threatened or endangered. Ongoing and future activities or phenomena that affect marine mammals in the inlet include onshore and offshore oil and gas development (and infrastructure); marine vessel traffic; commercial, recreational, and subsistence fishing; subsistence marine mammal harvests; pollution (and marine debris); military operations; development; climate change; and invasive species. Cumulative impacts on marine mammals in the Cook Inlet are considered to be minor to moderate.

Routine oil and gas-related activities (e.g., seismic surveys, facility construction, normal operations, and, eventually, decommissioning) would result in minor to moderate impacts on marine mammals. Impacts on marine mammals from these activities could include physical injury or death; behavioral disturbances; lethal or sublethal toxic effects; and loss of reproductive, nursery, feeding, and resting habitats. The contribution of Program activities to cumulative impacts on marine mammals would be negligible to small. The incremental impacts of expected accidental oil spills (most of which are less than 1,000 bbl) would be negligible to small, depending on the location, timing, and volume of the spills; the environmental settings of the spills; and the species exposed to the spills. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from minor to major if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to these impacts.

4.6.4.5.2 Terrestrial Mammals. There are about 40 species of terrestrial mammals in south central Alaska, many of which use the coastal habitats in the Cook Inlet region. These include bison, bears, sheep, beaver, river otters, and wolverine, among others. Ongoing and future activities or phenomena that affect terrestrial mammals in the inlet include onshore and offshore oil and gas development (and infrastructure), aircraft traffic, marine vehicle traffic, coastal and community development, timber harvests, hunting, pollution, climate change, and natural catastrophes. Cumulative impacts on terrestrial mammals in Cook Inlet are considered to be minor to moderate.

Routine oil and gas-related activities (e.g., facility construction including onshore pipelines, normal operations including aircraft and marine vessel traffic, and, eventually, decommissioning) would result in minor impacts on terrestrial mammals. Impacts on terrestrial mammals from these activities could include physical injury or death; behavioral disturbances; lethal or sublethal toxic effects; and loss of reproductive, nursery, feeding, and resting habitats. The contribution of Program activities to cumulative impacts would be negligible to small. The effects of expected accidental oil spills (most of which are less than 1,000 bbl) on terrestrial mammals would be negligible to small, depending on the location, timing, duration, and size of the spill; the proximity of the spill to feeding and other important habitats; the timing and nature of spill containment; and the status of the affected animals. An unexpected, low-probability CDE has a greater potential to affect the terrestrial habitats; therefore, impacts would range from minor to major if one were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to these impacts.

4.6.4.5.3 Marine and Coastal Birds. There are more than 492 naturally occurring bird species in Alaska. Annual use patterns of Cook Inlet are characterized by the sudden and rapid occurrence of very large numbers of birds in early May followed by a sudden and rapid departure in mid- to late-May. Cumulative impacts result from direct injury or mortality of marine and coastal birds due to collisions with onshore and offshore structures, ingestion of trash or debris, or exposure to discharges or emissions; loss or degradation of habitat due to coastal development, climate change, or construction and operations activities; and behavioral disturbance due to commercial and recreational boating and small aircraft traffic. Many bird species are currently experiencing a loss or degradation of habitat due to land development and climate change, and these impacts are expected to continue into the foreseeable future. Ongoing and future actions/trends that affect marine and coastal birds in the inlet include those related to oil and gas development (and infrastructure), coastal development, marine vessel traffic, dredging operations, and climate change. Cumulative impacts on marine and coastal birds in the Cook Inlet region are considered to be minor to moderate.

Routine operations may result in localized short-term impacts due to infrastructure construction and marine vessel and aircraft traffic. The contribution of the Program to cumulative impacts on marine and coastal birds therefore would be negligible to medium. Birds may also be adversely affected by exposure to oil, especially near coastal areas and affecting feeding and nesting areas. The incremental contribution of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on marine and coastal birds would be small to large, depending on the location, timing, duration, and size of the spill; the proximity of the spill to feeding and nesting areas; the timing and nature of spill containment; and the status of the affected birds. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from moderate to major if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to these impacts.

4.6.4.5.4 Fish. The waters of south central Alaska support at least 314 fish species; most of these species can be found in Cook Inlet. Some fish live in the water column (pelagic), others, on the seafloor or near bottom waters (demersal). There are also anadromous species (such as Pacific salmon) that spend most of their adulthood in saltwater but spawn in fresh water. Cumulative impacts result from activities that generate lethal or sublethal impacts to individuals as well as the loss or degradation of fish habitat. Ongoing and future actions/trends that affect fish in the inlet include oil and gas development, commercial and recreational fishing, noise, dredging operations, and wastewater discharge. Climate change is also expected to affect fish habitat, productivity, and community structure. Cumulative impacts on fish in Cook Inlet are considered to be moderate to major. The incremental contribution of routine Program activities to these impacts (primarily as a result of displacement, injury or mortality of fish and their food sources) would be negligible to small.

Fish communities may also be adversely affected by exposure to oil that is accidentally released from OCS and non-OCS activities as well as naturally occurring seeps. The cumulative impacts of past, present, and future oil spills on these resources would be minor to moderate. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on fish would be negligible to medium, depending on the location, timing, duration, and volume of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could range up to moderate if they were to occur.

4.6.4.5.5 Invertebrates and Lower Trophic Levels. Invertebrates (animals without a backbone) occupy the rocky and sandy substrates in the intertidal and subtidal zones. Water column invertebrates in Cook Inlet are composed of a mix of oceanic and coastal species. Several species of copepods (small crustaceans) dominate the macrozooplankton assemblage, peaking in late spring and summer. In lower Cook Inlet, benthic invertebrate communities vary spatially as a result of differences in ice formation, with Arctic species being more common on the western side of the inlet and temperate species being more common on the eastern side. Invertebrates and lower trophic level organisms in the rocky and sandy intertidal zone include echinoderms (sea urchins and sea stars), mollusks (bivalves, limpets, and snails), polychaetes (worms), and crustaceans (barnacles, crabs, and amphipods); clams and polychaetes are predominant in subtidal sandy and muddy sediments. Cumulative impacts on invertebrates and lower trophic organisms result from activities that generate lethal or sublethal impacts to individuals as well as habitat loss or degradation. Ongoing and future actions/trends that affect invertebrates in the inlet include oil and gas development, dredging, trawling, and wastewater discharge. Climate change (especially in terms of ocean acidification) is also expected to affect habitat, productivity, and community structure. Cumulative impacts on invertebrates in Cook Inlet are considered to be moderate to major.

Routine operations would result in minor to moderate localized impacts primarily due to bottom-disturbing activities and platform placement and removal. The contribution of the Program to cumulative impacts (mainly due to bottom-disturbing activities) would be negligible to medium, with the severity of the impacts generally decreasing with distance from bottom-disturbing activities. Invertebrate communities may also be adversely affected by exposure to oil that is accidentally released from OCS and non-OCS activities as well as naturally occurring seeps. The cumulative impacts of past, present, and future oil spills on these resources would be minor to moderate. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on invertebrates would be negligible to small, depending on the location, timing, duration, and size of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could range up to moderate if they were to occur.

4.6.4.6 Summary for Alaska – Arctic Region

4.6.4.6.1 Marine Mammals. All marine mammals in U.S. waters are protected under the Marine Mammal Protection Act of 1972. In the Arctic region, marine mammals are among the most important subsistence resources for coastal Alaskan Natives. There are 15 species of marine mammals in the Arctic region, four of which are listed as threatened or endangered. These include whales, seals, and polar bears. Polar bears are considered a marine mammal because they inhabit the sea ice surface rather than adjacent land. Ongoing and future activities or phenomena that affect marine mammals in Arctic waters include onshore and offshore oil and gas development (and infrastructure); marine vessel traffic; commercial, recreational, and subsistence fishing; marine mammal subsistence harvests; pollution (and marine debris); development; climate change (including temporal and spatial changes in sea ice); diseases; and natural catastrophes. Cumulative impacts on marine mammals in the Arctic region are considered to be minor to moderate.

Routine oil and gas-related activities (e.g., seismic surveys, facility construction, normal operations, and, eventually, decommissioning) would result in minor to moderate impacts on marine mammals. Impacts on marine mammals from these activities could include physical injury or death; behavioral disturbances; lethal or sublethal toxic effects; and loss of reproductive, nursery, feeding, and resting habitats. The contribution of Program activities to cumulative impacts would be negligible to small. The incremental impacts of expected accidental oil spills (most of which are less than 1,000 bbl) would be negligible to large, depending on the location, timing, and volume of the spills; the environmental settings of the spills; and the species (and number of individuals) exposed to the spills. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from minor to major if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to these impacts.

4.6.4.6.2 Terrestrial Mammals. There are about 30 species of terrestrial mammals in the Arctic region. These include the brown bear, caribou, muskox, the Arctic fox, brown lemming, and wolverine, among others. Ongoing and future activities or phenomena that affect terrestrial mammals in the Arctic region include onshore and offshore oil and gas development (and infrastructure), aircraft traffic, marine vehicle traffic, coastal and community development, timber harvests, hunting, pollution, climate change, and natural catastrophes. Cumulative impacts on terrestrial mammals in the Arctic region are considered to be minor to moderate.

Routine oil and gas-related activities (e.g., facility construction including onshore pipelines, normal operations including vehicle and aircraft traffic, and, eventually, decommissioning) would result in minor impacts on terrestrial mammals. Impacts on terrestrial mammals from these activities could include physical injury or death; behavioral disturbances; lethal or sublethal toxic effects; and loss of reproductive, nursery, feeding, and resting habitats. The contribution of Program activities to cumulative impacts would be negligible to small. The effects of expected accidental oil spills (most of which are less than 1,000 bbl) on terrestrial mammals would be negligible to large, depending on the location, timing, duration, and size of the spill; the proximity of the spill to feeding and other important habitats; the timing and nature of spill containment; and the status of the affected animals. An unexpected, low-probability CDE has a greater potential to affect the terrestrial habitats; therefore, impacts would range from minor to major if one were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to these impacts.

4.6.4.6.3 Marine and Coastal Birds. There are more than 492 naturally occurring bird species in Alaska. Because of the limited seasonal nature of open water and snow-free conditions, the Beaufort and Chukchi Seas support a much smaller number of birds than lower parts of Alaska. Most of the birds occurring in the Arctic region are migratory, being present for all or part of the period between May and early November. Cumulative impacts result from direct injury or mortality of marine and coastal birds due to collisions with onshore and offshore structures, ingestion of trash or debris, or exposure to discharges or emissions; loss or degradation of habitat due to coastal development, climate change, or construction and operations activities; and behavioral disturbance due to commercial and recreational boating and small aircraft traffic. Many bird species are currently experiencing a loss or degradation of habitat due to land development and climate change, and these impacts are expected to continue into the foreseeable future. Ongoing and future actions/trends that affect marine and coastal birds in the Arctic region include those related to oil and gas development (and infrastructure), coastal development, marine vessel traffic, and climate change. Cumulative impacts on marine and coastal birds in the Arctic region are considered to be minor to moderate.

Routine operations may result in localized short-term impacts due to infrastructure construction and marine vessel and aircraft traffic. The contribution of the Program to cumulative impacts on marine and coastal birds therefore would be negligible to medium. Birds may also be adversely affected by exposure to oil, especially near coastal areas and affecting feeding and nesting areas. The incremental contribution of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on marine and coastal birds would be small to large, depending on the location, timing, duration, and size of the spill; the proximity of the spill to feeding and nesting areas; the timing and nature of spill containment; and the status of the affected birds. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from moderate to major if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to these impacts.

4.6.4.6.4 Fish. The Beaufort and Chukchi Seas support at least 98 fish species, with the greatest number found in Chukchi Sea. Fish in the Arctic region must survive extended seasonal periods of frigid and harsh conditions such as reduced light, seasonal darkness, prolonged low temperatures, and ice cover. Food resources tend to be scare during winter months, so most of a fish's yearly food supply must be acquired during the brief Arctic summer. Many species found in the Beaufort and Chukchi Seas are at the northern limits of their range. Subsistence fishing has a long history in the region (commercial fishing occurred infrequently in the past). Cumulative impacts result from activities that generate lethal or sublethal impacts to individuals as well as the loss or degradation of fish habitat. Ongoing and future actions/trends that affect fish in Arctic waters include oil and gas development, noise, dredging operations, and the potential effects of climate change such as the loss of sea ice, habitat alteration, and changes in fish productivity and community structure. Cumulative impacts on fish in Arctic waters are considered to be moderate to major. The incremental contribution of routine Program activities to these impacts (primarily as a result of disturbance affecting demersal fishes) would be negligible to small, with the severity of impacts generally decreasing with distance from the disturbance.

Fish communities may also be adversely affected by exposure to oil that is accidentally released from OCS and non-OCS activities as well as naturally occurring seeps. The cumulative impacts of past, present, and future oil spills on these resources would be minor to moderate. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on fish would be negligible to medium, depending on the location, timing, duration, and volume of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could range up to moderate if they were to occur.

4.6.4.6.5 Invertebrates and Lower Trophic Levels. Invertebrates (animals without a backbone) occur in various intertidal and deepwater habitats in the Beaufort and Chukchi Seas. Benthic invertebrates are predominantly echinoderms, polychaetes, sponges, anemones, bivalves, gastropods, and bryozoans. The most common water column macroinvertebrates in the Arctic region are the copepods. Larger invertebrates tend to be sparse in much of the Beaufort Sea relative to the Chukchi Sea, where echinoderms, crabs, and shrimp are more abundant. Zooplankton productivity is highly seasonal. At the lowest trophic levels, microbes such as bacteria and protists are important in Arctic waters for breaking down and recycling nutrients and organic matter. Cumulative impacts on invertebrates and lower trophic organisms result from activities that generate lethal or sublethal impacts to individuals as well as habitat loss or degradation. Ongoing and future actions/trends that affect invertebrates and lower trophic organisms in Arctic waters include oil and gas development, dredging, trawling, and the potential effects of climate change (such as the loss of sea ice), changes in invertebrate habitat, and changes in invertebrate productivity and community structure. Cumulative impacts on invertebrates in Arctic waters are considered to be moderate to major.

Routine operations would result in negligible to moderate localized impacts primarily due to bottom-disturbing activities and platform placement and removal. The contribution of the Program to cumulative impacts (mainly due to bottom-disturbing activities) would be negligible to medium, with the severity of the impacts generally decreasing with distance from bottom-disturbing activities. Invertebrate communities may also be adversely affected by exposure to oil that is accidentally released from OCS and non-OCS activities. The cumulative impacts of past, present, and future oil spills on these resources would be minor to moderate. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on invertebrates would be negligible to small, depending on the location of the spill and the season in which the spill occurred. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could range up to moderate if they were to occur.

4.6.5 Social, Cultural, and Economic Resources

4.6.5.1 Gulf of Mexico Region

4.6.5.1.1 Areas of Special Concern. Section 4.4.8.1 identified potential effects of the Program on Areas of Special Concern in the GOM. This section identifies activities that could affect such areas in the GOM, including non-OCS activities and current and planned OCS activities that would occur during the life of the Program, and the potential incremental effects of implementing the Program.

National Marine Sanctuaries. The FGBNMS is the only National Marine Sanctuary located in the Western and Central GOM Planning Areas. The Flower Gardens Bank sanctuary is protected from direct mechanical damage due to oil and gas exploration and development by an MMS Topographic Features Stipulation, which includes a No Activity Zone (Section 4.4.6.2).

Additional OCS activities that could affect the marine sanctuaries include discharges of drilling cuttings, drilling muds, and produced waters. However, as identified in Section 4.4.6.2, the Topographic Features Stipulation does not allow discharges from OCS activities to be released within the vicinity of the FGBNMS. Consequently, it is anticipated that the sanctuary would not be affected by discharges from OCS activities.

Non-OCS activities that could affect the marine sanctuaries include fishing, diving, offshore marine transportation, and tankering. Natural events such as hurricanes could also impact the sanctuaries. Fishing and diving impacts are controlled by sanctuary guidelines regulating these activities. The distance of the Flower Garden Banks from shore (over 160 km [99 mi]) serves to reduce the number of visitors to the sanctuary, further reducing the potential for impacts from fishing and diving activities. Sanctuary regulations also prohibit collecting activities and ban anchoring within the sanctuary in order to minimize structural damage to the reef system from commercial and recreational vessels.

Climate change has the potential to profoundly affect coral communities on topographic features in several ways, including:

- Increased frequency of bleaching as a stress response to warming water temperatures (Hoegh-Guldberg et al. 2007);

- Excessive algal growth on reefs and an increase in bacterial, fungal, and viral agents (Boesch et al. 2000; Twilley et al. 2001);

- Greater frequency of mechanical damage to corals from greater severity of tropical storms and hurricanes (Janetos et al. 2008);

- Decreases in the oceanic pH and carbonate concentration are expected to reduce the reef formation rate, weaken the existing reef structure, and alter the composition of coral communities (Janetos et al. 2008); and

- Invasive species may expand their range into the GOM due to climate change.

Impacts on the marine sanctuaries could occur due to surface hydrocarbon discharges from platform spills, OCS and non-OCS tankers, or other marine traffic passing in the vicinity of the sanctuary. Discharges in the vicinity of the FGBNMS should be greatly diluted before they could reach reef features because water depths within the sanctuary are greater than 20 m (66 ft). Consequently, it is anticipated that concentrations of contaminants within such discharges would be diluted to levels unlikely to have toxic effects on reef organisms. Oil spills could also impact the Flower Garden Banks communities. The No Activity Zone mandated in the Topographic Features Stipulation and adopted as a regulation for the Flower Garden Banks precludes placement of platforms or pipelines immediately adjacent to the marine sanctuary and reduces the likelihood that oil from a pipeline leak would reach bank communities. If oil from a series of subsurface spills were to reach one of these banks, sensitive biota could be affected. Potential impacts have been discussed in Section 4.4.6.2. It is anticipated that impacts of a large oil spill reaching coral reef or hard-bottom habitat may be long-term.

National Parks, Reserves, and Refuges. As identified in Section 4.4.8.1, routine OCS activities potentially affecting parks, reserves, and refuges include placement of structures, pipeline landfalls, operational discharges and wastes, and vessel and aircraft traffic. It is assumed that pipeline landfalls, shore bases, and waste facilities would not be located in National Parks, NWRs, or National Estuarine Research Reserves because of the special status and protections afforded these areas. Consequently, there would be no direct impacts from these activities on any GOM national parks, reserves, or refuges.

It is possible that future pipeline landfalls, shore bases, and waste facilities could be located in one or more estuaries in the Western or Central GOM Planning Area that are included in the National Estuary Program. This includes Corpus Christi Bay (Coastal Bend Bays and Estuaries), Galveston Bay, Barataria-Terrebonne Estuarine Complex, and Mobile Bay. Under the cumulative scenario, it is anticipated that less than 40 new pipeline landfalls could occur in the GOM, with less than 12 of these resulting from the Program (Table 4.4.1-1). In addition, gas-processing facilities could be built in the GOM area under the cumulative scenario. It is assumed that new onshore facilities and structures would be subject to additional evaluations under the NEPA and that they would be sited to avoid national parks, reserves, and refuges and to limit impacts on estuarine and coastal habitats.

Trash and debris are a recognized problem affecting enjoyment and maintenance of recreational beaches along the GOM coast. From extensive aerial surveys conducted by NMFS over large areas of the GOM, floating offshore trash and debris was characterized by Lecke-Mitchell and Mullin (1997) as a ubiquitous, GOM-wide problem. Not surprisingly, such trash and debris frequently wash up on beaches, including those associated with Areas of Special Concern such as the Padre Island National Seashore. Trash and debris can detract from the aesthetic quality of beaches, can be hazardous to beach users and wildlife, and can increase the cost of maintenance programs.

Marine vessel wakes from a large number of vessel trips can, over time, erode shorelines along inlets, channels, and harbors. The GOM is one of the world's most concentrated shipping areas, and the Port of New Orleans supports extensive commercial shipping traffic. The GOM also supports extensive commercial fisheries as well as recreational boating. The GOM also supports training by U.S. Navy vessels as well as routine USCG activities (Section 4.3). The additional vessel activity that would occur under the Program will result in an increase in the overall potential for wakes to affect sensitive shorelines in the GOM OCS Planning Areas.

Overall, it is assumed that there could be 1,400–1,900 OCS-related vessel trips (to new facilities) per week in the GOM under the cumulative scenario; 300 to 600 of these would occur as a result of OCS activities attributable to the Program (Table 4.4.1.1-1). The majority of such vessel trips would occur in offshore waters, thereby precluding effects on shorelines associated with national parks, reserves, and refuges. Existing regulations typically limit vessel speeds in the sensitive inland waterways of Areas of Special Concern. With these measures in place, most impacts due to vessel traffic in such areas would be avoided.

Under the Program, National Parks, NWRs, National Estuarine Research Reserves, or National Estuary Program sites could be exposed to oil accidentally released from platforms, pipelines, and vessels (see Section 4.4.8.1). In addition to the potential for spills from OCS sources, storms, operator error, and mechanical failures could also result in accidental oil releases from a variety of non-OCS-related activities including domestic transportation of oil, importing foreign crude oil, and development of oil production under State programs. The potential exists for impacts to National Parks, Reserves, and Refuges that could result from both oiling of the shoreline and mechanical damage during the cleanup process. Most spills associated with the Program would be relatively small (less than 50 bbl), and most would be expected to occur in waters depths of 200 m (656 ft) or more (Table 4.4.2-1) where they are not likely to affect coastal areas. Because of the expected distribution of leasing activities, it is assumed that such spills would occur in either the Western or Central GOM Planning Area.

Based on the expected distribution of activities and facilities associated with current or proposed activities under OCS leasing programs, it is assumed that any accidental oil spills from OCS-activities would occur in either the Western or Central GOM Planning Area. In contrast, non-OCS spills could occur anywhere in the GOM. Thus, while it is considered likely that only national seashores, NWRs, national estuarine research reserves, and National Estuary Program sites in the Western or Central GOM are at risk from spills due to ongoing or proposed OCS activities, any of these types of properties located along the GOM coast has a potential to be affected by non-OCS accidental spills. Regardless of the source, oil from a large or catastrophic spill that reached the shoreline of any of these sites could have adverse effects on resources or resource values.

Hurricanes and tropical storms occur regularly in the GOM area. The natural environments that parks and refuges preserve and maintain have developed in a setting of regular occurrences of severe storms. In 2004 and 2005, however, Hurricanes Katrina, Rita, and Ivan severely impacted numerous national parks, NWRs, and national estuaries. In 2004, Hurricane Ivan damaged 10 NWRs between the Florida Panhandle and Louisiana. In 2005, Hurricane Katrina affected 16 refuges in the same area, temporarily closing all of them. Impacts included damage to beaches, dunes, vegetation and infrastructure. Breton NWR in Louisiana was reduced to about one-half its pre-Katrina size. Many impacted refuges remain impacted by huge quantities of debris and hazardous gases and liquids spread over large areas of wetlands within the sanctuaries. Should storms of similar strength and size occur during the life of the Program, long-term impacts on Areas of Special Concern in the GOM could occur.

Conclusion. Cumulative impacts on Areas of Special Concern in the GOM are considered to be negligible to moderate. In addition to OCS activities, non-OCS activities that could affect National Sanctuaries, Parks, Reserves and Refuges include fishing, diving, trash and debris, marine vessel traffic (and wakes), tankering, and oil and gas activities in State waters. Hurricanes and tropical storms also occur regularly in the GOM area potentially causing damage. Due to existing protections, it is anticipated that the FGBNMS would not be affected by OCS activities. Development of OCS onshore facilities within National Park lands is considered unlikely, making impacts from routine Program activities unlikely in these areas. Offshore construction of pipelines and platforms could contribute to cumulative effects on wildlife and on scenic values for park visitors. Impacts could also include increases to the amount of trash or debris that currently washes up on shorelines, and increases in shoreline erosion due to increased vessel traffic in inshore waters. Routine operations under the Program could result in a negligible to medium incremental increase in effects on Areas of Special Concern (see Section 4.4.8.1).

Expected oil spills (most of which are less than 1,000 bbl) that may occur during the Program could result in a negligible to small incremental contribution to cumulative impacts on Areas of Special Concern, depending on spill frequency, location, and volume; the type of product spilled; weather conditions; effectiveness of cleanup operations; and other environmental conditions at the time of the spill. Large spills (1,000 bbl and greater) or an unexpected, low-probability CDE in areas adjacent to the National Parks, NWRs, or National Forests, whether from OCS or non-OCS sources, would also depend on these factors, and could result in moderate impacts if they were to occur. Such spills could negatively impact the FGBNMS and coastal habitats and fauna, and could also affect subsistence uses, commercial or recreational fisheries, and tourism.

4.6.5.1.2 Population, Employment, and Income. Section 4.4.9.1 discusses the potential impacts from the Program on population, employment, and income in the GOM coast region. Cumulative impacts on these resources result from the incremental impacts of the Program when added to impacts from ongoing and reasonably foreseeable future OCS program activities (that are not part of the Program) and other non-OCS program activities. Specific types of impact-producing factors related to OCS program activities considered in this analysis include total employment and regional income for counties in the 23 LMAs in the five States in the GOM coast region (described in Section 3.10). Non-OCS program activities affecting the region include employment and earnings related to various other industrial sectors (e.g., construction, manufacturing, services, and State and local government) and the high unemployment rates in the five GOM coast States.

The population in the GOM coast counties increased at an average annual rate of 1.6% between 1980 and 1990, 1.2% between 1990 and 2000, and 1.5% between 2000 and 2009. During each of these periods, the greatest increases consistently occurred in Texas (with an average annual increase of 2.1% between 2000 and 2009) and Florida (with an average annual increase of 1.6% between 2000 and 2009). The components of population increase include the natural increase due to births and net positive domestic and international migration; these trends will likely continue in the GOM coast region over the next 40 to 50 years.

Although the Program would add an average of 128,150 to 196,350 direct and indirect jobs annually between 2012 and 2017, this increase is considered minor (but positive) since it would amount to between 1.2% and 1.8% of forecasted total GOM coast regional employment in 2015. The largest increases would occur in Louisiana and Texas. Likewise, direct and indirect income produced in the region would range from $6,705 million to $10,220 million, with the greatest impacts occurring in Louisiana and Texas.

Population increases of 175,473 to 261,202 would be expected in Texas on average in each year of the Program, with increases of 129,953 to 202,797 occurring in Louisiana. Smaller population increases of 16,382 to 27,519 would occur in Florida, with increases of 6,087 to 10,360 in Alabama and 4,015 to 6,669 in Mississippi. These increases also represent small changes (between 1.3% and 1.9% in the region overall in 2015), assuming a 1.5% average annual increase in population between 2009 and 2017.

Employment impacts of oil spills reaching landfall can vary considerably depending upon the total volume of oil reaching land, land area affected, and sensitivity of local environmental conditions to oil impacts. The primary impacts of oil spills would most likely fall on such coastal activities as beach recreation, diving, commercial fishing, recreational fishing, and sightseeing. Oil spills reaching land can have both short- and long-term effects on these activities. Past studies (Sorenson and McCreary 1990) have shown that there could be a one-time seasonal decline in tourist visits of 5 to 15% associated with a major oil spill. Since tourist movement to other coastal areas in the region often offsets a reduction in the number of visits to one area, the associated loss of business tends to be localized. As discussed in Section 4.4.9, the employment and regional income impact from an oil spill related to the Program would likely be greatest in Texas and Florida and this would likely continue over the next 40 to 50 years. Oil spills would generate only temporary employment (and population) increases during cleanup operations, because such operations are expected to be of short duration.

Hurricanes are recurring events in the GOM area to which the demographic and economic patterns have adjusted. In 2005, however, Hurricanes Katrina and Rita resulted in major socioeconomic changes throughout the GOM region, affecting population, employment, and regional income. Katrina-related flooding affected 49 counties in Alabama, Louisiana, and Mississippi, resulting in estimated damage of more than $155 billion (Burton and Hicks 2005). Damage or loss of hundreds of thousands of homes has resulted in the out-migration of hundreds of thousands of individuals from the region, with varying levels of long-term population displacement. Estimated declines in employment due to hurricane damage and population displacement have ranged from 150,000 to 500,000 jobs, although employment is expected to increase as reconstruction of impacted areas proceeds (Congressional Budget Office 2005). Estimated declines in the 2005 total annual personal income in the GOM range from $10 million in Texas to more than $18 million in Louisiana (Bureau of Economic Analysis 2006).

Conclusion. The cumulative impacts of ongoing and future OCS program and non-OCS program activities would be considered beneficial because these activities would increase employment and earnings in the region over the next 40 to 50 years. The Program would add to these beneficial impacts, especially in Texas and Louisiana. The incremental contribution of the Program is expected to be negligible, however, because the added employment demands are less than 2% of the total GOM coast regional employment (see Section 4.4.9.1).

In areas with a large proportion of impact-sensitive industry (such as tourism), the cumulative impacts of accidental oils spills could be moderate to major, depending on the total volume of oil reaching land, the land area affected, and the sensitivity of local environmental conditions to oil impacts. The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be negligible to small relative to those associated with ongoing and future OCS program and non-OCS program activities. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in minor to moderate impacts if they were to occur. In the short-term, impacts of a CDE could be large as a result of loss of employment, income, and possible shortages of commodities or services in both coastal and inland areas affected by the spill. Longer-term impacts could be smaller unless the fishing and tourism suffered as a result of real or perceived impacts of the event (see Section 4.4.9.1).

4.6.5.1.3 Land Use and Infrastructure. Localized impacts to land use and existing infrastructure are anticipated as a result of the construction of new OCS program oil and gas facilities in the GOM over the next 40 to 50 years. Depending on the location, onshore development may necessitate minimal changes of existing or potential future uses, as well as minor increases in demands on roads, utilities, and public services (MMS 2007c). Land use generally would evolve over time, with a majority of change to occur from general, regional economic, and demographic growth rather than from activities associated with ongoing and future OCS programs and/or State oil and gas development (BOEMRE 2011a).

Recently, deepwater gas production has increased while gas production along the coast has substantially decreased. These trends have combined to lower the need for new gas processing facilities along the GOM coast. As a result, BOEM has concluded that spare capacity at existing facilities is sufficient to satisfy new gas production for many years (although a new gas processing facility could be needed at some future date) (BOEMRE 2011a). With some modifications, current facilities and land use classifications would be expected to support oil and gas production associated with new OCS leases. Likewise, service-based infrastructure would be able to support offshore petroleum-related activities in both the Federal OCS and State waters (BOEMRE 2011a).

Ongoing non-OCS program activities that could affect land use and onshore infrastructure are expected to continue into the foreseeable future. These include offshore and onshore construction, the discharge of municipal and other waste effluents, and marine vessel traffic (MMS 2007c).

Activities within the GOM may be affected by post-DWH event conditions. A significant amount of information has been generated regarding the consequences of the oil spill and subsequent drilling moratorium. As the post-DWH event situation is dynamic, BOEM has been conducting ongoing monitoring of post-DWH event impacts on land use and coastal infrastructure. BOEM will continue to conduct targeted and peer-reviewed research, as long as the monitoring identifies long-term impacts of concern (BOEMRE 2011a).

Accidental oil releases may occur as a result of both OCS and non-OCS activities and from naturally occurring seeps. The extent of the impacts associated with accidental oil spills would depend on the location and size of the releases, but could include stresses of spill response on the community infrastructure, increased traffic to respond to cleanup (both onshore and offshore), and restricted access to affected lands while cleanup is conducted. In general, these releases would be expected to have only a temporary impact on land use and infrastructure (MMS 2007c).

Conclusion. Localized impacts to land use and existing infrastructure are anticipated over the next 40 to 50 years as a result of ongoing and future OCS program and non-OCS program activities in the GOM. These impacts could range from minor to major depending on the location and nature (extent and duration) of the land use change. The incremental contribution of routine operations under the Program to cumulative impacts in the GOM would be negligible to small because the existing infrastructure is considered sufficient to handle the small increases in demands for roads, utilities, and public services related to the Program. Activities within the GOM also may be affected by the post-DWH event conditions; BOEM continues to monitor the region to identify long-term impacts of concern (see Section 4.4.10.1).

Land use–related impacts resulting from expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program include stresses of spill response on community infrastructure, increased traffic in the response area (both onshore and offshore), and temporary restricted access to affected lands (while cleanup is conducted). Such spills would result in a negligible to small incremental contribution to cumulative impacts on land use and existing infrastructure. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in minor to moderate impacts if they were to occur.

4.6.5.1.4 Commercial and Recreational Fisheries.

Commercial Fisheries. Routine OCS activities over the next 40 to 50 years could harm or kill individual fishes, resulting in temporary movements of fishes away from areas where activities were being conducted. Impacts would vary depending on the nature of a particular structure, the phase of operation, the fishing method or gear, and the target species group. Impacts would be higher for drifting gear such as purse nets, bottom longlines, and pelagic longlines than for trawls and handlines (MMS 2005f). Nevertheless, areas in which commercial fishing would be affected are small relative to the entire fishing area available to surface longliners or purse seiners. Although long-term effects on populations of most fishes in the GOM as a whole are not anticipated, populations of rare fishes or those that have highly limited distributions within the GOM could be more substantially affected if activities occurred in areas with high concentrations of individuals.

Offshore oil and gas structures placed within the depth range 0 to 60 m (0 to 200 ft) would increase annual commercial fishing costs by between $1,993 and $3,819 in the Western Planning Area, while reducing costs by between $2,507 and $11,243 in the Central Planning Area. Currently, there are no data available on the placement of offshore platforms in the Eastern Planning Area; consequently, we can draw no conclusions regarding their impact on commercial fishing costs.

Depending upon the location, magnitude, and timing of accidental oil spills from OCS platforms or pipelines, lethal or sublethal toxic effects could occur, especially for species that have pelagic eggs and larvae. If spills occurred in areas with high concentrations of eggs or larvae of a particular species, the abundance of a particular year-class could be affected. The effects of spilled oil on commercial fisheries include fishing ground area closures, contaminated fish, fouled fishing gear and associated equipment, and degradation of fishing grounds. Accidental oil releases from non-OCS activities are possible anywhere on the OCS or in State waters (e.g., from vessel collisions or transfer/lightering operations); crude oil also enters the environment from naturally occurring seeps. Although such releases typically occur in deeper water, the released oil should rise to the surface relatively quickly, and although it is anticipated that most adult fish would be able to avoid the resulting plumes of oil, larvae or eggs of some fish species could be affected and commercial fishing gear could become fouled with oil. In many cases, commercial fisheries would be able to return to the area after slicks have been cleaned up or dispersed. However, shallow coastal spills could contaminate tissues of target organisms (e.g., oyster beds and shallow benthic fishes), and affected commercial fisheries could be closed for one or more seasons.

Non-OCS program activities and factors that could affect fish populations in the GOM include State oil and gas activities, commercial shipping (and other marine vessel traffic), land development, dredging and dredge-disposal operations, marine mineral mining, and water quality degradation from both point and nonpoint pollution sources. In particular, space-use conflicts resulting from exploration and delineation activities and establishment of development and production platforms could affect commercial fisheries, with some areas precluded from commercial fisheries. There are temporary exclusions from fishing in areas during exploration and delineation activities. Underwater OCS structures such as pipelines could also cause space- and gear-related conflicts, and increased vessel traffic to and from the rigs and platforms will also increase the amount of marine traffic and possible conflicts with commercial fishers. The potential for spatial preclusion also exists in both nearshore and offshore waters with increased levels of seismic survey activity.

Recreational Fisheries. While space-use conflicts with recreational fisheries caused by routine OCS operations would be minimal, there is recreational shrimp trawling for wild shrimp, and trawls could become entangled with OCS structures in the water. Deepwater recreational rod-and-reel anglers typically target oil and gas platforms because these structures usually attract target species. Noise from rig and platform installation and from seismic surveys during exploration and delineation activities could scatter target species away from some recreational fishing areas while activities are occurring and potentially for some period afterward. Temporary reductions in hook-and-line captures have been reported in some areas following seismic surveys. This may result in decreased recreational catch. Platform removal using explosives may also impact recreational fisheries. The noise would drive some fish away, some fish would be killed, and a structure that may be targeted as a fishing location by recreational anglers could be eliminated.

Oil spills from OCS or non-OCS sources could affect recreational fisheries by fouling gear with oil, tainting the catch, and degrading water quality and fishing grounds. Accidental oil releases from non-OCS activities are possible anywhere on the OCS or in State waters, and crude oil also enters the environment from naturally occurring seeps. The OCS oil spills most likely to affect recreational anglers would be shallow water spills, since recreational anglers are less likely to venture far offshore. Non-OCS oil and gas activities likely pose a greater risk in terms of potential oil spills that could affect recreational fisheries, because such activities are located closer to shore. Closure of some areas to fishing, perhaps for multiple seasons, could occur as a result of oil spills. In addition, public perception of the effects of a spill on marine life and its extent could result in a loss of revenue for the fishing-related recreation industry. Party and charter boat recreational fisheries often have losses of income because of reduced interest in fishing when a spill has occurred. Local hotels, restaurants, bait-and-tackle shops, and boat rental companies associated with recreational fisheries may experience reduced sales because of public perception related to an oil spill.

Conclusion. Cumulative impacts on commercial and recreational fisheries in the GOM as a result of ongoing and future OCS and non-OCS activities and natural phenomena are expected to be minor over the next 40 to 50 years. Non-OCS activities affecting fisheries in the GOM include State oil and gas activities, commercial shipping (and other marine vessel traffic), land development, dredging and dredge-disposal operations, marine mineral mining, and water quality degradation from both point and nonpoint pollution. The incremental contribution of routine operations under the Program to these impacts would be small since these activities would be unlikely to have population- or community-level effects on fishery resources because of the limited time frame over which most individual activities would occur and because a small proportion of habitat relative to similar available habitat would be affected during a given period. In addition, existing stipulations are in place to prevent or reduce impacts on sensitive habitats such as hard-bottom areas and topographic features. Construction of new platforms could represent a small increase in the availability of desirable recreational fishing locations for recreational anglers (see Section 4.4.11.1).

Commercial and recreational fisheries may be adversely affected by accidental oil releases from OCS and non-OCS activities (e.g., State oil and gas development, domestic transportation of oil or refined petroleum products, and commercial shipping). The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on would be medium, depending on the location, timing, and volumes of spills (among other environmental factors). Small spills are unlikely to affect a large number of fish or have a substantial effect on recreational fishing before dilution and weathering reduced concentrations of oil in the water. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be moderate if they were to occur. Spills of this scale could have significant localized effects on commercial fishing as a result of reduced catch, loss of gear, or loss of fishing opportunities during cleanup and recovery periods, and on recreational fishing as a consequence of contamination of fish tissues, degradation of aesthetic values that attract fishers, or temporary closure of fishing areas. Large spills or a CDE have a greater potential to contact intertidal habitat and subsequently contaminate or reduce the abundance of commercial and recreational species that depend on nearshore habitat. These impacts could be long term, but are not expected to result in the long-term loss of fisheries in the GOM.

4.6.5.1.5 Tourism and Recreation. Noise from platform installation and platform removal can affect recreational fishing by temporarily disturbing fish and by causing fish kills if explosives are used to remove platforms. Platforms installed within 16 km (10 mi) of coastal recreation areas, such as beaches, parks, and wilderness areas, can affect recreational experiences by affecting ocean views. Transportation of oil and gas, combined with other commercial, industrial, and recreational vessel traffic that continues to occur within the GOM, can affect recreational experiences through increased noise, boat wake disturbances, visual intrusions, and increased trash and debris washing ashore. In addition to transportation and oil and gas, other activities contribute to the trash and debris found on the beaches including (but not limited to) beach visitors, commercial and recreational fishing, merchant shipping, naval operations, and cruise lines.

Non-OCS activities that might impact recreation and tourism include offshore construction (e.g., dredging and dredge-disposal operations, marine mineral mining, State oil and gas development, domestic transportation of oil and gas, and foreign crude oil imports), onshore construction (e.g., coastal and community development), the discharge of municipal and other waste effluents, and marine vessel traffic (e.g., commercial shipping, recreational boating, and military training and testing).

Accidental oil releases may occur as a result of both OCS and non-OCS activities, and oil is also released from naturally occurring seeps. The magnitude of the impacts would depend on the location and size of the releases, as well as their timing with respect to peak tourism seasons. These releases are expected to have a temporary impact on recreation and tourism in the GOM region. Closures of recreational areas for up to 6 weeks could occur to accommodate cleanup operations. Most of the releases identified under the Program are anticipated to be small and would occur in waters greater than 200 m (660 ft) in depth. These releases would be a small addition to releases associated with other OCS and non-OCS activities.

Severe storm events such as hurricanes have the potential to impact the recreation and tourism economy if they result in severe beach damage and/or destruction of existing public infrastructure. While hurricanes are regularly occurring events in the GOM, Hurricanes Katrina and Rita in 2005 caused unusually large amounts of damage to the tourism and recreation infrastructure in the area. These storms destroyed recreational beaches, public piers, hotels, casinos, marinas, recreational pleasure craft and charter boats, and numerous other recreational infrastructure. Almost 70% of the recreational fishing assets in Mississippi alone were damaged by Katrina (Posadas 2005). Of the 13 casino-barge structures present along the Mississippi coast prior to Katrina, most suffered severe external damage, seven broke completely free of their moorings, two partially broke free and damaged adjoining structures, one sank, and one was deposited inland by the storm surge (NIST 2006). The full extent of impacts to tourism and recreation by the hurricanes has yet to be fully quantified, but it will likely take years for tourism and recreation to return to pre-hurricane levels.

Conclusion. Cumulative impacts on tourism and recreation in the GOM as a result of ongoing and future OCS and non-OCS activities and natural phenomena are expected to be minor over the next 40 to 50 years. Non-OCS activities or phenomena affecting these resources include offshore construction (e.g., dredging and dredge-disposal operations, marine mineral mining, State oil and gas development, domestic transportation of oil and gas, and foreign crude oil imports), onshore construction (e.g., coastal and community development), the discharge of municipal and other waste effluents, and marine vessel traffic. The incremental contribution of routine operations under the Program to these impacts would be small, with potential adverse aesthetic impacts on beach recreation and sightseeing and potential positive impacts on diving and recreational fishing (see Section 4.4.12.1).

Tourism and recreation may be adversely affected by accidental oil releases from OCS and non-OCS activities (e.g., State oil and gas development, domestic transportation of oil or refined petroleum products, and commercial shipping). The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on would be negligible to small, depending on the size, location, and timing of the spill (being greatest if it occurred during the peak recreational season). Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be moderate to major if they were to occur. Short-term impacts would include beach and coastal access restrictions; restrictions on visitation, fishing, or hunting while cleanup is being conducted; and aesthetic impacts associated with the event itself and with cleanup activities. Longer-term impacts could be substantial if tourism were to suffer as a result of the real or perceived impacts of the event, or if there were substantial changes to tourism and recreation sectors in the region as a result of the event.

4.6.5.1.6 Sociocultural Systems. The GOM coastal commuting zone is ethnically and culturally diverse and includes a well-established oil and gas industry focused mainly in Louisiana and Texas (Section 3.14.1.1). For the most part, oil and gas development on the OCS will make use of existing pipelines and onshore infrastructure. Increases in activities associated with the Program are anticipated to be incremental and qualitatively similar to current patterns. However, as deepwater drilling expands, jobs that require longer, unbroken periods of offshore work will increasingly attract a more international workforce promoting sociocultural heterogeneity in coastal support communities, particularly in Texas and Louisiana.

Non-OCS program activities and processes affecting sociocultural systems are expected to continue. These include oil and gas development in State waters, coastal habitat changes, coastal land loss, regional economic changes, and recovery from storms and major oil spills. These activities and processes can lead to major impacts related to population change, job creation and loss, and changes in social institutions including family, government, politics, and education.

Accidental oil and other spills over the next 40 to 50 years could result from both OCS and non-OCS activities. The magnitude of spill impacts depends on their size, location, and timing. With the exception of major spills (such as occurred with the DWH event), oil spills are expected to have only temporary physical and economic effects and therefore should not significantly alter sociocultural systems.

The wetlands that supply subsistence resources are susceptible to oil spills. The Louisiana parishes of St. Mary, Terrebonne, and Lafourche are home to populations engaged in renewable resource harvesting, and are also areas of heavy to moderate concentrations of oil and gas industry facilities. As discussed in Section 3.7, the wetlands in coastal Louisiana are rapidly diminishing because of engineering projects to control the Mississippi River, natural subsidence, the development of the oil and gas industry, and climate change (Field et al. 2007). Because of the construction of flood-control structures, the Mississippi River no longer floods Louisiana's wetlands; these floods previously deposited new silt to offset coastal erosion. Extraction of oil and gas from coastal areas may have resulted in some subsidence of bayou lands. In many areas, Louisiana's coastal wetlands have been cut by a network of canals constructed to lay pipes bringing oil and gas to onshore refining facilities (Field et al. 2007). Cut in straight lines from the shore, these canals exacerbate the erosive force of tides and storm surges. Climate change has resulted in slowly increasing sea levels and an increased intensity of coastal storms and hurricanes. The end result has been an overall decrease in Louisiana's wetlands and a reduction in fresh and brackish wetlands and the subsistence species they support, along with an increase in salt marshes. Cumulatively, these changes constitute major impacts on a way of life that was once common along the GOM coast.

It is anticipated that global climate change will result in increased temperatures and rising relative sea levels along the GOM coast and these changes will be accompanied by an increase in severe storms in the coming decades. Rising relative sea levels and increased erosion have been observed all along the coast (Field et al. 2007). Those who rely at least in part on harvesting renewable resources from the sea, either as subsistence or commercial fishers and shrimpers, are predicted to be most vulnerable to adverse effects resulting from these changes (Nicholls et al. 2007).

Conclusion. Cumulative impacts on sociocultural systems in the GOM as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be moderate over the next 40 to 50 years. Non-OCS activities or phenomena affecting these resources include oil and gas development in State waters, coastal habitat changes, coastal land loss, regional economic changes, and recovery from storms and major oil spills. In terms of subsistence and renewable resource harvesting, non-OCS activities such as flood control along the Mississippi River and natural trends such as global climate change have produced major adverse impacts on the GOM coast region. The incremental contribution of routine operations under the Program to these impacts would be small, since they are more likely to support the existing industry than to create industry growth. Any expansion of deepwater activities will result in jobs that require longer, unbroken periods of work offshore, specialized skills, and potential in-migration of part of the workforce (see Section 4.4.13.1).

Sociocultural systems may be adversely affected by accidental oil releases from OCS and non-OCS activities (State oil and gas development, domestic transportation of oil or refined petroleum products, and commercial shipping). The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program would be small to medium, especially on localized intertidal resources used by subsistence harvesters. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be moderate to major if they were to occur, especially if oil were to reach the shore. Such spills could lead to long-term closure of fisheries, resulting in social and cultural stress. GOM subsistence harvesters make up a relatively small segment of the coastal population and replacement food resources are more available than for subsistence harvesters in Alaska, so while the impact of the loss of subsistence resources would be moderate for the coastal population as a whole, it would be locally major for populations that depended on subsistence harvesting for a significant proportion of their diet.

4.6.5.1.7 Environmental Justice. Over the next 40 to 50 years, air emissions from OCS and non-OCS onshore facilities and helicopter and marine vessel traffic traversing coastal areas would be highest in States such as Texas and Louisiana that contain the greatest amounts of infrastructure. Lesser amounts of infrastructure would occur in Mississippi and Alabama. No onshore infrastructure supporting OCS operations currently exists in Florida, and none will be built as a result of the Program. It is assumed that 75% of the activity from the Program will occur in deep and ultra-deep waters, with offshore air emissions greatest in the coastal areas of Texas and Louisiana, the areas with the greatest amounts of oil and gas activity, with lesser amounts in occurring in Mississippi and Alabama. The coastal areas of Florida are located so far from OCS activities that no environmental justice issues from offshore air emissions are expected to impact the coastal parts of the State. The effects of the OCS program on air quality have been analyzed in Section 4.4.4. This analysis concluded that routine operations associated with the Program would result in NO_2, SO_2, PM_{10}, and CO levels that are well within the NAAQS. Disproportionate impacts on low-income or minority populations would be minor, because the coastal effects from offshore activities are expected to be small, based on the established and increasing trend toward movement of oil and gas activities into deeper waters of the GOM.

The Program would result in levels of infrastructure use and construction similar to those that have already occurred in the GOM coast region during previous OCS programs. These activities are not expected to expose residents to notably higher risks than currently occur. While the distribution of offshore-related activities and infrastructure indicates that some places and populations in the GOM region would continue to be of environmental justice concern, the incremental contribution of the Program is not expected to affect those places and populations.

Non-OCS activities and processes that are ongoing and expected to continue into the foreseeable future, and include non-OCS oil and gas development, coastal habitat changes, coastal land loss, economic development, regional economic changes, and recovery from storms. These activities and processes could disproportionately impact low-income and minority populations.

In addition to oil and chemical spills that could occur with the Program, oil releases and spills could also occur from other non-OCS sources such as natural oil seeps, State oil and gas activity, and petrochemical refining and processing. While the timing and location of these spills cannot be determined and some low-income and minority populations are resident in some areas of the GOM coast, in general the coasts are home to more affluent groups. Low-income and minority groups are not more likely to bear more negative impacts than are other groups.

Conclusion. In the GOM, ongoing and future OCS and non-OCS program activities in combination with the effects of storm and hurricane damage and regional economic issues would result in disproportionate moderate to major adverse cumulative impacts on low-income and minority populations. The incremental contribution of routine operations under the Program to these impacts would be negligible (see Section 4.4.14.1).

The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be negligible to medium because of the movement of oil and gas activities farther away from coastal areas and the demographic pattern of more affluent groups (and fewer low-income and minority populations) living in coastal areas. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in moderate to major impacts, depending on the location, size, and timing of the event.

4.6.5.1.8 Archeological and Historic Resources. Section 4.4.1.5 discusses the direct and indirect impacts from the Program in onshore and offshore environments in the GOM. Cumulative impacts on archeological and historic resources result from the incremental impacts of the Program when added to impacts from ongoing and reasonably foreseeable future OCS program activities (that are not part of the Program) and other non-OCS program activities. Table 4.6.1-2 presents the exploration and development scenario for the GOM cumulative case (encompassing the Program and other OCS program activities). Specific types of impact-producing factors related to OCS program activities considered in this analysis include drilling rig and platform emplacement, pipeline emplacement, anchoring, new onshore facilities, ferromagnetic debris associated with OCS activities, and oil spills. Non-OCS program activities include trawling, sport diving, commercial treasure hunting, and channel dredging. Natural phenomena such as waves, currents, and tropical storms are also considered.

Prehistoric Resources. Offshore development could result in an interaction between a drilling rig, platform, pipeline, or anchors and an inundated prehistoric site. This direct physical contact with a site could destroy artifacts or site features and could disturb the stratigraphic context of the site. The result would be the loss of archaeological data on prehistoric migrations, settlement patterns, subsistence strategies, and archaeological contacts for the Americas and the Caribbean.

Since 1973 when the Environment Studies Program (ESP) was initiated, the USDOI has required that an archaeological survey be conducted prior to development of mineral leases determined to have potential for cultural resources including prehistoric archaeological sites. High-probability areas for the occurrence of prehistoric sites in the GOM include the region of the OCS shoreward of the 45-m (50-ft) isobath. Although an archaeological survey would identify most of the cultural resources in the APE for the project and routine operations related to OCS program activities would avoid all known cultural resources, it is likely that impacts to prehistoric resources have already occurred as a result of OCS program and non-program activities that took place before implementation of the 1973 archaeological survey requirement.

Onshore development could result in direct physical contact between the construction of new onshore facilities or pipeline trenches and previously unidentified prehistoric sites. This direct physical contact with a prehistoric site could cause physical damage to or complete destruction of information on the prehistory of the region and North America. Federal and State laws and regulations initiated in the 1960s began requiring archaeological surveys prior to permitting any activity that might disturb a significant archaeological site. Therefore, it can be assumed that, since the introduction of the archaeological resource protection laws, most coastal archaeological sites have been located, evaluated, and mitigated prior to construction. However, impacts to coastal prehistoric resources may have already occurred as a result of various onshore construction activities prior to enactment of the archaeological resource protection laws.

Trawling activity in the GOM affects only the uppermost portion of the sediment column (Garrison et al. 1989). This zone would already have been disturbed by natural factors relating to the destructive effects of marine transgression and continuing effects of wave and current action. Therefore, the effect of future trawling on most prehistoric archaeological sites is expected to be minor.

Tropical storms and hurricanes are yearly occurrences in the GOM and may be increasing in intensity as a result of global climate change (Section 3.3.1). Past storm events have affected all areas of the GOM, from west Texas to south Florida, and broad areas are affected by each storm (DeWald 1980). Prehistoric sites in shallow waters or coastal beach sites are exposed to the destructive effects of wave action and scouring currents during these events. Under such conditions, it is highly likely that artifacts would be dispersed and the site context disturbed, resulting in the loss of archaeological information. Overall, a significant loss of data from nearshore and coastal prehistoric sites may have occurred, and will continue to occur, from the effects of tropical storms and hurricanes. It is assumed that some of the data lost have been significant and/or unique, resulting in a moderate to major level of impact.

Most channel dredging occurs at the entrances to bays, harbors, and ports. These areas have a high probability for prehistoric archaeological sites, as they are associated with drowned river valleys, which are known to have a high probability for prehistoric sites. It is assumed that some of the archaeological data that have been lost as a result of dredging have been significant and unique; therefore, the impact to prehistoric archaeological sites as a result of past channel dredging activities has probably been moderate to major. In many areas, the USACE now requires remote-sensing surveys prior to dredging activities to minimize such impacts (Espey, Huston & Associates 1990).

An accidental oil spill could affect coastal prehistoric archaeological sites, but the direct impact of oil on most sites is uncertain. Protection of such sites during an oil spill event requires specific knowledge of its location, condition, nature, and extent prior to impact; however, the GOM coastline has not been systematically surveyed for archaeological sites. Existing information indicates that, in coastal areas of the GOM, prehistoric sites occur frequently along the barrier islands and mainland coast and along the margins of bays and bayous. Thus, any spill that contacts land would involve potential impacts on prehistoric sites.

Heavy oiling of a coastal area could conceal intertidal sites that may not be recognized until they are inadvertently damaged during cleanup (Whitney 1994). Crude oil may also contaminate organic material used in ^{14}C dating, and, although there are methods for cleaning contaminated ^{14}C samples, greater expense is incurred (Dekin et al. 1993). The major source of potential impacts from oil spills is the harm that could result from unmonitored shoreline cleanup activities. Unauthorized collecting of artifacts by cleanup crew members is also a concern, albeit one that can be mitigated with effective training and supervision. Damage or loss of significant archaeological information could result from the contact between an oil spill and a prehistoric archaeological site; therefore, cumulatively the level of impacts from oil spills (past, present, and future) to prehistoric archaeological sites ranges from moderate to high.

Historic Resources. Direct physical contact between a routine activity and a shipwreck site could destroy fragile ship remains, such as the hull and wooden or ceramic artifacts, and could disturb the site context. The result would be the loss of archaeological data on ship construction, cargo, and the social organization of the vessel's crew, and the concomitant loss of information on maritime culture for the time period from which the ship dates.

Since 1973 when the ESP was initiated, the USDOI has required archaeological (historical) surveys be conducted prior to development of mineral leases determined to have potential for historic-period shipwrecks. The high-probability areas for the occurrence of historic-period shipwrecks in the GOM consist of nearshore areas, port vicinities, and ship-specific polygons. Based on experience from the last 10 years (as reported by Church and Warren [2008]; Ford et al. [2008]; Atauz et al. [2006]), archaeological surveys are now also being requested for the APE that includes any potential bottom-disturbing activities in deepwater areas that could be affected by a project. Although an archaeological survey would identify most of the cultural resources in the area of potential effect (APE) for the project and routine operations related to OCS program activities would avoid all known cultural resources, it is likely that impacts on historic-period shipwrecks may have already occurred as a result of OCS program and non-program activities that took place before implementation of the archaeological survey requirement in 1973.

Onshore development could result in direct physical contact between the construction of new onshore facilities or pipeline trenches and previously unidentified historic sites. Federal and State laws and regulations initiated in the 1960s began requiring archaeological surveys prior to permitting any activity that might disturb a significant archaeological site. Therefore, it can be assumed that, since the introduction of the archaeological resource protection laws, most coastal archaeological sites have been located, evaluated, and mitigated prior to construction. However, impacts to coastal historic sites may have already occurred as a result of various onshore construction activities prior to enactment of the archaeological resource protection laws.

Trawling activities in the GOM only affect the uppermost portion of the sediment column (Garrison et al. 1989). On many wrecks, this zone would already have been disturbed by natural factors and would contain only artifacts of low specific gravity (e.g., ceramics and glass) which have lost all original contexts. Therefore, the effect of future trawling on most historic shipwreck sites would be minor.

Sport diving and commercial treasure hunting are significant factors in the loss of historic data from shipwreck sites. While commercial treasure hunters generally affect wrecks having intrinsic monetary value, sport divers may collect souvenirs from all types of shipwrecks. It is assumed that some of the data lost have been significant and/or unique. The known extent of these activities suggests that they have resulted in a major impact to historic-period shipwrecks.

Tropical storms and hurricanes are yearly occurrences in the GOM and may be increasing as a result of global climate change (Section 3.3.1). Past storms have affected all areas of the GOM, from west Texas to south Florida, and broad areas are affected by each storm (DeWald 1980). Shipwrecks in shallow waters and coastal historic sites are exposed to greatly intensified longshore currents and high-energy waves during tropical storms (Clausen and Arnold 1975). Under such conditions, it is highly likely that artifacts of low specific gravity would be dispersed. Some of the original information contained in the site would be lost in this process, but a significant amount of information may also remain. BOEM-sponsored studies conducted specifically to examine the effect of hurricanes on shipwrecks in the GOM found that storm effects on wrecks varied, with some wrecks being damaged, some unaffected, and others protected because the storm caused sediment to be deposited on the wreck (Gearhart et al. 2011).

Overall, a significant loss of data from historic sites has probably occurred, and will continue to occur, from the effects of tropical storms and hurricanes. It is assumed that some of the data lost has been significant and/or unique, resulting in a moderate to major level of impact.

Most channel dredging occurs at the entrances to bays, harbors, and ports. These areas have a high probability for historic shipwrecks, and the greatest concentrations of historic wrecks are likely to be associated with these features (Garrison et al. 1989). Assuming that some of the data lost have been unique, the impact to historic sites as a result of past channel dredging activities has probably been moderate to major. In many areas, the USACE requires remote-sensing surveys prior to dredging activities, to minimize such impacts (Espey, Huston & Associates 1990).

Past, present, and future oil and gas exploration and development on the OCS will result in the deposition of tons of ferromagnetic debris on the seafloor. This modern marine debris tends to mask the magnetic signatures of historic shipwrecks, particularly in areas that were developed prior to requiring archaeological surveys. Such masking of the signatures characteristic of historic shipwrecks increases the potential that significant or unique historic information may be lost. However, BOEM requires avoidance or investigation of any unidentified magnetic anomaly that could be related to a shipwreck site prior to permitting bottom-disturbing activities. The impacts to historic shipwrecks from magnetic masking could range from minor to moderate.

An accidental oil spill could affect a coastal historic site, but the direct impact of oil on most historic sites is uncertain. The primary source of potential impacts from oil spills is unmonitored shoreline cleanup activities (Bittner 1996; see Section 4.4.15.1.2). Unauthorized collecting of artifacts by cleanup crew members is also a concern, albeit one that can be mitigated with effective training and supervision. Damage or loss of significant historic information could result from oil spill cleanup activities; therefore, the cumulative impact from oil spills (past, present, and future) on historic sites could range from moderate to major.

Conclusion. The cumulative impacts of ongoing and future OCS and non-OCS program activities on prehistoric and historic archaeological sites in the GOM are currently unknown, but could range from minor to moderate, mainly because activities occurring on the OCS prior to the USDOI's survey requirement (in effect since 1973) may already have affected significant archaeological sites. Other important impact-producing factors that likely have had, and will continue to have, an impact on both prehistoric and historic archaeological sites are channel dredging, tropical storms, and hurricanes. Commercial treasure hunting and sport diving may also result in a loss of artifacts at historic-period shipwreck sites. The incremental contribution of routine operations under the Program is expected to be negligible to large, depending on whether significant resources are located in the area of effect. Archaeological surveys that would identify significant cultural resources to be avoided could reduce these impacts (see Section 4.4.15.1).

Cumulative impacts on prehistoric and historic archaeological sites due to expected accidental oil spills and related cleanup activities could range from negligible to major, depending on the location of the spill in relation to sensitive resources. The incremental contribution of oil spills associated with the Program could be small to large relative to those associated with ongoing and future OCS and non-OCS program activities. Impacts associated with an unexpected, low-probability CDE would also depend on location, and could range from minor to major if it were to occur. There is a greater likelihood that more of the resources would be affected at a major level during a CDE. A more detailed discussion of the effects of oil spills on archaeological and historic resources in the GOM is presented in Section 4.4.15.1.

4.6.5.2 Alaska – Cook Inlet

4.6.5.2.1 Areas of Special Concern. Section 4.4.8.2 identifies potential impacts that could result from routine activities or accidents related to the proposed leasing program on Areas of Special Concern adjacent to and in the Cook Inlet Planning Area. In considering the potential cumulative effects of OCS activities on these areas, the level of routine activities and the potential for accidental spills under the Program must be considered with other past, present, and reasonably foreseeable future actions that would occur during the 40-year life of the proposed program. Overall cumulative impacts on these Areas of Special Concern in Cook Inlet consider impacts from both OCS and non-OCS activities.

National Park Service Lands. As identified in Section 4.4.8.2, NPS lands are potentially susceptible to cumulative impacts from activities related to OCS oil and gas development as a consequence of the proposed 5-year leasing program in Cook Inlet. The potentially affected lands include the Lake Clark National Park and Preserve and the Katmai National Park and Preserve and Aniachak National Monument. Kenai Fjords National Park is east of Cook Inlet on the GOA, but it could be affected by an oil spill associated with OCS activities in Cook Inlet.

Impacts from routine OCS operations could come from facilities developed to support oil drilling and production, and could include effects from pipeline landfalls, dredging, air pollution, and the construction of roads and new facilities. Onshore oil facilities are permissible only on private acreage within each National Park. All of these National Parks, Monuments, and Preserves contain privately held acreage, and development of onshore oil support facilities is possible in these areas. Because of the more confined nature of Cook Inlet, OCS construction of facilities within the Cook Inlet Planning Area could have some negative effects on scenic values for some users if the facilities were visible from shore or air during flightseeing. It is assumed that pipeline landfalls, shore bases, and waste facilities would not be located in National Parks, because of the special status and protections afforded these areas.

Increased traffic (i.e., land, sea, and air) and development within the vicinity of NPS lands could also contribute to cumulative impacts on these areas. Because the amount of traffic is restricted and activities within the parks regulated, traffic would likely create a minor addition to cumulative impacts on the NPS lands. It is anticipated that noise generated by OCS offshore construction activities would be at low levels and intermittent, and would not persist for more than a few months at any one time. It is considered unlikely that these additional activities would noticeably affect wildlife or park user values compared to current (non-OCS) activities within the considered planning areas. Increased traffic may also affect air quality (see Section 4.4.4.2 and Section 4.6.2.1.2). Air quality in Alaska is expected to remain good, with pollutant concentrations associated with offshore and onshore emission sources well within applicable State and Federal standards. The contribution of OCS program activities to cumulative air quality impacts would be small. Air quality impacts from oil spills and fires would be localized and short in duration.

Impacts on these areas could occur due to accidental releases of oil spilled from onshore facilities and offshore drilling rigs (Table 4.6.1-3). Non-OCS activities, such as oil and gas development in State waters, the domestic transportation of oil or refined petroleum products including LNG from Cook Inlet and the Alaska Peninsula, the production and storage of petroleum products and LNG, and commercial shipping, could also result in accidental spills that could affect park lands. In addition to affecting the National Parks mentioned above, oil spills from tankering to and from Valdez could also affect Kenai Fjords NP and Wrangell St Elias NPP. Naturally occurring seeps may also be a source of crude oil introduced into nearshore waters (Kvenvolden and Cooper 2003). An oil spill would have the greatest effect if it came into contact with shoreline habitats. Impacts would depend primarily on the spill location, size, and time of year. In general, directly affected coastal fauna could include invertebrates; marine mammals; fishes that reproduce in, inhabit, or migrate through coastal areas; terrestrial mammals that feed on these fishes; and marsh birds and seabirds. Spilled oil could also affect subsistence harvests in those parks in which subsistence hunting and fishing are allowed (see Section 4.6.5.2) and could affect the number of park visitors.

National Wildlife Refuges. NWRs in the vicinity of Cook Inlet are identified in Section 3.9.2.2. NWRs potentially affected by OCS activities in the Cook Inlet Planning Area include the Alaska Peninsula NWR, Becharof NWR, Kodiak NWR, Kenai NWR, and Izembek NWR. These refuges could be contaminated by oil spilled from offshore projects or could be subject to negative effects from routine operations associated with the development of onshore oil and gas support facilities. They could also be affected by non-OCS activities within or adjacent to refuges, including oil and gas development in State waters, the domestic transportation of oil or refined petroleum products including LNG from Cook Inlet and the Alaska Peninsula, the production and storage of petroleum products and LNG, and commercial shipping. Numerous refuge lands have been conveyed to private owners and Native corporations. Section 22(g) of ANCSA requires that new development on these lands must be in accordance with the purpose for which the refuge was formed. Thus, while development of onshore oil and gas support facilities is technically possible, such development would be subject to intensive review (as would any other development).

The potential cumulative effects of routine operations and accidental events on these NWRs are essentially the same as those discussed above for the NPS lands. In addition, subsistence hunting and fishing are permitted on all refuges in Alaska and could, therefore, be affected by accidents and routine operations in the immediate vicinity of refuge properties.

National Forests. The only National Forest within the vicinity of the Cook Inlet Planning Area is the Chugach National Forest, which is located mainly on the eastern side of the Kenai Peninsula (Figure 3.9.2-1). Because there would be no OCS-related development, such as pipelines or other onshore facilities, within the Chugach National Forest, it would not be affected by routine OCS activities associated with lease sales in the Cook Inlet Planning Area. Because of the forest location, oil spills from OCS platforms or pipelines within the Cook Inlet Planning Area would not be expected to affect shoreline areas or other resources within Chugach National Forest.

The Chugach National Forest is adjacent to the Gulf of Alaska. It also borders Prince William Sound and is close to Valdez. The Chugach National Forest is, therefore, potentially susceptible to cumulative effects of routine oil-related operations from transport and tanker loading of oil produced (OCS and non-OCS) in other regions (e.g., the Beaufort Sea Planning Area) and transported by pipeline to the Port of Valdez. Potential effects include increased noise and air pollution from tanker traffic.

Additional, non-OCS-related cumulative impacts in the National Forest could result from mining operations (e.g., for gold or gravel/stone), hunting, flightseeing, ski resorts, trains, and tourism. However, the impacts of these activities are regulated through a permitting process following an approved resource use plan.

The Chugach National Forest would be potentially susceptible to oil (mostly non-OCS) spilled from tankers that utilize the loading facilities at the Port of Valdez. Oil spills that reached the coastline could affect coastal fauna; subsistence, recreational, and commercial fishing; and tourism. Impacts would depend on the size and timing of a spill and would be expected to be minor to moderate.

Other Areas of Special Concern. There are multiple State parks and State recreation areas near the Cook Inlet Planning Area, many of which border Cook Inlet or are located in areas that could be contacted by accidental oil spills. Such areas include Captain Cook State Recreation Area, Clam Gulch State Recreation Area, Chugach State Park, Kachemak Bay State Park and State Wilderness Park, and Ninilchik State Recreation Area. In addition, the Kachemak Bay National Estuarine Research Reserve is located in Cook Inlet on the southern end of the Kenai Peninsula. Cumulative impacts from offshore activities would be similar to those described above for National Parks and Refuges. Existing protections and restrictions on uses should limit the direct terrestrial cumulative impacts from OCS and non OCS activities on these areas. There is existing oil and gas infrastructure in State waters of Cook Inlet and the addition of OCS infrastructure and activities could have negative effects on scenic values for some users if the facilities were visible from shore or the air during flightseeing. It is assumed that pipeline landfalls, shore bases, and waste facilities would not be located in the State parks and recreation areas. Increased traffic (i.e., land, sea, and air) and development within the vicinity of State parks lands could also contribute to cumulative impacts on these areas. It is anticipated that noise generated by OCS offshore construction activities would be at low levels, intermittent, and would not persist for more than a few months at any one time. It is considered unlikely that these additional activities would noticeably affect wildlife or park user values compared to current (non-OCS) activities within the considered planning areas.

As described above, impacts on State parks and recreational areas could occur due to accidental releases of oil spilled from onshore facilities and offshore drilling rigs. An oil spill contacting shoreline habitats could affect subsistence harvests in those parks in which recreation and subsistence hunting and fishing are allowed and could affect the number of park visitors. Impacts would depend primarily on the spill location, size, and time of year.

Conclusion. Cumulative impacts on Areas of Special Concern in Cook Inlet are considered to be negligible to moderate. Routine operations under the Program could result in negligible to medium incremental increases in effects on National Sanctuaries, Parks, Refuges, and Estuarine Research Reserves (see Section 4.4.8.2). Development of onshore facilities within NPS lands in the vicinity of the areas included in the Program is considered unlikely, thereby making impacts from routine Program activities unlikely in these areas. Offshore construction of pipelines and platforms could contribute to cumulative effects on wildlife and on scenic values for park visitors due to noise and activity levels, particularly in the vicinity of Cook Inlet. However, such effects would be localized, intermittent, and temporary.

Expected oil spills (most of which are less than 1,000 bbl) that occur during the Program could result in a negligible to small incremental contribution to cumulative impacts on Areas of Special Concern, depending on spill frequency, location, and volume; the type of product spilled; weather conditions; effectiveness of cleanup operations; and other environmental conditions at the time of the spill. Large spills (1,000 bbl and greater) or an unexpected, low-probability CDE in areas adjacent to the National Parks, NWRs, or National Forests, whether from OCS or non-OCS sources, would also depend on these factors, and could result in moderate impacts if they were to occur. Such spills could negatively impact coastal habitats and fauna, and could also affect subsistence uses, commercial or recreational fisheries, and tourism.

4.6.5.2.2 Population, Employment, and Income. Section 4.4.9 discusses the potential impacts from the Program on population, employment, and income in the south-central Alaska region. Cumulative impacts on these resources result from the incremental impacts of the Program when added to impacts from reasonably foreseeable future OCS program activities (there are no ongoing OCS program activities) and ongoing and future non-OCS program activities. Specific types of impact-producing factors related to OCS program activities considered in this analysis include total employment and regional income for the south Alaska region, which corresponds to the Cook Inlet Planning Area (described in Section 3.10). Non-OCS program activities affecting the region include employment and earnings related to various other industrial sectors (e.g., construction, manufacturing, services, and State and local government).

The population in the Cook Inlet Planning Area increased at an average annual rate of 3.2% between 1980 and 1990, 1.3% between 1990 and 2000, and 1.2% between 2000 and 2009. During each of these periods, the greatest increases consistently occurred on the Kenai Peninsula (with an average annual increase of 1.1% between 2000 and 2009) and in Anchorage (also with an average annual increase of 1.1% between 2000 and 2009). The components of population increase include the natural increase due to births and net positive domestic and international migration; these trends would likely continue in south central Alaska over the next 40 to 50 years.

Although the Program would add an average of 1,372 to 3,792 direct and indirect jobs annually in Alaska between 2012 and 2017, this increase is considered minor (but positive) since it would amount to less than 2% of total Alaska employment. Likewise, direct and indirect income produced in the region would range from $87 million to $256 million annually in south central Alaska, which constitutes less than 2% of income in Alaska overall.

Employment impacts of oil spills reaching landfall can vary considerably depending upon the total volume of oil reaching land, the land area affected, and the sensitivity of local environmental conditions to oil impacts. The primary impacts of oil spills would most likely fall on such activities as beach recreation, commercial fishing, recreational fishing, and sightseeing. Oil spills reaching land can have both short- and long-term effects on these recreational coastal activities. Past studies (Sorenson 1990) have shown that there could be a one-time seasonal decline in tourist visits of 5% to 15% associated with a major oil spill. Since tourist movement to other coastal areas in the region often offsets a reduction in the number of visits to one area, the associated loss of business tends to be localized. Although an oil spill could occur anywhere in the lease sale area, cleanup-related employment would likely occur in the area directly affected, generally in locations remote from communities. Oil spills will generate only temporary employment (and population) increases during cleanup operations, because such operations are expected to be of short duration.

Conclusion. The cumulative impacts of future OCS program and ongoing and future non-OCS program activities would be considered beneficial because these activities would increase employment and earnings in the region over the next 40 to 50 years. The Program would add to these beneficial impacts, especially on the Kenai Peninsula and in Anchorage. The incremental contribution of the Program is expected to be small, however, because the added employment demands are less than 2% of total Alaska employment (see Section 4.4.9.2).

In areas with a large proportion of impact-sensitive industry (such as commercial and recreational fishing), the cumulative impacts of accidental oils spills could be moderate to major, depending on the total volume of oil reaching land, the land area affected, and the sensitivity of local environmental conditions to oil impacts. The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be negligible to small relative to those associated with future OCS program and ongoing and future non-OCS program activities. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in minor to moderate impacts. In the short term, impacts of a CDE could be large as a result of loss of employment, income, and property value; increased traffic congestion; increased cost of service provision; and possible shortages of commodities or services. Longer-term impacts could be smaller unless the fishing and tourism suffered as a result of real or perceived impacts of the event (see Section 4.4.9.1).

4.6.5.2.3 Land Use and Infrastructure. Localized impacts to land use and existing infrastructure are anticipated as a result of the construction of new OCS program oil and gas facilities in Cook Inlet over the next 40 to 50 years. Impact-producing factors from OCS program activities would include increased aircraft traffic (e.g., helicopter trips); modifications to current land use designations to incorporate new facilities, if they are needed; and some infrastructure expansion. Ongoing non-OCS program activities affecting land use and onshore infrastructure are expected to continue into the foreseeable future. These include offshore construction, onshore construction, and marine vessel traffic. Where land is largely undeveloped and no established oil and gas infrastructure is present, development could result in land use impacts, such as the conversion of existing land use (e.g., undeveloped, residential, or commercial) to industrial land use to accommodate oil and gas production (MMS 2007e).

Accidental oil releases may occur as a result of both OCS and non-OCS activities, and oil is also released from naturally occurring seeps. The extent of the impacts would depend on the location and size of the releases, but could include stresses of spill response on the community infrastructure, increased traffic to respond to cleanup, and restricted access to particular lands while cleanup is conducted. In general, these releases would be expected to have a temporary impact on land use and infrastructure (MMS 2007c).

Conclusion. Localized impacts to land use and existing infrastructure are anticipated over the next 40 to 50 years as a result of future OCS and ongoing and future non-OCS program activities in Cook Inlet. These impacts could range from minor to major depending on the location and nature (extent and duration) of the land use change. The incremental contribution of routine operations under the Program to cumulative impacts in Cook Inlet would be negligible to small because the Program would not introduce new kinds of activities that would alter existing land uses (see Section 4.4.10.2).

Land use–related impacts resulting from expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program include stresses of spill response on community infrastructure, increased traffic in the response area (both onshore and offshore), and temporary restricted access to affected lands (while cleanup is conducted). Such spills would result in a small incremental contribution to cumulative impacts on land use and existing infrastructure. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in moderate impacts if they were to occur.

4.6.5.2.4 Commercial Fisheries and Recreational Fisheries. Some OCS exploration, development, and production activities have the potential to result in space-use conflicts with fishing activities over the next 40 to 50 years. In some cases, fishing vessels could be excluded from normal fishing grounds for safety reasons during construction periods or after facilities are in place. In other instances, fishery crews or anglers could decide to avoid certain areas to reduce the potential for gear loss. Such conflicts can sometimes be avoided by conducting construction activities or seismic surveys during closed fishing periods or seasons. A potential also exists for loss of gear or loss of access to fishing areas when floating drill rigs used for exploration are being moved and during other vessel operations.

Offshore construction of platforms or artificial islands could infringe on commercial fishing activities by excluding commercial fishing from adjacent areas due to safety considerations. Drilling discharges associated with exploration activities would likely affect only a small area near drilling platforms or islands, and are not expected to interfere with commercial fishing. During development and production phases, potential effects of such discharges would cease because all muds, cuttings, and produced waters would be discharged into wells instead of being released to open waters. Potential effects of platform construction and operation are expected to be highly localized. Because only a very small area of the individual planning areas would be affected, interference with commercial fisheries is expected to be small.

The impacts of oil and gas development on commercial fishing costs would vary considerably by placement depth. In the Kodiak area, the largest cost increases would occur with structures located in water between 300 and 1,500 m (984 and 4,921 ft) deep, with an annual increase of $43 in costs from a single structure; a single structure in each depth range would increase annual costs by $44. In the Cook Inlet area, the largest increase would come with a single structure placed in water between 150 and 300 m (492 and 984 ft), with an overall increase in costs of $57 per year. Cost impacts in the Gulf of Alaska area would be the largest, at $93 per year with a structure in each depth range, the largest cost increases occurring with a structure placed at between 300 to 1,500 m (984 and 4,921 ft). In each of the areas, single structures would have relatively insignificant impacts compared to fishery revenues in each depth range.

Various non-OCS activities, including State oil and gas programs, dredging and dredge-disposal operations, logging operations, and commercial or sport fishing activities, could also contribute to cumulative impacts on fisheries. Drilling of wells under State oil and gas programs would also require construction of pipelines and artificial islands or platforms in Alaskan waters. Potential effects on fishery resources and on space-use conflicts from State oil and gas activities would be similar to those described above for OCS program oil and gas activities. Dredging and marine disposal activities would involve excavation of nearshore sediments and subsequent disposal in offshore or nearshore areas, thereby disturbing seafloor habitats in some areas and burying benthic organisms that help to support fishery resources. Logging operations have a potential to contribute to cumulative effects on fishery resources by degrading riverine habitats that are important for salmon reproduction and the rearing of juveniles.

Non-OCS activities, such as State oil and gas development, domestic transportation of oil or refined petroleum products, and commercial shipping (and other marine vessel traffic), may also result in accidental spills that could affect fisheries within the waters of the south central Alaska region. Fisheries resources could become exposed to oil as a consequence of accidental oil spills, which could cause declines in subpopulations of some species inhabiting the affected planning areas. It is anticipated that there would be no long-term effects on overall fish populations in Alaskan waters as a result of such spills. However, even localized decreases in stocks of fish could have effects on some fisheries by reducing catches or increasing the amount of effort or the distances that must be traveled to obtain adequate catches.

Even if fish stocks are not reduced as a consequence of a spill, specific fisheries could be closed due to actual or perceived contamination of fish or shellfish. It is anticipated that most small to medium spills would have limited effects on fisheries because of the relatively small areas likely to be exposed to high concentrations of hydrocarbons and the short period of time during which oil slicks would persist. In the event of a large spill, commercial, recreational, or subsistence fisheries for shellfish in nearshore subtidal and intertidal areas that become oiled are likely to be affected. Fisheries for shellfish that occur in deeper waters, where oil concentrations would likely be too low to cause direct effects on biota, are less likely to be affected. Regardless, even shellfish from deeper areas could become commercially unacceptable for market due to actual or perceived contamination and tainting.

Oil spills that enter nearshore waters could also damage setnet fisheries, as evidenced by the *Exxon Valdez* oil spill of 1989. While only a relatively small volume of weathered oil entered the lower Cook Inlet region as a result of that spill, the commercial salmon fishery was closed to protect both gear and harvest from possible contamination. Within the Cook Inlet Planning Areas, a spill the size of the assumed largest OCS spill could result in temporary closures to commercial and subsistence setnet fishing until cleanup operations or natural processes reduced oil concentrations to levels considered safe.

Although pelagic fishes likely would be less affected than fishes in shallow subtidal or intertidal areas, spilled oil could contaminate gear used for pelagic fishing, such as purse seines and drift nets. A large oil spill before or during the season when such fishing gears are in use could result in closures of some short-period, high-value commercial fisheries in order to protect gear or harvests from potential contamination. Lines from longline fisheries for halibut, Pacific cod, black cod, and other fish species in the Cook Inlet Planning Area could also be affected by oil. Some lines and buoys fouled with small amounts of oil could be unfit for future use. Although it is unlikely that a trawler would be operating in an oiled area, the trawl catches could be contaminated by oil and rendered unfit for consumption and unprofitable if passed through such an area.

Conclusion. Cumulative impacts on commercial and recreational fisheries in Cook Inlet as a result of ongoing and future OCS and non-OCS activities and natural phenomena are expected to be minor over the next 40 to 50 years. Non-OCS activities affecting fisheries in the inlet include State oil and gas programs, dredging and dredge-disposal operations, logging operations, and commercial or sport fishing activities. The incremental contribution of routine Program activities to these impacts would be small. Routine operations under the Program would be unlikely to have population-level effects on fishery resources or result in long-term loss of fishery resources (see Section 4.4.11.2).

Commercial and recreational fisheries may be adversely affected by accidental oil releases from OCS and non-OCS activities (e.g., State oil and gas development, domestic transportation of oil or refined petroleum products, and commercial shipping). The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on would be negligible to medium, depending on the location, timing, and volumes of spills (among other environmental factors). Small spills are unlikely to affect a large number of fish or have a substantial effect on recreational fishing before dilution and weathering reduced concentrations of oil in the water. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be moderate if they were to occur. Large spills or a CDE could have significant localized effects on commercial fishing as a result of reduced catch, loss of gear, or loss of fishing opportunities during cleanup and recovery periods, and on recreational fishing as a consequence of contamination of fish tissues, degradation of aesthetic values that attract fishers, or temporary closure of fishing areas. Large spills or a CDE have a greater potential to contact intertidal habitat and subsequently contaminate or reduce the abundance of commercial and recreational species that depend on nearshore habitat. These impacts could be long-term, but are not expected to result in the long-term loss of fisheries in Cook Inlet.

4.6.5.2.5 Tourism and Recreation. Platform, pipeline, causeway, and facility construction and vessel traffic could interfere with water-based recreational activities (fishing, boating, sightseeing, cruise ships) and could result in some disruption to land-based activities (hiking, picnicking, hunting, visiting Native communities, camping, wildlife viewing, and sightseeing), depending on the location of recreational activities relative to proposed development; increases in amounts of trash and debris from OCS activities; and possible competition between workers and tourists for local services, such as air transport, hotel accommodations, and other visitor services. Non-OCS activities that could have an impact on tourism and recreation include offshore construction (e.g., State oil and gas development, domestic transportation of oil and gas), onshore construction (e.g., coastal and community development), and marine vessel traffic (e.g., commercial shipping, recreational boating, military training and testing).

Non-OCS activities and proposed and future OCS activities represent a continuation of existing onshore and offshore oil and gas construction trends close to the Cook Inlet Planning Area. Substantial infrastructure for related oil and gas development already exists in this area (especially in the upper inlet), including platforms, exploration and production wells, pipelines to transport oil from offshore platforms to common-carrier pipeline systems onshore, and processing facilities. Therefore, there should not be additional visual disruption for the tourists in these areas. Pipeline construction would present a temporary disruption to tourism and recreation due to workers competing with tourists for short-term housing (hotels) and air transport; aesthetic impacts (visual and auditory) associated with construction sites; and possible temporary prevention of access to some recreational or wilderness areas. In addition, the new pipeline in the Arctic region could create road access into previously undeveloped lands used primarily for subsistence, creating a potential conflict between subsistence practices and recreational hunting or other possible tourist activities.

Oil spills associated with OCS and non-OCS activities, as well as oil from naturally occurring seeps, could also affect recreation and tourism, and could result in both short-term and long-term effects, depending on public perception and reaction. Potential cumulative impacts include direct land impacts (e.g., oil contamination of a national wildlife refuge or recreational port); aesthetic impacts of the spill and associated cleanup; increased traffic to respond to cleanup operations; and restricted access to particular lands while cleanup is being conducted.

Conclusion. Cumulative impacts on tourism and recreation in Cook Inlet as a result of ongoing and future OCS and non-OCS activities and natural phenomena would be minor over the next 40 to 50 years. Non-OCS activities or phenomena affecting these resources include offshore construction (e.g., State oil and gas development, domestic transportation of oil and gas), onshore construction (e.g., coastal and community development), and marine vessel traffic. The incremental contribution of routine operations under the Program to these impacts would be small, with potential adverse aesthetic impacts on sightseeing, boating, fishing, and hiking activities in the inlet (see Section 4.4.12.1).

Tourism and recreation may be adversely affected by accidental oil releases from OCS and non-OCS activities (e.g., State oil and gas development, domestic transportation of oil or refined petroleum products, and commercial shipping). The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program would be negligible to small, depending on the size, location, and timing of the spill (being greatest if it occurred during the peak recreational season). Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be minor to moderate if they were to occur. Short-term impacts would include beach and coastal access restrictions; restrictions on visitation, fishing, or hunting while cleanup is being conducted; and aesthetic impacts associated with the event itself and with cleanup activities. Longer-term impacts could be substantial if tourism were to suffer as a result of the real or perceived impacts of the event, or if there were substantial changes to tourism and recreation sectors in the region as a result of the event.

4.6.5.2.6 Sociocultural Systems. The area surrounding the Cook Inlet Planning Area is demographically diverse and includes relatively remote Native villages that rely on subsistence harvesting, towns that rely on commercial fishing, and ethnically diverse cities (Section 3.14.1.2). Future non-OCS activities affecting sociocultural systems include oil and gas development on State submerged lands, changes in commercial fishing patterns and maritime shipping, and limited industrialization; these activities are expected to continue in the foreseeable future.

The Cook Inlet Planning Area is already the location of offshore oil and gas development (in State waters). Supporting infrastructure and a trained workforce are already available in relative proximity. As part of this industrial mix, development of the OCS is likely to have minor cumulative impacts relative to development in the region. No new shore bases are planned and only one new pipeline is projected under the Program (Table 4.6.1-3).

Oil spills can cause damage to resources important to subsistence harvesters, affect fish populations important to commercial fishers, and have sociological impacts in affected communities. Most spills projected to result from exploration and development of the OCS would be a relatively minor component of the existing mix of impacts from oil and gas development and commercial shipping. However, as the *Exxon Valdez* event has shown, coastal communities are susceptible to sociocultural disruption as the result of large-scale spills that disrupt commercial fishing and subsistence harvesting.

OCS program development could temporarily displace fish and sea mammal populations harvested by subsistence hunters and fishers. Helicopter flights associated with development could disturb nesting and roosting sites of birds that are harvested, and temporarily and locally disturb terrestrial game animals.

Conclusion. Cumulative impacts on sociocultural systems in Cook Inlet as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be minor to moderate over the next 40 to 50 years. Important impacting factors include the displacement of fish and sea mammal populations and the disturbance of nesting and roosting sites and terrestrial game animals (e.g., by noise). Non-OCS activities or phenomena affecting these resources include oil and gas development in State waters, changes in commercial fishing patterns and maritime shipping, air traffic, and limited industrialization. The incremental contribution of routine Program activities to these impacts would be small, since they would not introduce new kinds of activities that would alter existing socioeconomic systems. In addition, the relatively small number of new residents that would come into the area because of the Program should likewise not alter existing sociocultural systems (see Section 4.4.13.2).

Sociocultural systems may be adversely affected by accidental oil releases from OCS and non-OCS activities. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on would be small to large, especially in intertidal and estuarine zones used by subsistence harvesters. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be major if they were to occur, especially if resources important to subsistence harvesters, including intertidal resources, migrating fishes, and fishes with strong ties to the shore, were affected.

4.6.5.2.7 Environmental Justice. Although no new pipe yards, pipeline landfalls, or gas processing facilities would be built as a result of the proposed 5-year OCS program, additional offshore construction could include increased noise and traffic, air and water pollution, impacts to residential property values, and land use changes. Much of the Alaska Native population resides in the coastal areas of Alaska. New offshore infrastructure resulting from this program could be located near areas where subsistence hunting occurs. The OCS program would result in levels of infrastructure use and construction similar to what is occurring in south central Alaska. These activities are not expected to expose residents to notably higher risks than currently occur.

Any adverse environmental impacts to fish and mammal subsistence resources from installation of infrastructure and routine operations of these facilities could have disproportionately higher health or environmental impacts to Alaska Native populations. OCS activities could potentially disrupt marine mammal harvests (primarily walrus, seals, and beluga whales) by diverting marine migrations or by causing other behavioral changes such as increased wariness.

Air emissions from onshore facilities and helicopter and vessel traffic traversing coastal areas will be highest in areas containing the greatest amounts of infrastructure. It is assumed that the majority of the activity from the Program would occur in deep waters, with offshore air emissions greatest in the coastal areas with the greatest amounts of oil and gas activity, with lesser amounts occurring elsewhere. The effects of the OCS program on air quality have been analyzed in Section 4.4.4.2. This analysis concluded that routine operations associated with the proposed 5-year program would result in NO_2, SO_2, PM_{10}, and CO levels that are well within the NAAQS. Disproportionate impacts on low-income or minority populations of the inlet would be minor, because coastal effects from offshore activities are expected to be small, based on the established and increasing trend toward movement of oil and gas activities into deeper waters of the inlet.

Oil spill events in the region and related cleanup activities pose the greatest potential for cumulative effects on low-income and minority population groups. It is reasonable to expect that most of these spills will occur in deepwater areas located away from the coast, based on the established trend for oil and gas activity to move into deep waters located for the most part at a substantial distance from the coast. The magnitude of impacts from such spills cannot be predicted, should they contact the coast, and depends on their location, size, and timing. While the location of possible oil spills cannot be determined and while low-income and minority populations are resident in some areas of the coast, in general, the coasts are home to more affluent groups. Low-income and minority groups are not more likely to bear more negative impacts than are other groups.

Conclusion. In the Cook Inlet Planning Area, future OCS program and ongoing and future non-OCS program activities in combination with the effects of onshore and offshore construction, increased marine vessel and helicopter traffic, and land use changes would result in disproportional moderate to major adverse cumulative impacts on low-income and minority populations (especially those dependent on subsistence harvesting and fishing). The incremental contribution of routine operations under the Program to these impacts would be small (see Section 4.4.14.2).

The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be negligible to small. Large spills (1,000 bbl or greater) and unexpected CDEs could result in moderate to major impacts on the Alaska Native population, especially if subsistence resources were diminished or tainted as a result of the spill. Mitigation measures, cooperative agreements between Native and industry groups, and government-to-government consultations are designed to limit the effects from oil spills and routine operations.

4.6.5.2.8 Archeological and Historic Resources. Section 4.4.15.2 discusses the indirect and direct impacts from the Program (OCS program activities from 2012 to 2017) on archeological and historic resources in the Cook Inlet Planning Area. Cumulative impacts on archeological and historic resources result from the incremental impacts of the Program when added to impacts from existing and reasonably foreseeable future OCS program activities (that are not part of the Program) and other non-OCS program activities. Table 4.6.1-3 presents the exploration and development scenario for the Cook Inlet cumulative case (encompassing the Program and future OCS program activities). Specific types of impact-producing factors related to OCS program activities considered in this analysis include drilling rig and platform emplacement, pipeline emplacement, new onshore facilities, and oil spills. Non OCS-program activities (e.g., oil and gas industry in State waters) and natural geologic processes such as ice gouging and erosion due to high-energy waves/currents and thermokarst collapse are also considered.

Archeological Resources. Offshore development could result in an interaction between a drilling rig, platform, pipeline, or anchors and an inundated prehistoric site. This direct physical contact with a site could destroy artifacts or site features and could disturb the stratigraphic context of the site. The result would be the loss of archaeological data on prehistoric migrations, settlement patterns, subsistence strategies, and archaeological contacts between northeast Asia and the Americas.

Since 1973 when the ESP was initiated, the USDOI has required that an archaeological survey be conducted prior to development of mineral leases determined to have potential for cultural resources, including prehistoric archaeological sites. Relative sea-level data, which are used to define the portion of the continental shelf having potential for prehistoric sites, suggest that the portion of the continental shelf shoreward of about the 60-m (200-ft) isobath would have potential for prehistoric sites. Although an archaeological survey would identify most of the cultural resources in the APE for the project and routine operations related to OCS program activities would avoid all known cultural resources, it is likely that impacts to prehistoric resources have already occurred as a result of non-OCS program activities prior to the implementation of the 1973 archaeological survey requirement.

Onshore development could result in direct physical contact between the construction of new onshore facilities or pipeline trenches and previously unidentified prehistoric sites. This direct physical contact with a prehistoric site could cause physical damage to or complete destruction of information on the prehistory of the region and North America. Federal and State laws and regulations initiated in the 1960s began requiring archaeological surveys prior to permitting any activity that might disturb a significant archaeological site. Therefore, it can be assumed that, since the introduction of the archaeological resource protection laws, most coastal archaeological sites have been located, evaluated, avoided, or mitigated prior to construction. However, impacts to coastal prehistoric resources may have already occurred as a result of various onshore construction activities prior to enactment of the archaeological resource protection laws.

Trawling activity in Cook Inlet only affects the uppermost portion of the sediment column (Krost et al. 1990). This zone would already be disturbed by natural factors relating to the destructive effects wave and current action (Cook Inlet is a high-energy wave environment; see Section 4.2.3.2.2). Therefore, the effect of trawling on most prehistoric archaeological sites would be minor.

Most channel dredging occurs at the entrances to bays, harbors, and ports. These areas have a high probability for prehistoric archaeological sites, as they are often associated with drowned river valleys, which are known to have a high probability for prehistoric sites. It is assumed that some of the archaeological data that have been lost as a result of dredging have been significant and unique; therefore, the impact to prehistoric archaeological sites as a result of past channel dredging activities has probably been moderate to major. In many areas, the USACE now requires remote-sensing surveys prior to dredging activities to minimize such impacts (Espey, Huston & Associates 1990).

Natural geologic processes such as ice gouging and thermokarst erosion may affect prehistoric archaeological sites associated with Cook Inlet. No specific studies examining the effects of geological processes on archaeological sites have been conducted in Cook Inlet. However, coastal prehistoric sites are exposed to the erosional effects of high-energy waves and thermokarst erosion. These natural processes could cause artifacts to be dispersed and the site context to be disturbed or even completely destroyed, resulting in the loss of archaeological information. Cook Inlet is a high-energy area affected by strong tidal movements. The seafloor of lower Cook Inlet contains characteristics such as lag gravels, sand ribbons, and sand wave fields (MMS 2003a). These features are formed only in areas of high energy. High-energy water movement may have removed the potential for archaeological resources to be present. Additional research is needed to determine the extent of the disturbance. Studies conducted in the Beaufort Sea indicate that seafloor sediments have been affected by ice gouging and by increased river flows resulting from glaciation (Darigo et al. 2007). It is likely that similar processes have operated in Cook Inlet and that they have affected the integrity of archaeological sites. Overall, some loss of data from submerged and coastal prehistoric sites has probably occurred, and will continue to occur, from the effects of natural geologic processes. It is assumed that some of the data lost have been significant and/or unique, resulting in a major level of impact. Additional studies specifically addressing these topics are required.

An accidental oil spill could affect coastal prehistoric archaeological sites, but the direct impact of oil on most sites is uncertain. Protection of such sites during an oil spill requires specific knowledge of their location, condition, nature, and extent prior to impact; however, the Cook Inlet coastline has not been systematically surveyed for archaeological sites.

Heavy oiling of a coastal area could conceal intertidal sites that may not be recognized until they are inadvertently damaged during cleanup (Whitney 1994). Crude oil may also contaminate organic material used in ^{14}C dating, and although there are methods for cleaning contaminated ^{14}C samples, greater expense is incurred (Dekin et al. 1993). The major source of potential impact from oil spills is the harm that could result from unmonitored shoreline cleanup activities. Unauthorized collecting of artifacts by cleanup crew members is also a concern, albeit one that can be mitigated with effective training and supervision. Damage or loss of significant archaeological information could result from the contact between an oil spill and a prehistoric archaeological site; therefore, cumulatively the level of impacts from oil spills (past, present, and future) to prehistoric archaeological sites ranges from moderate to high.

Historic Resources. Direct physical contact between a routine activity and a shipwreck site could destroy fragile ship remains, such as the hull and wooden or ceramic artifacts, and could disturb the site context. The result would be the loss of archaeological data on ship construction, cargo, and the social organization of the vessel's crew, and the concomitant loss of information on maritime culture for the time period from which the ship dates.

Since 1973 when the ESP was initiated, the USDOI has required archaeological (historical) surveys be conducted prior to development of mineral leases when a historic-period shipwreck is reported to lie within or adjacent to the lease area. Although an archeological survey would identify most of the cultural resources in the APE for the project and routine operations related to OCS activities would avoid all known cultural resources, it is likely that impacts on historic-period shipwrecks may have already occurred as a result of non-OCS program activities that took place before implementation of the 1973 archaeological survey requirement.

Onshore development could result in direct physical contact between the construction of new onshore facilities or pipeline trenches and previously unidentified historic sites. Federal and State laws and regulations initiated in the 1960s began requiring archaeological surveys prior to permitting any activity that might disturb a significant archaeological site. Therefore, it can be assumed that, since the introduction of the archaeological resource protection laws, most coastal archaeological sites that would have been impacted have been located, evaluated, avoided, or mitigated prior to construction. However, impacts to coastal historic sites may have resulted from onshore construction activities prior to enactment of the archaeological resource protection laws, but the magnitude of this possible impact is impossible to quantify.

Trawling activity in south central Alaska affects only the uppermost portion of the sediment column (Krost et al. 1990). On many wrecks, this zone would already be disturbed by natural factors and would contain only artifacts of high specific gravity which have lost all original context. Therefore, the effect of trawling on most historic shipwreck sites would be minor.

Most channel dredging occurs at the entrances to bays, harbors, and ports. These areas have a high probability for historic shipwrecks. Assuming that some of the data lost have been unique, the impact on historic sites as a result of past channel dredging activities has probably been moderate to major. In many areas, the USACE now requires remote-sensing surveys prior to dredging activities to minimize such impacts (Espey, Huston & Associates 1990).

Natural geologic processes such as ice gouging and erosion due to high-energy waves/currents and thermokarst collapse affect historic sites in Cook Inlet. No specific studies addressing this topic have been undertaken. Coastal historic sites are exposed to the erosional effects of wave energy and thermokarst erosion, which can cause artifacts to be dispersed and the site context to be disturbed or even completely destroyed. Cook Inlet is a high-energy area affected by strong tidal movements. The seafloor of lower Cook Inlet contains seafloor characteristics such as lag gravels, sand ribbons, and sand wave fields (MMS 2003a). These features are only formed in areas of high energy. High-energy water movement may have removed the potential for historic resources to be present. Additional research is needed to determine the extent of the disturbance. Overall, a significant loss of data from submerged and coastal historic sites may have already occurred from the effects of natural geologic processes. It is assumed that some of the data lost have been significant and/or unique, resulting in a major level of impact. Additional studies specifically addressing these topics are required.

An accidental oil spill could affect a coastal historic site, but the direct impact of oil on most historic sites is uncertain. The primary source of potential impacts from oil spills is unmonitored shoreline cleanup activities (Bittner 1996; see Section 4.4.14.2.2). Unauthorized collecting of artifacts by cleanup crew members is also a concern, albeit one that can be mitigated with effective training and supervision. Damage or loss of significant historic information could result from oil spill cleanup activities; therefore, the cumulative impact of oil spills (past, present, and future) on historic sites could range from moderate to major.

Conclusion. The cumulative impacts of future OCS program and ongoing and future non-OCS program activities on prehistoric and historic archaeological sites in Cook Inlet are currently unknown, but could range from minor to moderate, mainly because activities occurring on the OCS prior to the USDOI's survey requirement (in effect since 1973) may already have affected significant archaeological sites. Other important impacting factors that have had, and will continue to have, an impact on both prehistoric and historic archaeological sites are channel dredging and geologic processes, such as ice gouging and erosion due to high-energy waves/currents and thermokarst collapse. Commercial treasure hunting and sport diving may also result in a loss of artifacts at historic-period shipwreck sites. The incremental contribution of routine operations under the Program is expected to be negligible to large, depending on the presence of significant resources in the area of potential effect. Archaeological surveys that would identify significant cultural resources to be avoided could reduce these impacts (see Section 4.4.15.2).

Cumulative impacts on prehistoric and historic archaeological sites due to expected accidental oil spills and related cleanup activities could range from negligible to major. The incremental contribution of oil spills associated with the Program could be negligible to large relative to those associated with future OCS program and ongoing and future non-OCS program activities. Impacts associated with an unexpected, low-probability CDE would also depend on location, and could range from minor to major if they were to occur. There is a greater likelihood that more of the resources would be affected at a major level during a CDE. A more detailed discussion of the effects of oil spills on archaeological and historic resources in Cook Inlet is presented in Section 4.4.15.2.

4.6.5.3 Alaska Region – Arctic

4.6.5.3.1 Areas of Special Concern. Cumulative impacts to these Areas of Special Concern include impacts from both OCS and non-OCS activities. Section 4.4.8.3 identifies potential impacts that could result from routine activities or accidents related to the proposed leasing program on Areas of Special Concern adjacent to and in the Beaufort Sea and Chukchi Sea Planning Areas.

National Park Service Lands. In the Arctic, activities associated with the Red Dog Mine and its port facility south of Kivalina on the Chukchi Sea would contribute to cumulative impacts on the Cape Krusenstern National Monument. The road from the mine (located just outside the monument) to the port crosses the northern boundary of the monument. Impacts from this facility, such as habitat loss or disturbance, are expected to be minor due to the limited activity associated with the mine.

There is minor land and air traffic in the Arctic and most visitors would arrive by sea. Because the amount of traffic is restricted and activities within the parks regulated, traffic would likely create a minor addition to cumulative impacts on the NPS lands. It is anticipated that noise generated by OCS offshore construction activities would be at low levels, intermittent, and would not persist for more than a few months at any one time. It is considered unlikely that these additional activities would noticeably affect wildlife or park user values compared to current (non-OCS) activities within the Beaufort and Chukchi Sea Planning Areas.

Impacts on these areas could occur due to accidental releases of oil spilled from onshore facilities and offshore drilling rigs. Non-OCS activities, such as oil and gas development in State waters, the domestic transportation of oil or refined petroleum products, the production and storage of petroleum products, and commercial shipping (tanker traffic) could also result in accidental spills that could affect park lands. Naturally occurring seeps may also be a source of crude oil introduced into nearshore waters (Kvenvolden and Cooper 2003). Noatak National Preserve, Kobuuk River National Preserve, Cape Krusenstern National Monument, and Bering Land Bridge National preserve all have coastlines on or near the Chukchi Sea and could potentially be affected by spills from tanker traffic. Although not an NPS land, the National Petroleum Reserve is managed by BLM and has a large shoreline component that borders the Chukchi Sea. An oil spill would have the greatest effect if it came into contact with shoreline habitats. Impacts would depend primarily on the spill location, size, and time of year. In general, directly affected coastal fauna could include marine mammals; fishes that reproduce in, inhabit, or migrate through coastal areas; terrestrial mammals that feed on these fishes; and marsh birds and seabirds. Spilled oil could also affect subsistence harvests in those parks in which subsistence hunting and fishing are allowed and could affect the number of park visitors.

National Wildlife Refuges. NWRs in the vicinity of the Beaufort Sea and Chukchi Sea Planning Areas are identified in 3.9.3.2 for the Beaufort and Chukchi Seas. NWRs (including three units of the Alaska Maritime NWR) potentially affected by OCS activities include the Arctic National Wildlife Refuge (ANWR) and the Alaska Maritime NWR (Chukchi Sea Unit, Gulf of Alaska Unit, Alaska Peninsula Unit).

Oil drilling and facility development are prohibited in the ANWR and are discretionary on all other refuges; however, refuges could potentially be affected by OCS oil and gas development from adjacent regions under the cumulative case scenario. These refuges could be contaminated by oil spilled from offshore projects, or could be subject to negative effects from routine operations associated with the development of onshore oil and gas support facilities. They could also be affected by non-OCS activities within or adjacent to refuges including State oil and gas development, the domestic transportation of oil or refined petroleum products, the production and storage of petroleum products and LNG, and commercial shipping. Numerous refuge lands have been conveyed to private owners and Native corporations. Section 22(g) of the Arctic Native Claims Settlement Act (1971) requires that new development on these lands must be in accordance with the purpose for which the refuge was formed. Thus, while development of onshore oil and gas support facilities is technically possible, such development would be subject to intensive review (as would any other development).

The potential cumulative effects of routine operations and accidental events on these NWR's are essentially the same as those discussed above for the NPS lands. In addition, subsistence hunting and fishing are permitted on all refuges in Alaska and could, therefore, be affected by accidents and routine operations in the immediate vicinity of refuge properties.

National Forests. There are no National Forests in the Beaufort Sea and Chukchi Sea Planning Areas.

Conclusion. Cumulative impacts on Areas of Special Concern in Arctic waters are considered to be negligible to moderate. Routine operations under the Program could result in negligible to medium incremental increases in effects on National Parks and Wildlife Refuges (see Section 4.4.8.3). Development of onshore facilities within NPS lands in the vicinity of the areas included in the Program is considered unlikely, thereby making impacts from routine Program activities unlikely in these areas. Offshore construction of pipelines and platforms could contribute to cumulative effects on wildlife and on scenic values for park visitors due to noise and activity levels. However, such effects would be localized, intermittent, and temporary. It is anticipated that lease stipulations applied at the lease sale stage could minimize the potential for cumulative impacts from routine operations on these areas.

Expected accidental oil spills (most of which are less than 1,000 bbl) that occur during the Program could result in a negligible to medium incremental contribution to cumulative impacts on Areas of Special Concern, depending on spill frequency, location, and volume; the type of product spilled; weather conditions; effectiveness of cleanup operations; and other environmental conditions at the time of the spill. Large spills (1,000 bbl and greater) or an unexpected CDE in areas adjacent to the National Parks or NWRs, whether from OCS or non-OCS sources, would also depend on these factors, and could result in moderate impacts if they were to occur. Such spills could also negatively impact coastal habitats and fauna, and could also affect subsistence uses.

4.6.5.3.2 Population, Employment, and Income. Section 4.4.9.2 discusses the potential impacts from the Program on population, employment, and income in the Arctic region. Cumulative impacts on these resources result from the incremental impacts of the Program when added to impacts from reasonably foreseeable future OCS program activities (there are no ongoing OCS program activities) and ongoing and future non-OCS program activities. Specific types of impact-producing factors related to OCS program activities considered in this analysis include total employment and regional income for the North Slope Borough, which corresponds to the Beaufort Sea and Chukchi Sea Planning Areas (described in Section 3.10). Non-OCS program activities affecting the region include employment and earnings related to various other industrial sectors (e.g., construction, manufacturing, services, and State and local government).

The population in the Beaufort Sea and Chukchi Sea Planning Areas is concentrated in Barrow. It increased at an average annual rate of 3.6% between 1980 and 1990, and 2.1% between 1990 and 2000; it decreased by 1.0% between 2000 and 2009. The components of population increase include the natural increase due to births and net positive domestic migration; the population trend is uncertain over the next 50 years and will likely depend on the availability of jobs. Most communities in the borough have a high percentage of American Indian or Alaska Natives.

The Program would add an average of 3,457 to 12,665 direct and indirect jobs in Alaska annually between 2012 and 2017, an increase that is considered moderate (but positive) since it would amount to less than 6% of total Alaska employment. Likewise, direct and indirect income produced in Alaska would range from $233 million to $904 million annually, which constitutes less than 6% of income in Alaska overall. Most of the workers directly associated with OCS oil and gas activities would work offshore or onshore in worker enclaves separated from local communities, and most workers will likely commute to work sites from Alaska's larger population centers or from outside the immediate area. While OCS jobs would be available to the local populations in all areas, rural Alaskan employment in the petroleum industry, especially among Alaska Natives, would likely remain relatively low. However, a contingent of Alaska Natives from the Fairbanks area and members of the Doyon Corporation do work in the oil fields of the North Slope, and these jobs are important to them.

Employment impacts of oil spills reaching landfall can vary considerably depending upon the total volume of oil reaching land, the land area affected, and the sensitivity of local environmental conditions to oil impacts. The primary impacts of oil spills would most likely fall on such activities as beach recreation, commercial fishing, recreational fishing, and sightseeing. Oil spills reaching land can have both short- and long-term effects on these recreational coastal activities. Although an oil spill could occur anywhere in the lease sale area, cleanup-related employment would likely occur in the area directly affected, generally in locations remote from communities. The hiring of cleanup workers would have a regional and State of Alaska emphasis. Oil spills will generate only temporary employment (and population) increases during cleanup operations, because such operations are expected to be of short duration. Employment generated by spills will be a function of the size and frequency of spills.

Conclusion. The cumulative impacts of future OCS program and ongoing and future non-OCS program activities would be considered beneficial because these activities would increase employment and earnings in the region over the next 40 to 50 years (although rural Alaskan employment in the petroleum industry, especially among Alaska Natives, would likely remain relatively low). The Program would add to these beneficial impacts. The incremental contribution of routine operations under the Program is expected to be small, however, because the added employment demands are less than 10% of total Alaska employment (see Section 4.4.9.3).

The cumulative impacts of accidental oil spills could be minor to major, depending on the total volume of oil reaching land, the land area affected, and the sensitivity of local environmental conditions to oil impacts. The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be negligible to small relative to those associated with ongoing and future OCS program and non-OCS program activities. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in minor to moderate impacts if they were to occur. In the short term, impacts of a CDE could be large as a result of loss of employment, income, and possible shortages of commodities or services in both coastal and inland areas affected by the spill. Longer-term impacts could be smaller unless recreational activities and tourism suffered as a result of real or perceived impacts of the event (see Section 4.4.9.1).

4.6.5.3.3 Land Use and Infrastructure. Localized impacts to land use and existing infrastructure are anticipated as a result of the construction of new oil and gas facilities in the Beaufort Sea and Chukchi Sea Planning Areas over the next 40 to 50 years. Impact-producing factors from OCS program activities would include increased vehicular traffic (e.g., helicopter trips); modifications to current land use designations to incorporate new facilities, if they are needed; and some infrastructure expansion.

Ongoing non-OCS program activities that could affect land use and onshore infrastructure are expected to continue into the foreseeable future. These include offshore construction, onshore construction, and vessel traffic. Where land is largely undeveloped and no established oil and gas infrastructure is present, development could result in land use and infrastructure impacts, such as the conversion of existing land use (e.g., undeveloped, residential, or commercial) to industrial land use to accommodate oil and gas production (MMS 2007e).

Accidental oil releases may occur as a result of both OCS and non-OCS activities. The extent of impacts would depend on the location and size of the releases, but could include stresses of spill response on the community infrastructure, increased traffic to respond to cleanup, and restricted access to particular lands while cleanup is conducted. In general, these releases would be expected to have a temporary impact on land use and infrastructure (MMS 2007c).

Conclusion. Localized impacts to land use and existing infrastructure are anticipated over the next 40 to 50 years as a result of future OCS program and ongoing and future non-OCS program activities in the Beaufort and Chukchi Seas. These impacts could range from minor to major depending on the nature (extent and duration) of the land use change. The incremental contribution of routine operations under the Program in the Arctic to cumulative impacts would be small to medium because the existing infrastructure is considered sufficient to handle the land use changes needed for new onshore pipeline construction and transportation network (see Section 4.4.10.3).

Land use–related impacts resulting from expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program include stresses of spill response on community infrastructure, increased traffic in the response area (both onshore and offshore), and temporary restricted access to affected lands (while cleanup is conducted). Such spills would result in a small incremental contribution to cumulative impacts on land use and existing infrastructure. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in moderate to major impacts if they were to occur.

4.6.5.3.4 Commercial and Recreational Fisheries. There currently is no commercial fishing and little data on recreational fishing in the Beaufort or Chukchi Sea (although the North Pacific Fishery Management Council has concluded that there are few recreational fisheries in these waters). Sport fishing likely occurs in coastal areas of larger population centers such as Barrow. Subsistence fishing is widespread in coastal areas of the Arctic. Given the importance of this fishing to local villages in the Arctic region, any impacts from the Program may directly affect the local economy by causing declines in salmon availability for harvest. Greater declines in the harvest would lead to greater impacts on local communities. However, it is anticipated that impacts from routine OCS operations would be minor as a result of adherence to mitigation measures and compliance with Federal, State, and local requirements.

The Program would represent a small increment to the potential for overall cumulative effects on fishing by local villages in the Arctic region. Routine OCS program activities would be unlikely to have cumulative population- or community-level effects on local fishery resources because of the limited time frame over which most individual activities would occur; because a small proportion of habitat, relative to similar available habitat, could be affected during a given period; and because of existing stipulations that are in place to avoid impacts to sensitive habitats such as hard bottom areas and topographic features. Non-OCS activities, including State oil and gas development and sportfishing, could also contribute to cumulative effects on local fisheries.

Depending on specific conditions during a large oil spill, there could be substantial economic losses for commercial fisheries as a consequence of reduced catch, loss of gear, or loss of fishing opportunities during cleanup and recovery periods. Non-OCS sources of spills, including State oil and gas production, have a potential to cause similar effects. The occurrence of a catastrophic spill, such as could occur from a tanker accident, could have substantially greater effects on fisheries.

Conclusion. Cumulative impacts on fisheries in the Beaufort and Chukchi Seas as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be moderate to major over the next 40 to 50 years. Non-OCS activities affecting fisheries include State oil and gas development and sportfishing. The incremental contribution of routine operations under the Program to these impacts would be small, since these activities would not occur in the immediate area where fisheries are located (see Section 4.4.11.3).

Fisheries may be adversely affected by accidental oil releases from OCS and non-OCS activities (e.g., State oil and gas development, domestic transportation of oil or refined petroleum products, and commercial shipping). The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on would be medium, depending on the location, timing, and volumes of spills (among other environmental factors). Small spills are unlikely to affect a large number of fish or have a substantial effect on fishing before dilution and weathering reduced concentrations of oil in the water. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be moderate if they were to occur. Large spills or a CDE could have significant localized effects on fishing as a result of reduced catch, loss of gear, or loss of fishing opportunities during cleanup and recovery periods, and on recreational fishing as a consequence of contamination of fish tissues, degradation of aesthetic values that attract fishers, or temporary closure of fishing areas. Large spills or a CDE have a greater potential to contact intertidal habitat and subsequently contaminate or reduce the abundance of commercial and recreational species that depend on nearshore habitat. These impacts could be long term, but are not expected to result in the long-term loss of fisheries in Arctic waters.

4.6.5.3.5 Tourism and Recreation. Platform, pipeline, causeway, and facility construction and vessel traffic could interfere with water-based recreational activities (fishing, boating, sightseeing, cruise ships); cause some disruption to land-based activities (hiking, picnicking, hunting, visiting Native communities, camping, wildlife viewing, and sightseeing), depending on the location of recreational activities relative to proposed development; increase amounts of trash and debris from OCS activities; and cause possible competition between workers and tourists for local services, such as air transport, hotel accommodations, and other visitor services. Non-OCS activities that could have an impact on tourism and recreation include offshore construction (e.g., State oil and gas development, domestic transportation of oil and gas), onshore construction (e.g., coastal and community development), and vessel traffic (e.g., commercial shipping, recreational boating, military training and testing).

Non-OCS activities and proposed and future OCS activities represent a continuation of existing onshore and offshore oil and gas construction trends in the Beaufort Sea and Chukchi Sea Planning Areas. Substantial infrastructure for related oil and gas development already exists in both of these areas, including platforms, exploration and production wells, pipelines to transport oil from offshore platforms to common-carrier pipeline systems onshore, and processing facilities; therefore, there should not be additional visual disruption for the tourists in these areas. Pipeline construction would present a temporary disruption to tourism and recreation due to workers competing with tourists for short-term housing (hotels) and air transport; aesthetic impacts (visual and auditory) associated with construction sites; and possible temporary prevention of access to some recreational or wilderness areas. In addition, the new pipeline in the Arctic region could create road access into previously undeveloped lands used primarily for subsistence, creating a potential conflict between subsistence practices and recreational hunting or other possible tourist activities.

Oil spills associated with OCS and non-OCS activities, as well as oil releases from naturally occurring seeps, could also affect recreation and tourism, and could result in both short-term and long-term effects, depending on public perception and reaction. Potential cumulative impacts include direct land impacts (e.g., oil contamination of a National Wildlife Refuge); aesthetic impacts of the spill and associated cleanup; increased traffic to respond to cleanup operations; and restricted access to particular lands while cleanup is being conducted.

Conclusion. Cumulative impacts on tourism and recreation in the Beaufort Sea and Chukchi Sea Planning Areas as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be moderate to major over the next 40 to 50 years because they would be noticeable to the recreation and tourism community, as no similar infrastructure yet exists in that region, and competition for accommodations and air transport may slow tourism for a time. Non-OCS activities or phenomena affecting these resources include offshore construction (State oil and gas development, domestic transportation of oil and gas), onshore construction (e.g., coastal and community development), and marine vessel traffic. The incremental contribution of routine operations under the Program to these impacts would be small, with potential adverse aesthetic impacts on sightseeing, hiking, and rafting activities (see Section 4.4.12.1).

Tourism and recreation may be adversely affected by accidental oil releases from OCS and non-OCS activities. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on would be negligible to small, depending on the size, location, and timing of the spill (being greatest if it occurred during the peak recreational season). Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be minor to moderate if they were to occur. Short-term impacts would include beach and coastal access restrictions; restrictions on visitation, fishing, or hunting while cleanup is being conducted; and aesthetic impacts associated with the event itself and with cleanup activities. Longer-term impacts could be substantial if tourism were to suffer as a result of the real or perceived impacts of the event, or if there were substantial changes to tourism and recreation sectors in the region as a result of the event.

4.6.5.3.6 Sociocultural Systems. Small, primarily Alaska Native communities along the Arctic coast are heavily dependent on subsistence harvesting of sea mammals, fish, and terrestrial fauna Enclaves of workers at Prudhoe Bay and nearby oil fields are employed by the oil and gas industry. They commute from mostly south-central Alaska, Fairbanks, and States outside of Alaska. For the most part, these two communities (Alaska Native communities and worker enclaves) have had little interaction because of the physical distance that separates them. The exception is Nuiqsuit. Further development of the oil and gas industry, increases in marine shipping as a result of the diminishing polar ice caps, and the effects of climate change coupled with development of oil and gas resources on the OCS could contribute to cumulative effects on the subsistence harvesting and sociocultural structure of the region.

A primary concern of Alaska Natives is the health and accessibility of sea mammals including whales, walrus, and seals, which could be affected by the cumulative effects of climate change, increased industrial activity, and increased shipping along the northern coast of Alaska. Warming climatic conditions have resulted in the early retreat of the polar ice pack, less shore-fast ice, and more young ice. Ice flow haulouts used by seals and walrus are thus farther from shore, increasing the effort required for subsistence hunters to harvest them. Young ice is less thick and less able to support hunting and whale butchering, making the subsistence harvest more difficult. More ice-free lanes along the coast have resulted in an increase in marine traffic, including cargo shipping and tourist cruise ships, through the Bering Strait and the Chukchi and Beaufort Seas, a pattern that is likely to continue. Increased commercial and tourist shipping added to increased vessel traffic supporting new oil and gas development would likely exacerbate adverse effects on subsistence resources. Noise from increased shipping would disturb bowhead and beluga whale migration patterns, already affected by the noise of seismic survey vessels during oil and gas exploration and to a lesser extent drilling and operation of wells. Increased shipping could increase the number of ship strikes on marine mammals; the risk of introduction of alien aquatic nuisance species from bilge water and other discharges; and chances of spills of fuel and other hazardous materials from shipping accidents. Eco-tourists seek many of the same species as subsistence hunters and can make them more wary and more difficult to hunt. The effects of increased shipping would be particularly acute in narrow ice-free corridors along the Beaufort and Chukchi coast and in narrow passages, such as the Bering Strait, where migrating sea-mammals and Arctic shipping would share the same narrow waterway. In addition, the likely concomitant increase in the use of ice breakers has the potential for disrupting Native travel across the ice in pursuit of marine mammals, potentially cutting them off from the shore, and leading whales following open water farther offshore (Arctic Council 2009). The whale harvest is central to Alaska Native culture in terms of the food it provides, the inter-community ties built on barter and exchange of whale products, and its association with Native cultural identity and spirituality. Oil and gas exploration and development combined with increased shipping and the effects of climate change would have an adverse cumulative effect on subsistence harvesting.

Warming temperatures have also reduced the amount of permafrost underlying Arctic communities, resulting in increased coastal erosion and less stable sediments, rendering traditional ice cellars cut into the permafrost useless, further stressing the subsistence harvest through loss of storage facilities, and in some cases requiring villages to move back from the coast (USGCRP 2003).

The construction and operation of linear features such as oil and gas pipelines and roads can deflect migration patterns of terrestrial mammals such as caribou that are an important part of the subsistence harvest. As onshore oil and gas development expands from Prudhoe Bay, Native communities such as Nuiqsut feel increasingly cut off from traditional subsistence resource harvesting areas. To the extent that offshore oil development requires onshore support infrastructure, it contributes to a cumulative negative impact on onshore access to subsistence resources. As the distance between Native communities and oil and gas worker enclaves decreases, the interaction between these two groups is likely to increase, raising the potential for cross-cultural conflicts and changes in traditional culture.

Conclusion. Cumulative impacts on sociocultural systems in the Arctic Planning Areas as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be moderate over the next 40 to 50 years. Important impacting factors include early retreat of the polar ice pack (due to warming climate conditions), increased marine shipping (due to more ice-free lanes along the coast), and increased noise (due to increased shipping, increased tourism, seismic surveys and other oil and gas activities) — all of which could disturb sea mammals and their migration patterns. Some factors, such as the loss of polar ice are beyond the control of local communities, BOEM, or oil and gas developers and may be considered unavoidable at the local community level. They would require some adjustment in subsistence harvesting patterns, a moderate effect. Effects would only be major if a subsistence resource were eliminated or rendered unavailable. The effects of other factors, such as increased shipping and ice breaking, can be mitigated through conflict avoidance agreements and regulation of coastal shipping. The incremental contribution of routine operations under the Program to these impacts would range from small to medium, especially if subsistence-related activities, central to the well-being of Alaska Natives who inhabit the area, are affected. Many of these potential effects are mitigatable (see Section 4.4.13.3).

Onshore linear features (e.g., pipelines and roads) affect the migration patterns of terrestrial mammals. Because of the high level of dependence on subsistence harvesting, the incremental contribution of the Program to cumulative impacts on subsistence activities near the Beaufort and Chukchi Seas would be expected to be small to medium (see Section 4.4.13.3). It is likely that onshore subsistence harvesting practices would have to be adjusted. Effects would be major only if important resources were eliminated or made unavailable. Design stipulations and operational procedures could reduce the impact of onshore development.

Sociocultural systems may be adversely affected by accidental oil releases from OCS and non-OCS activities. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program would be small to medium, depending on the location, volume, and timing (i.e., season) of the spill. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be major if they were to occur, especially if they disrupt sea mammal harvest or resulted in the IWC reducing or eliminating whale quotas in the Alaska Arctic. A CDE would prove challenging for existing response capacity and capability, especially if the spill were under ice or in broken ice. The cleanup process itself has the potential to cause displacement of subsistence resources and subsistence hunters, and would have major impacts in the short term depending on the timing and duration of the displacement. The associated influx of cleanup workers would likely overwhelm the resources of local communities and could result in cross-cultural conflicts.

4.6.5.3.7 Environmental Justice. Additional offshore construction under the Program could include increased noise and traffic, air and water pollution, impacts on residential property values, and land use changes. Much of the Alaska Native population resides in the coastal areas of Alaska. New offshore infrastructure resulting from this program could be located near areas where subsistence hunting occurs. The proposed 5-year program will result in levels of infrastructure use and construction similar to what has occurred in the south Alaska region during previous programs. These activities are not expected to expose residents to notably higher risks than currently occur.

Any adverse environmental impacts on fish and mammal subsistence resources could have disproportionately higher health or environmental impacts on Alaska Native populations. OCS activities could potentially disrupt marine mammal harvests (primarily walrus, seals, and beluga whales) by diverting marine migrations or by causing other behavioral changes, such as increased wariness or having to go further from shore because of the diminishing polar ice cap, and whales migrating further from shore or the synergistic effects of all these factors combined.

Air emissions from onshore facilities and helicopter and vessel traffic traversing coastal areas will be highest in areas containing the greatest amounts of infrastructure. It is assumed that the majority of the activity from the proposed 5-year program will occur in waters no more than 100 m (30 ft) deep, with the most offshore air emissions occurring in the coastal areas with the greatest amounts of oil and gas activity and with fewer emissions occurring elsewhere. The effects of the OCS program on air quality have been analyzed in Section 4.4.4. This analysis concluded that routine operations associated with the proposed 5-year program would result in NO_2, SO_2, PM_{10}, and CO levels that are well within the NAAQS. Coastal effects from offshore activities are expected to be small, based on the established and increasing trend toward movement of oil and gas activities into deeper waters.

Oil spill events in the region, and related cleanup activities, pose the greatest potential for impacts on low-income and minority population groups. It is reasonable to expect that most of these spills would occur in deepwater areas located away from the coast, based on the established trend for oil and gas activities to move into deep waters located for the most part at a substantial distance from the coast. The magnitude of impacts from such spills cannot be predicted, should they contact the coast, and depends on their location, size, and timing. However, according to MMS (2002b), the probability that an offshore oil spill occurring and impacting coastal populations is low. While the location of possible oil spills cannot be determined, low-income and minority populations are resident in some areas of the coast. Low-income and minority groups could bear more negative impacts than other population groups.

Conclusion. In the Beaufort Sea and Chukchi Sea Planning Areas, OCS and non-OCS program activities in combination with the effects of increased marine traffic and climate change could result in moderate to major adverse cumulative impacts on human health and the environment, especially if a large oil spill were to occur, because oil spill contamination of subsistence foods is the main concern regarding potential effects on Native health. Impacts on marine and terrestrial ecosystems in the region (described in Section 4.6.4) could affect subsistence resources, traditional culture, and community infrastructure; indigenous communities that are subsistence-based would likely experience disproportionate, highly adverse environmental and health effects. However, the incremental change due to impacts from Program activities is expected to be small.

The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be negligible to small. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in moderate to major impacts on the Alaska Native population, especially if subsistence resources were diminished or tainted as a result of the spill. Mitigation measures, cooperative agreements between Native and industry groups, and government-to-government consultations are designed to limit the effects from oil spills and routine operations.

4.6.5.3.8 Archeological and Historic Resources. Section 4.4.15.3 discusses the potential impacts from the Program on onshore and offshore environments in the Beaufort Sea and Chukchi Sea Planning Areas. Cumulative impacts on archeological and historic resources result from the incremental impacts of the Program when added to impacts from ongoing and reasonably foreseeable future OCS program activities (that are not part of the proposed action) and other non-OCS program activities. Table 4.6.1-3 presents the exploration and development scenario for the Arctic region cumulative case (encompassing the proposed and future OCS program activities). Specific types of impact-producing factors related to OCS program activities considered in this analysis include drilling rig and platform emplacement, pipeline emplacement, new onshore facilities, and oil spills. Non-OCS program activities (e.g., oil and gas industry in State waters) and natural geologic processes such as ice gouging and thermokarst erosion are also considered (see also Section 4.2.2.2).

Archeological Resources. Offshore development could result in an interaction between a drilling rig, platform, pipeline, or anchors and an inundated prehistoric site. This direct physical contact with a site could destroy artifacts or site features and could disturb the stratigraphic context of the site. The result would be the loss of archaeological data on prehistoric migrations, settlement patterns, subsistence strategies, and archaeological contacts between northeast Asia and the Americas.

Since 1973 when the ESP was initiated, the USDOI has required that an archaeological survey be conducted prior to development of mineral leases determined to have potential for cultural resources, including prehistoric archaeological sites. Relative sea-level data, which are used to define the portion of the continental shelf having potential for prehistoric sites, suggest that the portion of the continental shelf shoreward of about the 60-m (200-ft) isobath would have potential for prehistoric sites. Although an archaeological survey would identify all cultural resources in the APE for the project and routine operations related to OCS program activities would avoid all known cultural resources, it is likely that impacts to prehistoric resources may have already occurred as a result of non-OCS program activities prior to the implementation of the archaeological survey requirement.

Onshore development could result in direct physical contact between the construction of new onshore facilities or pipeline trenches and previously unidentified prehistoric sites. This direct physical contact with a prehistoric site could cause physical damage to or complete destruction of information on the prehistory of the region and North America. Federal and State laws and regulations initiated in the 1960s began requiring archaeological surveys prior to permitting any activity that might disturb a significant archaeological site. Therefore, it can be assumed that, since the introduction of the archaeological resource protection laws, most coastal archaeological sites have been located, evaluated, avoided, or mitigated prior to construction. However, impacts to coastal prehistoric resources may have already occurred as a result of various onshore construction activities prior to enactment of the archaeological resource protection laws.

Trawling activity in the Arctic region affects only the uppermost portion of the sediment column (Krost et al. 1990). This zone would already be disturbed by natural factors relating to the destructive effects of ice gouging and scouring (see Section 4.2.2). Therefore, the effect of trawling on most prehistoric archaeological sites would be minor.

Most channel dredging occurs at the entrances to bays, harbors, and ports. These areas have a high probability for prehistoric archaeological sites, as they are often associated with drowned river valleys, which are known to have a high probability for prehistoric sites. It is assumed that some of the archaeological data that have been lost as a result of dredging have been significant and unique; therefore, the impact to prehistoric archaeological sites as a result of past channel dredging activities has probably been moderate to major. In many areas, the USACE now requires remote-sensing surveys prior to dredging activities to minimize such impacts (Espey, Huston & Associates 1990).

Natural geologic processes such as ice gouging and thermokarst erosion have caused and will continue to cause a significant loss of prehistoric archaeological data in the Alaska region. For example, ice gouges on the Beaufort Sea shelf can create a furrow up to 67 m (220 ft) wide and 4 m (13 ft) deep; however, the average ice gouge is about 8 m (26 ft) wide and 0.5 m (1.6 ft) deep (Barnes 1984). Coastal prehistoric sites are exposed to the destructive effects of thermokarst erosion. These natural processes would cause artifacts to be dispersed and the site context to be disturbed or even completely destroyed, resulting in the loss of archaeological information. Overall, a significant loss of data from submerged and coastal prehistoric sites has probably occurred, and will continue to occur, from the effects of natural geologic processes. It is assumed that some of the data lost have been significant and/or unique, resulting in a major level of impact.

An accidental oil spill could affect coastal prehistoric archaeological sites, but the direct impact of oil on most sites is uncertain. Protection of such sites during an oil spill requires specific knowledge of their location, condition, nature, and extent prior to impact; however, the Beaufort Sea and Chukchi Sea coastlines have not been systematically surveyed for archaeological sites.

Heavy oiling of a coastal area could conceal intertidal sites that may not be recognized until they are inadvertently damaged during cleanup (Whitney 1994). Crude oil may also contaminate organic material used in ^{14}C dating, and, although there are methods for cleaning contaminated ^{14}C samples, greater expense is incurred (Dekin et al. 1993). The major source of potential impact from oil spills is the harm that could result from unmonitored shoreline cleanup activities. Unauthorized collecting of artifacts by cleanup crew members is also a concern, albeit one that can be mitigated with effective training and supervision. Damage or loss of significant archaeological information could result from the contact between an oil spill and a prehistoric archaeological site; therefore, the cumulative impact from oil spills to prehistoric archaeological sites could range from moderate to major.

Historic Resources. Direct physical contact between a routine activity and a shipwreck site could destroy fragile ship remains, such as the hull and wooden or ceramic artifacts, and could disturb the site context. The result would be the loss of archaeological data on ship construction, cargo, and the social organization of the vessel's crew, and the concomitant loss of information on maritime culture for the time period from which the ship dates.

Since 1973 when the ESP was initiated, the USDOI has required archaeological (historical) surveys be conducted prior to development of mineral leases when a historic-period shipwreck is reported to lie within or adjacent to the lease area. Although an archeological survey would identify all cultural resources in the APE for the project and routine operations related to OCS activities would avoid all known cultural resources, it is likely that impacts to historic-period shipwrecks may have already occurred as a result of non-OCS program activities that took place before implementation of the 1973 archaeological survey requirement.

Onshore development could result in direct physical contact between the construction of new onshore facilities or pipeline trenches and previously unidentified historic sites. Federal and State laws and regulations initiated in the 1960s began requiring archaeological surveys prior to permitting any activity that might disturb a significant archaeological site. Therefore, it can be assumed that, since the introduction of the archaeological resource protection laws, most coastal archaeological sites that would have been impacted have been located, evaluated, avoided, or mitigated prior to construction. However, impacts to coastal historic sites may have resulted from onshore construction activities prior to enactment of the archaeological resource protection laws.

Trawling activity in the Alaska subregion only affects the uppermost portion of the sediment column (Krost et al. 1990). On many wrecks, this zone would already be disturbed by natural factors and would contain only artifacts of high specific gravity which have lost all original context. Therefore, the effect of trawling on most historic shipwreck sites would be minor.

Most channel dredging occurs at the entrances to bays, harbors, and ports. These areas have a high probability for historic shipwrecks. Assuming that some of the data lost have been unique, the impact to historic sites as a result of past channel-dredging activities has probably been moderate to major. In many areas, the USACE now requires remote-sensing surveys prior to dredging activities to minimize such impacts (Espey, Huston & Associates 1990).

Natural geologic processes such as ice gouging and thermokarst erosion may cause a loss of historic data in the Beaufort and Chukchi Seas (see study conducted in the Beaufort Sea by Darigo et al. [2007]). For example, ice gouges on the Beaufort Sea shelf can create furrows up to 67 m (220 ft) wide and 4 m (13 ft) deep; however, the average ice gouge is about 8 m (26 ft) wide and 0.5 m (1.6 ft) deep (Barnes 1984). Darigo et al. (2007) suggest that areas close to islands and the shore may be protected from the effects of ice gouging. Coastal historic sites are exposed to the erosional effects of wave energy and thermokarst erosion, which would cause artifacts to be dispersed and the site context to be disturbed or even completely destroyed. No specific studies have examined the effect of geological processes on site integrity. Overall, a significant loss of data from submerged and coastal historic sites may have already occurred from the effects of natural geologic processes. It is possible that some of the data lost may have been significant and/or unique, resulting in a major level of impact. Additional studies are needed to assess the effect of geological processes on cultural resources.

An accidental oil spill could affect a coastal historic site, but the direct impact of oil on most historic sites is uncertain. The primary source of potential impact from oil spills is unmonitored shoreline cleanup activities (Bittner 1996; see Section 4.4.15.3.2). Unauthorized collecting of artifacts by cleanup crew members is also a concern, albeit one that can be mitigated with effective training and supervision. Damage or loss of significant historic information could result from oil spill cleanup activities; therefore, the cumulative impact from oil spills (past, present, and future) on historic sites could range from moderate to major.

Conclusion. The cumulative impacts of future OCS program and ongoing and future non-OCS program activities on prehistoric and historic archaeological sites in the Beaufort and Chukchi Seas are currently unknown, but could range from minor to moderate, mainly because activities occurring on the OCS prior to BOEM's survey requirement (in effect since 1973) may already have affected significant archaeological sites. Other important impact-producing factors that likely have had, and will continue to have, an impact on both prehistoric and historic archaeological sites are channel dredging and geologic processes, such as ice gouging and thermokarst erosion. Commercial treasure hunting and sport diving may also result in a loss of artifacts at historic-period shipwreck sites. The incremental contribution of routine operations under the Program is expected to be negligible to large. Archaeological surveys that would identify significant cultural resources to be avoided could reduce these impacts (see Section 4.4.15.3).

Cumulative impacts on prehistoric and historic archaeological sites due to expected accidental oil spills and related cleanup activities could range from negligible to major, depending on the location of the spill in relation to sensitive resources. The incremental contribution of oil spills associated with the Program could be small to large relative to those associated with future OCS program and ongoing and future non-OCS program activities. Impacts associated with an unexpected, low-probability CDE would also depend on location, and could range from minor to major if they were to occur. There is a greater likelihood that more of the resources would be affected at a major level during a CDE. A more detailed discussion of the effects of oil spills on archaeological and historic resources in Arctic waters is presented in Section 4.4.15.3.

4.6.5.4 Summary for Gulf of Mexico Region

4.6.5.4.1 Areas of Special Concern. In the GOM, Areas of Special Concern are federally managed areas such as marine protected areas, National Marine Sanctuaries, National Parks, and National Wildlife Refuges. In addition to these areas, a number of locations have been given special designations by Federal, State, and nongovernmental organizations. These include the National Estuarine Research Reserves, National Estuary Program Sites, and the Military and NASA Use Areas. Cumulative impacts on these resources result from activities that could potentially cause damage to or degradation of fauna or habitats within these areas. Ongoing and future activities or trends that affect Areas of Special Concern in/near the GOM include fishing, diving, dredging operations, marine vessel traffic (and wakes), tankering, trash and debris accumulation (from various sources), onshore infrastructure (e.g., roads and vehicle traffic), and oil and gas development and infrastructure (e.g., pipeline landfalls and onshore facilities). Extreme weather events such as hurricanes and tropical storms also occur regularly in the GOM region and potentially cause damage by increasing shoreline erosion. Climate change has the potential to profoundly affect coral communities within these areas (e.g., in the FGBNMS, the only marine sanctuary in the GOM). Cumulative impacts on Areas of Special Concern in the GOM are considered to be negligible to moderate. The impacts of activities taking place within the Areas of Special Concern located onshore, such as National Parks and National Forests, are regulated through permitting processes. The cumulative impacts from spills would be minor to major, depending on spill frequency, location, and size; the type of product spilled; weather conditions; effectiveness of cleanup operations; and other environmental conditions at the time of the spill.

Routine operations under the Program could result in a negligible to medium incremental increase in effects on Areas of Special Concern. Expected oil spills (most of which are less than 1,000 bbl) that may occur during the Program could result in a small incremental contribution to cumulative impacts on Areas of Special Concern, depending on spill frequency, location, and volume; the type of product spilled; weather conditions; effectiveness of cleanup operations; and other environmental conditions at the time of the spill. Impacts associated with large spills (1,000 bbl and greater) or an unexpected, low-probability CDE in areas adjacent to the National Parks, NWRs, or National Forests, whether from OCS or non-OCS sources, would also depend on these factors, and could result in moderate impacts if they were to occur. Such spills could negatively impact the FGBNMS and coastal habitats and fauna, and could also affect subsistence uses, commercial or recreational fisheries, and tourism.

4.6.5.4.2 Population, Employment, and Income. Population in counties of the GOM coastal region has been steadily increasing since 1980, with the highest growth occurring in Texas. Most of the employment (and earnings) in the region is concentrated in Florida and Texas, which together provide about 81% of the employment in the GOM region. The largest employing sectors are in services, retail and wholesale trade, and State and local government. Cumulative economic impacts result from direct employment and income created through the development of offshore oil and gas resources, and the indirect employment and income produced through the spending of wages and salaries, and from the procurement of materials and services in the Gulf coast region. In-migration of workers and their families into the region produces population impacts. Oil and gas development has created employment and income in the coastal economies of the GOM coast, and this has led to rapid increases in population. Small incremental increases in employment, income, and population are expected with the development of offshore oil and gas resources in the GOM under the Program.

The cumulative impacts of ongoing and future OCS program and non-OCS program activities would be considered beneficial because these activities would increase employment and earnings in the region over the next 40 to 50 years. The Program would add to these beneficial impacts, especially in Texas and Louisiana. The incremental contribution of the Program is expected to be negligible, however, because the added employment demands are less than 2% of the total GOM coast regional employment. In areas with a large proportion of impact-sensitive industry (such as tourism), the cumulative impacts of accidental oil spills could be moderate to major, depending on the total volume of oil reaching land, the land area affected, and the sensitivity of local environmental conditions to oil impacts. The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be negligible to small relative to those associated with ongoing and future OCS program and non-OCS program activities. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in minor to moderate impacts if they were to occur. In the short term, impacts of a CDE could be large as a result of loss of employment, income, and possible shortages of commodities or services in both coastal and inland areas affected by the spill.

4.6.5.4.3 Land Use and Infrastructure. Most of the equipment and facilities supporting offshore oil and gas operations are located in the western and central GOM. Currently, there are hundreds of onshore facilities that support offshore industry. These include ports, refineries, and waste management facilities, among others. Cumulative impacts on land use and infrastructure result from demands on roads, utilities, and public services and the need to develop additional onshore facilities to accommodate ongoing and future activities in the GOM. Oil spill response also places stresses on community infrastructure and increases traffic in the affected area. Cumulative impacts on land use and onshore resources from ongoing and future activities in the GOM could range from minor to major depending on the nature and location of demands. Most of these impacts are expected to be temporary.

The incremental contribution of routine operations under the Program to cumulative impacts in the GOM would be negligible to small because the existing infrastructure is considered sufficient to handle the small increases in demands for roads, utilities, and public services related to the Program. Activities within the GOM also may be affected by the post-DWH event conditions; BOEM continues to monitor the region to identify long-term impacts of concern. Land use–related impacts resulting from expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program include stresses of spill response on community infrastructure, increased traffic in the response area (both onshore and offshore), and temporary restricted access to affected lands (while cleanup is conducted). Such spills would result in a negligible to small incremental contribution to cumulative impacts on land use and existing infrastructure. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in minor to moderate impacts if they were to occur.

4.6.5.4.4 Commercial and Recreational Fisheries. Commercial fisheries are very important to the economies of the GOM coast States; in 2009, commercial fishery landings in the GOM reached almost 649,000 metric tons, worth more than $629 million. When related processor, wholesale, and retail businesses are included, the GOM seafood industry supports more than 200,000 jobs, with related income impacts of $5.5 billion. In 2009, Louisiana led the States in total landings and value, followed by Mississippi, Texas, and Florida. Recreational fishing is also important to the region. In 2010, more than 4.5 million people engaged in some form of recreational fishing. Most recreational fishing in the region is done on private/rental boats (about 60%), followed by fishing from shore, then fishing from charter vessels. Angling trips are also made in inland waters. The majority of recreational fish landings in 2010 were in Florida, followed by Louisiana, Alabama, and Mississippi. Cumulative impacts on commercial and recreational fishing result from changes in commercial fishing costs with the development of offshore oil and gas resources in the GOM coast region, and changes in accessibility of fisheries resources. Ongoing oil and gas development has affected commercial fishing costs both positively and negatively in the GOM coast through the effect offshore infrastructure placement has on the concentration of fisheries resources, and disused platforms have enhanced recreational fisheries. The cumulative effects of ongoing and future GOM activities on commercial and recreational fisheries are considered to be minor.

The incremental contribution of routine Program activities to cumulative impacts in the GOM would be small, since these activities would be unlikely to have population- or community-level effects on fishery resources because of the limited time frame over which most individual activities would occur and because a small proportion of habitat relative to similar available habitat would be affected during a given period. In addition, existing stipulations are in place to prevent or reduce impacts on sensitive habitats such as hard-bottom areas and topographic features. Construction of new platforms could represent a small increase in the availability of desirable recreational fishing locations for recreational anglers. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on would be medium, depending on the location, timing, and volumes of spills (among other environmental factors). Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be moderate if they were to occur. Large spills or a CDE could have significant localized effects on commercial fishing as a result of reduced catch, loss of gear, or loss of fishing opportunities during cleanup and recovery periods, and on recreational fishing as a consequence of contamination of fish tissues, degradation of aesthetic values that attract fishers, or temporary closure of fishing areas. Large spills or a CDE have a greater potential to contact intertidal habitat and subsequently contaminate or reduce the abundance of commercial and recreational species that depend on nearshore habitat.

4.6.5.4.5 Tourism and Recreation. The GOM coastal zone is one of the major recreational regions of the United States, with marine fishing and beach-related recreation being particularly popular. The coasts in GOM States offer diverse natural and developed landscapes and seascapes, and the beaches, barrier islands, estuarine bays and sounds, river deltas, and tidal marshes are visited by residents and tourists throughout the year. In 2000, Florida was the most important destination for marine recreation, with more than 22 million people participating in the State. Cumulative impacts on tourism and recreation therefore result when there are changes in the accessibility of beach and offshore resources for recreational use, and from increases in marine vessel and aircraft traffic in the vicinity of recreational resources. Oil and gas development has had an important impact on tourism and recreation in the GOM coast through the effect of offshore infrastructure placement and the proximity of platform servicing traffic to recreational resources, as well as the visibility of offshore platforms from onshore recreational areas. Given the existence of offshore oil and gas developments and other ongoing activities in the GOM, however, cumulative impacts on tourism and recreation from ongoing and future OCS and non-OCS activities are expected to be minor.

The incremental contribution of routine operations under the Program to cumulative impacts in the GOM would be small, with potential adverse aesthetic impacts on beach recreation and sightseeing and potential positive impacts on diving and recreational fishing. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program would be small to medium, depending on the size, location, and timing of the spill (being greatest if it occurred during the peak recreational season). Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be minor to moderate if they were to occur. Short-term impacts would include beach and coastal access restrictions; restrictions on visitation, fishing, or hunting while cleanup is being conducted; and aesthetic impacts associated with the event itself and with cleanup activities. Longer-term impacts could be substantial if tourism were to suffer as a result of the real or perceived impacts of the event, or if there were substantial changes to tourism and recreation sectors in the region as a result of the event.

4.6.5.4.6 Sociocultural Systems. The counties along the GOM coast are home to a large and heterogeneous mix of cultures, subcultural groups, and populations. Within the coastal region, the effects of the offshore oil and gas industry are felt most directly by populations living within the coastal community commuting zone where industry support facilities and the people who work in them are located. Coastal estuaries provide a wealth of wild resources for subsistence harvesting. Although many of the subsistence activities in the GOM region are practiced recreationally, some Native American groups, such as the United Houma Nation and the federally-recognized Chittimacha Tribe in southern Louisiana, depend on fishing, hunting, and gathering for at least part of their domestic subsistence. Commercial Vietnamese fishers also retain a quarter of their catch for family use and barter. Cumulative impacts to sociocultural systems occur when ongoing and future actions (OCS and non-OCS program) cause changes in local populations and social institutions or when jobs are lost or created. Subsistence practices have already been stressed by natural trends associated with climate change (e.g., flood control along the Mississippi River). Cumulative impacts on sociocultural systems in the GOM as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be moderate over the next 40 to 50 years.

The incremental contribution of routine operations under the Program to cumulative impacts in the GOM would be small, since they are more likely to support the existing industry than to create industry growth. Any expansion of deepwater activities will result in jobs that require longer, unbroken periods of work offshore, specialized skills, and potential in-migration of part of the workforce. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program would be small to medium, especially on localized intertidal resources used by subsistence harvesters. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be moderate to major if they were to occur, especially if oil from a CDE were to reach the shore. Such spills could lead to long-term closure of fisheries, resulting in social and cultural stress. GOM subsistence harvesters make up a relatively small segment of the coastal population and replacement food resources are more available than for subsistence harvesters in Alaska, so while the impact of the loss of subsistence resources would be moderate for the coastal population as a whole, it would be locally major for populations that depended on subsistence harvesting for a significant proportion of their diet.

4.6.5.4.7 Environmental Justice. In general, environmental justice impacts occur when any activity or trend (OCS program- or non-OCS program-related) results in adverse health or environmental impacts that are significantly high and disproportionately affect minority and low-income populations. A large number of minority and low-income individuals are located in the LMA counties along the GOM coast. In this region, the adverse effects of several hurricanes over the past decade are still being felt; these events have had high and disproportionate effects on minority and low-income populations, especially in terms of property damage and loss of income. These effects are considered to be long-term, if not irreversible, and will likely persist into the foreseeable future. Cumulative impacts could result from changes in the proximity of onshore oil and gas infrastructure and to marine vessel and aircraft traffic, especially when these changes occur in counties where there are minority and low-income populations composing 50% or more of the total county population, or are more than 20 percentage points higher than the State average. Ongoing and future oil and gas development would continue to affect low-income and minority populations in some regions of the GOM coast by increasing the proximity to existing oil and gas infrastructure and associated health, environmental, and visibility impacts. It is likely that hurricanes in the region will increase in frequency and increase in the coming decades. Given all these factors, cumulative impacts on minority and low-income populations are considered to be moderate to major.

Because of the long-established and well-developed oil and gas industry present in the GOM and the fact that an estimated 75% of activity from the Program would occur in deep and ultra-deep waters, routine operations under the Program are not expected to cause additional environmental justice concerns; their contribution to cumulative impacts on low-income and minority populations therefore would be negligible. The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be negligible to medium because of the movement of oil and gas activities farther away from coastal areas and the demographic pattern of more affluent groups (and fewer low-income and minority populations) living in coastal areas. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in moderate to major impacts, depending on the location, size, and timing of the event.

4.6.5.4.8 Archaeological and Historical Resources. Onshore cultural resources are highly varied in coastal areas of the GOM. Prehistoric cultural resources range from small, temporary-use sites to substantial permanent settlements, some from the earliest known human occupation of the areas, about 12,000 years ago. Based on current water levels, it is likely that sites older than 3,000 years could be located underwater in the region. Offshore cultural resources mainly consist of shipwrecks dating from as early as the sixteenth century; however, other structures, such as the Ship Shoal Lighthouse, can also be found offshore. Studies have indicated that two-thirds of all shipwrecks in the northern GOM are located within 1.5 km (0.9 mi) of the shore, with the highest concentration of ships occurring in areas that experienced high-volume marine traffic. Shipwrecks are also thought to be concentrated in the open sea of the eastern GOM. To date, shipwrecks have been found in water depths of up to 1,981 m (6,500 ft). Cumulative impacts to these resources occur when operations involving bottom-disturbing activities (e.g., channel dredging) come into physical contact with artifacts or their site context, or as a result of natural phenomena such as waves, currents, and tropical storms. The cumulative impacts of ongoing and future activities (OCS and non-OCS) are not currently known, but could range from minor to moderate, mainly because activities occurring on the OCS prior to USDOI's survey requirement, which went into effect in 1973, may already have affected (i.e., damaged or destroyed) significant sites.

Routine operations under the Program could affect significant archaeological and historic resources, especially offshore resources, with construction activities such as platform and pipeline construction, and dredging, potentially damaging or destroying affected resources. Onshore impacts include resource damage or loss, or visual effects and are possible from pipeline landfall, onshore pipeline, and road construction. Anchor drags could adversely affect shipwrecks. Impacts could range from negligible to major, depending on the presence of significant archaeological or historic resources in the area of potential effect. The incremental contribution of routine operations under the Program could be negligible to large, depending on the presence of significant archaeological or historic resources in the area of potential effect. Archaeological surveys that would identify significant cultural resources to be avoided could reduce these impacts.

The incremental contribution of expected accidental oil spills associated with the Program (most of which are less than 1,000 bbl) to cumulative impacts on archaeological and historical resources in the GOM would be negligible to large, depending on the presence of significant resources in the area of potential effect and the spill location, timing, duration, and size. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from minor to major if it were to occur.

4.6.5.5 Summary for Alaska – Cook Inlet

4.6.5.5.1 Areas of Special Concern. The Alaska National Interest Lands Conservation Act of 1980 designated certain public lands in Alaska as National Parks, Wildlife Refuges, Wild and Scenic Rivers, for the National Wilderness Preservation and National Forest Systems. Many of these occur in the Cook Inlet region. Other Areas of Special Concern include MPAs, National Estuarine Research Reserves, National Estuary Program Areas, MUAs, and NOAA-designated HCAs. In addition, there are several State parks and recreation areas bordering Cook Inlet. Cumulative impacts on these resources result from activities that could potentially cause damage to or degradation of fauna or habitats within these areas. Ongoing and future activities or trends that affect Areas of Special Concern in or near Cook Inlet include fishing, diving, dredging operations, marine vessel traffic (and wakes), tankering, trash and debris accumulation (from various sources), onshore infrastructure (e.g., roads and vehicle traffic), and oil and gas development and infrastructure (e.g., pipeline landfalls and onshore facilities). Cumulative impacts on Areas of Special Concern in the Cook Inlet would be negligible to moderate. The impacts of activities taking place within the Areas of Special Concern located onshore, such as National Parks and National Forests, are regulated through permitting processes. The cumulative level of impacts from spills would be minor to major, depending on spill frequency, location, and size; the type of product spilled; weather conditions; effectiveness of cleanup operations; and other environmental conditions at the time of the spill.

Routine operations under the Program could result in negligible to medium incremental increases in effects on National Sanctuaries, Parks, Refuges, and Estuarine Research Reserves. Expected oil spills (most of which are less than 1,000 bbl) that occur during the Program could result in a negligible to small incremental contribution to cumulative impacts on Areas of Special Concern, depending on spill frequency, location, and volume; the type of product spilled; weather conditions; effectiveness of cleanup operations; and other environmental conditions at the time of the spill. Large spills (1,000 bbl and greater) or an unexpected, low-probability CDE in areas adjacent to the National Parks, NWRs, or National Forests, whether from OCS or non-OCS sources, would also depend on these factors, and could result in moderate impacts if they were to occur. Such spills could negatively impact coastal habitats and fauna, and could also affect subsistence uses, commercial or recreational fisheries, and tourism.

4.6.5.5.2 Population, Employment, and Income. Between 2005 and 2009, the Municipality of Anchorage had a population of 280,389, about 45% of the total population in Alaska. Employment is concentrated in Anchorage, which provides about 83% of employment in the region. The largest employing sectors in 2008 were in services, wholesale and retail trade, and State and local government. Oil and gas employment is concentrated in Anchorage, with a total of 8,636 workers employed directly in oil and gas extraction activities, pipeline and refinery activities, and support activities in 2007. Cumulative economic impacts result from direct employment and income created through the development of offshore oil and gas resources and the indirect employment and income produced through the spending of wages and salaries and from the procurement of materials and services in the region. Oil and gas development has created large increases in employment and income in the economy of Alaska as a whole, and has led to rapid increases in population. In-migration of workers and their families into the region produces population impacts. Small incremental increases in employment, income, and population are expected with the development of offshore oil and gas resources in the Cook Inlet region under the Program.

The cumulative impacts of future OCS program and ongoing and future non-OCS program activities would be considered beneficial because these activities would increase employment and earnings in the region over the next 40 to 50 years. The Program would add to these beneficial impacts, especially on the Kenai Peninsula and in Anchorage. The incremental contribution of the Program is expected to be small, however, because the added employment demands are less than 5% of baseline levels in Alaska. In areas with a large proportion of impact-sensitive industry (such as commercial and recreational fishing), the cumulative impacts of accidental oils spills could be moderate to major, depending on the total volume of oil reaching land, the land area affected, and the sensitivity of local environmental conditions to oil impacts. The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be negligible to small relative to those associated with future OCS program and ongoing and future non-OCS program activities. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in minor to moderate impacts if they were to occur. In the short-term, impacts of a CDE could be large as a result of loss of employment, income, and property value; increased traffic congestion; increased cost of service provision; and possible shortages of commodities or services.

4.6.5.5.3 Land Use and Infrastructure. Anchorage is the State center for scheduled aircraft and the regional center for chartered aircraft. It has a cargo facility served by a railroad connecting it to Alaska's interior and the port of Seward and two military bases (Joint Base Elmendorf-Richardon). It is also the center for the State's overall road network. Much of the on-land infrastructure around Cook Inlet supports offshore oil and gas development; facilities/complexes include the Trading Bay production facility, the Tesoro Refinery, the Drift River Terminal, and the Nikiski complex (Agrium and ConocoPhillips LNG). Cumulative impacts on land use and infrastructure result from demands on roads, utilities, and public services and the need to develop additional onshore facilities to accommodate ongoing and future activities in the inlet. Oil spill response also places stresses on community infrastructure and increases traffic in the affected area. Cumulative impacts on land use and onshore resources could range from minor to major, depending on the nature and location of demands. These impacts are generally considered temporary.

The incremental contribution of routine operations of the Program to cumulative impacts in Cook Inlet would be small to medium because land use changes would be needed for new onshore pipeline construction and transportation network. Land use–related impacts resulting from expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program include stresses of spill response on community infrastructure, increased traffic in the response area (both onshore and offshore), and temporary restricted access to affected lands (while cleanup is conducted). Such spills would result in a small incremental contribution to cumulative impacts on land use and existing infrastructure. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in moderate impacts if they were to occur.

4.6.5.5.4 Commercial and Recreational Fisheries. Commercial fisheries of Cook Inlet and the Gulf of Alaska target groundfish, Pacific halibut, Pacific salmon, herring, crab, shrimp, clams, scallops, sea urchins, and sea cucumbers. The groundfish fisheries accounted for the largest share ($640 million, or about 48%) of the ex-vessel value of all commercial fisheries in Alaska in 2009. Recreational fishing in the Cook Inlet region includes marine sport fishing, freshwater fishing, and shellfish gathering activities, which contribute substantially to the area's economy. On the western bank of upper Cook Inlet, there are recreational fisheries for razor clams, several species of hardshell clams, and crab. Cumulative impacts on commercial and recreational fishing result from changes in commercial fishing costs with offshore oil and gas development and changes in accessibility of fishery resources. The cumulative impacts on commercial and recreational fisheries in Cook Inlet are considered to be minor.

The incremental contribution of routine operations under the Program to cumulative impacts in Cook Inlet would be small since these would be unlikely to have population-level effects on fishery resources or result in long-term loss of fishery resources. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on would be negligible to medium, depending on the location, timing, and volumes of spills (among other environmental factors). Small spills are unlikely to affect a large number of fish or have a substantial effect on recreational fishing before dilution and weathering reduced concentrations of oil in the water. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be moderate if they were to occur. Large spills or a CDE could have significant localized effects on commercial fishing as a result of reduced catch, loss of gear, or loss of fishing opportunities during cleanup and recovery periods, and on recreational fishing as a consequence of contamination of fish tissues, degradation of aesthetic values that attract fishers, or temporary closure of fishing areas. Large spills or a CDE have a greater potential to contact intertidal habitat and subsequently contaminate or reduce the abundance of commercial and recreational species that depend on nearshore habitat.

4.6.5.5.5 Tourism and Recreation. Opportunities for recreational activities such as hunting, hiking, boating, wildlife viewing, and sightseeing are abundant in the Cook Inlet region. Visitors reach the area via tour ships and ferries, as well as helicopters, small aircraft, and fishing charters. The Kenai Peninsula and Prince William Sound receive the heaviest recreational use by residents and nonresidents, and are in close proximity to Cook Inlet and Anchorage. The Chugach National Forest attracts hikers, campers, and other users. Cumulative impacts on tourism and recreation result from changes in accessibility of beach and offshore resources for recreational use, and from increases in marine vessel and aircraft traffic in the vicinity of recreational resources; these impacts are expected to be minor.

The incremental contribution of routine operations under the Program to cumulative impacts in Cook Inlet would be small, with potential adverse aesthetic impacts on sightseeing, boating, fishing, and hiking activities in the inlet. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program would be negligible to small, depending on the size, location, and timing of the spill (being greatest if it occurred during the peak recreational season). Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be minor to moderate if they were to occur. Short-term impacts would include beach and coastal access restrictions; restrictions on visitation, fishing, or hunting while cleanup is being conducted; and aesthetic impacts associated with the event itself and with cleanup activities. Longer-term impacts could be substantial if tourism were to suffer as a result of the real or perceived impacts of the event, or if there were substantial changes to tourism and recreation sectors in the region as a result of the event.

4.6.5.5.6 Sociocultural Systems. The region surrounding Cook Inlet includes economically complex cities such as Anchorage and its suburbs, the largest urban community in the State; towns such as Kenai, Soldotna, and Nikiski that are centers of the oil and gas industry; smaller towns such as Port Lions that depend on commercial fishing; and small predominantly Alaska Native communities. Subsistence harvesting plays some role in communities of all types. Cumulative impacts to sociocultural systems occur when ongoing and future actions (OCS and non-OCS programs) cause changes in local populations and social institutions or when jobs are lost or created. Subsistence harvesting could also be affected by activities that affect marine fauna, such as increases in airborne or subsea noise (e.g., aircraft or marine vessel traffic, seismic surveys, drilling) or degradation of water quality (e.g., fuel or oil spills, chemical releases, or dredging operations that increase turbidity), or that necessitate changes in subsistence fishing practices. Cumulative impacts on sociocultural systems in Cook Inlet as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be minor to moderate over the next 40 to 50 years.

The incremental contribution of routine Program activities to cumulative impacts would be small, since they would not introduce new kinds of activities that would alter existing socioeconomic systems. In addition, the relatively small number of new residents that would come into the area because of the Program should likewise not alter existing sociocultural systems. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on would be small to large, especially in intertidal and estuarine zones used by subsistence harvesters. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be major if they were to occur, especially if resources important to subsistence harvesters, including intertidal resources, migrating fishes, and fishes with strong ties to the shore, were affected.

4.6.5.5.7 Environmental Justice. In general, environmental justice impacts occur when any activity or trend (OCS program- or non-OCS program-related) results in adverse health or environmental impacts that are significantly high and disproportionately affect minority and low-income populations. A large number of minority and low-income individuals live in the south-central Alaska region; however, the number of minority individuals in each of the local boroughs does not exceed 50% of the population and does not exceed the State average by 20 percentage points or more in any of the boroughs. Thus, there is no minority population in south central Alaska. Likewise, there are no low-income populations in any of the boroughs around Cook Inlet. Subsistence hunting and fishing are an important part of the economies in rural communities. Although there are no environmental justice concerns here, cumulative impacts on local communities could result from changes in the proximity of onshore oil and gas infrastructure and to marine vessel and aircraft traffic. Ongoing and future oil and gas development would continue to affect populations in some regions of Cook Inlet by increasing the proximity to existing oil and gas infrastructure and associated health, environmental, and visibility impacts. Given these factors, cumulative impacts on local populations are considered to be moderate to major.

The incremental contribution of routine operations under the Program to cumulative impacts in Cook Inlet would be small, depending on the proximity of onshore pipelines and offshore infrastructure to communities and their subsistence harvest areas, but are not expected to cause additional environmental justice concerns; their contributions to cumulative impacts on low-income and minority populations therefore would be negligible. The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be negligible to small. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in moderate to major impacts on the Alaska Native population, especially if subsistence resources were diminished or tainted as a result of the spill. Mitigation measures, cooperative agreements between Native and industry groups, and government-to-government consultations are designed to limit the effects from oil spills and routine operations.

4.6.5.5.8 Archaeological and Historic Resources. Onshore archaeological and historic resources occur along the shoreline surrounding Cook Inlet; the predominant types of prehistoric features are house pits containing household and subsistence artifacts like stone lamps, sinkers, and arrowheads. Historic sites onshore consist of early Russian houses, churches, roadway inns, fish camps, and mining camps. Little research has been done to characterize prehistoric resources in the offshore waters of Cook Inlet; however, it is likely that high-energy tidal movement has removed at least some resources from their original resting place. The best-preserved shipwrecks are likely to be found on the OCS, because wave action and ice are less likely to contribute to the breakup of ships in deeper waters. Cumulative impacts to these resources occur when operations involving bottom-disturbing activities (e.g., channel dredging) come into physical contact with artifacts or their site context, or as a result of natural phenomena such as high-energy waves and currents, ice gouging, and thermokarst collapse. The cumulative impacts of future OCS and ongoing and future non-OCS activities are not currently known, but could range from minor to moderate, mainly because activities occurring on the OCS prior to USDOI's survey requirement, which went into effect in 1973, may already have affected (i.e., damaged or destroyed) significant sites.

Routine operations could affect significant archaeological and historic resources, especially offshore resources, with construction activities such as platform and pipeline construction potentially damaging or destroying affected resources. Onshore impacts include resource damage or loss, or visual effects and are possible from pipeline landfall, onshore pipeline, and road construction. Anchor drags could adversely affect shipwrecks. The incremental contribution of routine operations under the Program is could be negligible to large, depending on the presence of significant resources in the area of potential effect. Archaeological surveys that would identify significant cultural resources to be avoided could reduce these impacts.

The incremental contribution of expected accidental oil spills associated with the Program (most of which are less than 1,000 bbl) to cumulative impacts on archaeological and historical resources in Cook Inlet would be negligible to large, depending on the presence of significant resources in the area of potential effect and the spill location, timing, duration, and size. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from minor to major if they were to occur.

4.6.5.6 Summary for Alaska – Arctic

4.6.5.6.1 Areas of Special Concern. The Alaska National Interest Lands Conservation Act of 1980 designated certain public lands in Alaska as National Parks, Wildlife Refuges, Wild and Scenic Rivers, and as designated for the National Wilderness Preservation and National Forest Systems. Some of these occur in the Arctic region. Other Areas of Special Concern include MPAs; there are no MUAs, National Estuarine Research Reserves, National Estuary Program Areas, or NOAA-designated HCAs in or adjacent to the Beaufort Sea or Chukchi Sea Planning Area. Cumulative impacts on these resources result from activities that could potentially cause damage to or degradation of fauna or habitats within these areas. Ongoing and future activities or trends that affect Areas of Special Concern in or near Arctic waters include fishing, diving, dredging operations, marine vessel traffic (and wakes), tankering, trash and debris accumulation (from various sources), onshore infrastructure (e.g., roads and vehicle traffic), and oil and gas development and infrastructure (e.g., pipeline landfalls and onshore facilities). Cumulative impacts on Areas of Special Concern in Arctic waters would be negligible to moderate. The impacts of activities taking place within the Areas of Special Concern located onshore, such as National Parks and National Forests, are regulated through permitting processes. The cumulative level of impacts from spills would be minor to major, depending on spill frequency, location, and size; the type of product spilled; weather conditions; effectiveness of cleanup operations; and other environmental conditions at the time of the spill.

Routine operations under the Program could result in negligible to medium incremental increases in effects on National Parks and Wildlife Refuges. Expected oil spills (most of which are less than 1,000 bbl) that occur during the Program could result in a negligible to small incremental contribution to cumulative impacts on Areas of Special Concern, depending on spill frequency, location, and volume; the type of product spilled; weather conditions; effectiveness of cleanup operations; and other environmental conditions at the time of the spill. Large spills (1,000 bbl and greater) or an unexpected, low-probability CDE in areas adjacent to the National Parks, NWRs, or National Forests, whether from OCS or non-OCS sources, would also depend on these factors, and could result in moderate impacts if they were to occur. Such spills could negatively impact coastal habitats and fauna, and could also affect subsistence uses.

4.6.5.6.2 Population, Employment, and Income. Population in the North Slope Borough is concentrated in Barrow, with a population of 4,078 between 2005 and 2009. Unemployment, especially in smaller villages, is high, especially during the winter when there is little alternate market-based activity; however, subsistence-related transactions play a key role in the economic well-being of those living in these communities. The largest employing sectors in 2008 were mining (including oil and gas), services, and State and local government. Oil and gas employment is relatively small, mainly because large numbers of oil and gas workers in the Arctic region reside in other parts of Alaska and the United States, relocating temporarily to work locations in the Arctic, as needed. The oil and gas industry employed about 7,540 workers who were employed directly in oil and gas extraction activities, pipeline and refinery activities, and support activities in 2007. Cumulative economic impacts result from direct employment and income created through the development of offshore oil and gas resources and the indirect employment and income produced through the spending of wages and salaries and from the procurement of materials and services in Alaska as a whole. In-migration of workers and their families into the region produces population impacts. Oil and gas development has created large increases in employment and income in the economy of Alaska as a whole, and has led to rapid increases in population. Small incremental increases in employment, income, and population in Alaska as a whole are expected with the development of offshore oil and gas resources in the Arctic region under the Program.

The cumulative impacts of future OCS program and ongoing and future non-OCS program activities would be considered beneficial because these activities would increase employment and earnings in the region over the next 40 to 50 years (although rural Alaskan employment in the petroleum industry, especially among Alaska Natives, would likely remain relatively low). The Program would add to these beneficial impacts. The incremental contribution of routine operations under the Program is expected to be small, however, because the added employment demands are less than 10% of total Alaska employment. The cumulative impacts of accidental oil spills could be minor to major, depending on the total volume of oil reaching land, the land area affected, and the sensitivity of local environmental conditions to oil impacts. The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be negligible to small relative to those associated with ongoing and future OCS program and non-OCS program activities. Large spills (1,000 bbl or greater) or an unexpected CDE could result in minor to moderate impacts. In the short-term, impacts of a CDE could be large as a result of loss of employment, income, and possible shortages of commodities or services in both coastal and inland areas affected by the spill.

4.6.5.6.3 Land Use and Infrastructure. Land use in much of the Arctic region is not intense, with oil and gas-related development (onshore and offshore in State waters) and subsistence being the predominant uses. There are only a few small communities in the area, the largest of which is Barrow. Barrow is the economic, transportation, and administrative center for the North Slope Borough. Transportation-related infrastructure is minimal, but concentrated in the Prudhoe Bay oil field area. Marine shipping to North Slope communities is by barge and by lightering of cargo to shore because of the shallow coastal waters and the lack of dredging and heavy-lift equipment. Paved and unpaved roads are generally limited to the area within communities. During the winter, many residents travel by snowmobile. Airports and related service facilities are also limited. Most of the oil and gas-related infrastructure in the Arctic region is along the Beaufort Sea coastline. The Prudhoe Bay/Kuparuk oil field infrastructure is served by about 480 km (300 mi) of interconnected gravel roads, 640 km (400 mi) of pipeline routes, and related processing and distribution facilities. Cumulative impacts on land use and infrastructure result from demands on roads, utilities, and public services and the need to develop additional onshore facilities to accommodate ongoing and future activities in the region. Oil spill response also places stresses on community infrastructure and increases traffic in the affected area. Cumulative impacts on land use and onshore resources could range from minor to major, depending on the nature and location of demands. These impacts are generally considered temporary.

The incremental contribution of routine operations under the Program to cumulative impacts in the Arctic region would be small to medium because of land use changes needed for new onshore pipeline construction and transportation network. Land use–related impacts resulting from expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program include stresses of spill response on community infrastructure, increased traffic in the response area (both onshore and offshore), and temporary restricted access to affected lands (while cleanup is conducted). Such spills would result in a small incremental contribution to cumulative impacts on land use and existing infrastructure. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in moderate to major impacts.

4.6.5.6.4 Commercial and Recreational Fisheries. There currently is no commercial fishing and little data on recreational fishing in the Beaufort or Chukchi Seas (although the North Pacific Fishery Management Council has concluded that there are few recreational fisheries in these waters). Sport fishing likely occurs in coastal areas of larger population centers such as Barrow. Subsistence fishing is widespread in coastal areas of the Arctic; fisherman target Pacific herring, Dolly Varden char, whitefish, Arctic cod, and sculpin. Given the importance of fishing to local communities in the Arctic region, the most important cumulative impacts would result from any activities that cause a decline in fish availability for subsistence harvest. The cumulative impacts on recreational (and subsistence) fisheries in Arctic waters are considered to be moderate to major.

The incremental contribution of routine Program activities to cumulative impacts would be small, since routine operations under the Program would not occur in the immediate area where fisheries are located. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program would be medium, depending on the location, timing, and volumes of spills (among other environmental factors). Small spills are unlikely to affect a large number of fish or have a substantial effect on fishing before dilution and weathering reduced concentrations of oil in the water. Impacts associated with large spills (1,000 bbl or greater) and unexpected, low-probability CDEs could be moderate if they were to occur. Large spills or an unexpected, low-probability CDE could have significant localized effects on fishing as a result of reduced catch, loss of gear, or loss of fishing opportunities during cleanup and recovery periods, and on recreational fishing as a consequence of contamination of fish tissues, degradation of aesthetic values that attract fishers, or temporary closure of fishing areas. Large spills or a CDE have a greater potential to contact intertidal habitat and subsequently contaminate or reduce the abundance of commercial and recreational species that depend on nearshore habitat.

4.6.5.6.5 Tourism and Recreation. Tour groups to the North Slope Borough make up most of the nonresidential recreational activity. Most visitors stay in Barrow or Deadhorse. Travel to these areas is primarily by air, although bus tours occasionally arrive via the Dalton Highway. Hikers and river rafters also visit the Arctic National Wildlife Refuge and other areas using scheduled or chartered airplanes for access. An increasing number of cruise ships are entering the Chukchi and Beaufort Seas. Cumulative impacts on tourism and recreation result from disruptions to land-based activities, increases in the trash and debris accumulation, and competition between workers and tourists for local services, such as air transport and hotel accommodations; these impacts are expected to be moderate to major.

The incremental contribution of routine operations under the Program to cumulative impacts would be small, with potential adverse aesthetic impacts on sightseeing, hiking, and rafting activities. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program would be negligible to small, depending on the size, location, and timing of the spill (being greatest if it occurred during the peak recreational season). Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be minor to moderate if they were to occur. Short-term impacts would include beach and coastal access restrictions; restrictions on visitation, fishing, or hunting while cleanup is being conducted; and aesthetic impacts associated with the event itself and with cleanup activities. Longer-term impacts could be substantial if tourism were to suffer as a result of the real or perceived impacts of the event, or if there were substantial changes to tourism and recreation sectors in the region as a result of the event.

4.6.5.6.6 Sociocultural Systems. Most of the sparsely populated rural lands in the Arctic region are inhabited by indigenous Alaskans. Barrow is the largest permanent community on the North Slope and serves as the administrative and commercial hub of the region. The Alaska Natives living in communities along the coast of the Beaufort and Chukchi Seas are primarily Iñupiaq Eskimo. Alaska Native communities along the Arctic coast are heavily dependent on subsistence harvesting of sea mammals, fish, and terrestrial fauna. Enclaves of workers at Prudhoe Bay and nearby oil fields are employed by the oil and gas industry. They commute from mostly south central Alaska, Fairbanks, and States outside of Alaska. For the most part, these two communities (Alaska Native communities and worker enclaves) have had little interaction because of the physical distance that separates them. Cumulative impacts to sociocultural systems occur when ongoing and future actions (OCS and non-OCS program) cause changes in local populations and social institutions or when jobs are lost or created. Subsistence harvesting could also be affected by activities that affect marine fauna, such as increases in airborne or subsea noise (e.g., aircraft or marine vessel traffic, seismic surveys, drilling) or degradation of water quality (e.g., fuel or oil spills, chemical releases, or dredging operations that increase turbidity), or that necessitate changes in subsistence fishing practices. Cumulative impacts on sociocultural systems in the Arctic Planning Areas as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be moderate over the next 40 to 50 years.

The incremental contribution of routine operations under the Program to cumulative impacts would range from small to medium, especially if subsistence-related activities, central to the well-being of Alaska Natives who inhabit the area, are affected. Many of these potential effects are mitigatable. Onshore linear features (e.g., pipelines and roads) affect the migration patterns of terrestrial mammals. Because of the high level of dependence on subsistence harvesting, the incremental contribution of the Program to cumulative impacts on subsistence activities near the Beaufort and Chukchi Seas would be expected to be small to medium. Effects would be major only if important resources were eliminated or made unavailable. Design stipulations and operational procedures could reduce the impact of onshore development.

The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on would be small to medium, depending on the location, volume, and timing (i.e., season) of the spill. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be major if they were to occur, especially if they disrupt sea mammal harvest or resulted in the IWC reducing or eliminating whale quotas in the Alaska Arctic. A CDE would prove challenging for existing response capacity and capability, especially if the spill were under ice or in broken ice. The cleanup process itself has the potential to cause displacement of subsistence resources and subsistence hunters, and would have major impacts in the short term depending on the timing and duration of the displacement. The associated influx of cleanup workers would likely overwhelm the resources of local communities and could result in cross-cultural conflicts.

4.6.5.6.7 Environmental Justice. In general, environmental justice impacts occur when any activity or trend (OCS program or non-OCS program related) results in adverse health or environmental impacts that are significantly high and disproportionately affect minority and low-income populations. A large number of minority and low-income individuals are located in the Arctic region, although the number of low-income individuals does not exceed 50% of the total population (thus there is no low-income population in the region). Subsistence hunting and fishing are an important part of the economies in Arctic communities. Cumulative impacts on local communities could result from changes in the proximity of onshore oil and gas infrastructure and to marine vessel and aircraft traffic. Ongoing and future oil and gas development would continue to affect populations in some regions along the Beaufort and Chukchi Seas by increasing the proximity to existing oil and gas infrastructure and associated health, environmental, and visibility impacts. Given these factors, cumulative impacts on local populations are considered to be moderate to major.

The incremental contribution of routine operations under the Program to cumulative impacts in the Arctic region would be negligible small, depending on the proximity of onshore pipelines and offshore infrastructure to communities and their subsistence harvest areas, but are not expected to cause additional environmental justice concerns; their contribution to cumulative impacts on low-income and minority populations therefore would be small. The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be negligible to small. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in moderate to major impacts on the Alaska Native population, especially if subsistence resources were diminished or tainted as a result of the spill. Mitigation measures, cooperative agreements between Native and industry groups, and government-to-government consultations are designed to limit the effects from oil spills and routine operations.

4.6.5.6.8 Archaeological and Historic Resources. At the height of the late Wisconsinan glacial advance, about 19,000 years ago, the global sea level was much lower than at present, which created land bridges between the North American and Asian continents. During this time, large expanses of the OCS were exposed as dry land and shorelines shifted depending on the location of ice. These relict shorelines (and other relevant landforms) are currently inundated. Some studies indicate that ice gouging may have altered the seafloor in the Arctic region, removing all archaeological evidence of the first peoples; however, the extent of the disturbance is not known. To date, studies have been done in the Beaufort Sea, but more will be needed to fully understand the potential for significant artifacts to be present. Numerous shipwrecks have been documented in the Beaufort and Chukchi Seas. Most of these were associated with commercial whaling that occurred in the region between 1849 and 1921. Most of the shipwrecks are likely to be in State waters. There are significant onshore historic sites in the Arctic region; these include Cold War–era outposts, radar stations, and missile sites, and the Ipiutak Site National Historic Landmark at Point Hope, among others. Cumulative impacts to these resources occur when operations involving bottom-disturbing activities (e.g., channel dredging) come into physical contact with artifacts or their site context, or as a result of natural phenomena such as high-energy waves and currents, ice gouging, and thermokarst collapse. The cumulative impacts of future OCS and ongoing and future non-OCS activities are not currently known, but could range from minor to moderate, mainly because activities occurring on the OCS prior to USDOI's survey requirement, which went into effect in 1973, may already have affected (i.e., damaged or destroyed) significant sites.

Routine operations could affect significant archaeological and historic resources, especially offshore resources, with construction activities such as platform and pipeline construction potentially damaging or destroying affected resources. Onshore impacts include resource damage or loss, or visual effects, and are possible as a result of pipeline landfall, onshore pipeline, and road construction. Anchor drags could adversely affect shipwrecks. Impacts could range from negligible to major, depending on the presence of significant archaeological or historic resources in the area of potential effect. The incremental contribution of routine operations under the Program could be negligible to large, depending on the presence of resources in the area of potential effect. Archaeological surveys that would identify significant cultural resources to be avoided could reduce these impacts.

The incremental contribution of expected accidental oil spills associated with the Program (most of which are less than 1,000 bbl) to cumulative impacts on archaeological and historical resources in Arctic waters would be small to large, depending on the presence of significant resources in the area of potential effect and the spill location, timing, duration, and size. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from minor to major if they were to occur.

4.6.6 Cumulative Impacts Summary Tables

Anticipated trends and conclusions concerning cumulative impacts for the GOM, Cook Inlet, and Arctic regions, and the Program's incremental contribution to cumulative impacts in these regions, are summarized in Tables 4.6.6-1 (GOM), 4.6.6-2 (Cook Inlet), and 4.6.6-3 (Arctic region). Impact conclusions for potential cumulative impacts on each resource or system are provided in the second column of these tables using the same four-level classification scheme (negligible, minor, moderate or major) as was used for the direct/indirect impacts analyses (see Section 4.1.4). The incremental contribution of the 2012-2017 Program to cumulative impacts on a given resource or system, presented in the third column, is characterized in terms of small, medium, and large. The incremental contribution only takes into account effects from routine operations and expected accidental events and spills under the Program. A potential CDE that may occur in the future (an unexpected, low-probability event) from operations associated with past or future 5-year programs or other cumulative actions is described principally in terms of its direct and indirect impact (if it were to occur) in the body of analysis and is not incorporated into the overall effects or incremental contribution conclusions. In the case of the GOM, the 2010 DWH event has been accounted for in the cumulative impacts analysis as part of the existing baseline.

TABLE 4.6.6-1 Summary of Cumulative Impacts and Incremental Contributions of the Program – Gulf of Mexico

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Water Quality	There are many factors affecting the water quality in the GOM currently and all of these factors are expected to continue into the foreseeable future. In general, these include marine vessel traffic, wastewater discharge, dredging and marine disposal, oil and gas production (in State waters and on the OCS), military operations, LNG terminal operations, LOOP operations, and natural oil seepage along the continental slope. Coastal waters are also affected by numerous other factors, including river inflows, urbanization, agricultural practices, municipal waste discharges, and coastal industry. Climate change is also expected to affect water quality in the coming decades, especially in terms of surface temperature, salinity, vertical stratification, and pH. Another issue of importance to water quality in the GOM concerns an area known as the hypoxic zone, a zone of oxygen depletion (due to high nutrient loads) which is located at the bottom of the continental shelf of Louisiana and Texas. Cumulative impacts on water quality are attributed to a combination of all these factors and, overall, are considered to be **moderate**.	The incremental contribution of routine operations under the Program would be **small** to **medium**. Compliance with NPDES permits and USCG regulations would reduce the magnitude of most impacts. The effects of expected accidental oil spills (most of which are less than 1,000 bbl) would depend upon weather and sea conditions at the spill site, the type of oil spilled, the depth of the spill event, and the volume and rate of spillage; therefore, the incremental contribution of expected oil spills to cumulative water quality impacts could range from **small** to **large**. Water quality impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from **moderate** to **major** if it were to occur. Spill response and cleanup activities could also contribute to water quality impacts.
Air Quality	The ambient air quality in coastal counties along the GOM is relatively good. Coastal counties are in attainment for all criteria pollutants except 8-hr ozone (in some areas of Texas and Louisiana). Most of the human-caused visibility degradation is attributed to sulfate particles, but also to organic or elemental carbon particles, and nitrate particles. The effects of various USEPA regulations and standards are expected to result in a steady, downward trend in future air emissions in the coming decades. Cumulative impacts on air quality in the GOM region are attributed to both offshore and onshore activities. Offshore activities in the GOM are mainly associated with the oil and gas industry, but also include various marine vessel traffic (shipping, fishing, cruise ships), tanker lightering, and military operations. Onshore emission sources include power generation, industrial processing, manufacturing, refineries, commercial and home heating, on-road	The incremental contribution of routine operations under the Program would be **small**, because they would not cause exceedance of the NAAQS in public access areas or affect visibility. The effects of expected accidental oil spills (most of which are less than 1,000 bbl) would be localized and temporary due to dispersion; therefore, the incremental contribution of expected oil spills to cumulative air impacts could range from **small** to **medium**. Air quality impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could be **moderate** if it were to occur. Spill response and cleanup activities could also contribute to air quality impacts.

TABLE 4.6.6-1 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Air Quality (Cont.)	vehicles, and non-road engines (e.g., aircraft, locomotives, and construction equipment). Cumulative impacts on air quality in the GOM over the next 40 to 50 yr are expected to be **minor** to **moderate**.	
Acoustic Environment	Sources of ambient noise in the GOM include wind and wave activity, precipitation (rain and hail), lightening, biological noise, and distant marine vessel traffic. The main sources of anthropogenic noise in the GOM are numerous and include marine vessel traffic, dredging, construction, oil and gas activities (exploration, development, and production), marine mineral mining, geophysical survey, sonar, explosions, and ocean science studies. The quality of the acoustic environment in the GOM would continue to be adversely affected by ongoing and future OCS and non-OCS activities. The magnitude of cumulative impacts on the GOM acoustic environment is time- and location-specific and could range from **minor** to **major**, depending on the ambient acoustic conditions and the nature and combination of noise sources from all OCS and non-OCS activities in the GOM. See also Marine Mammals (this table).	The contribution of routine operations under the Program to cumulative impacts would vary with time and location could range from **small** to **medium** and would depend on the characteristics of the noise sources present. The incremental increase in adverse acoustic environmental impacts from expected accidental oil spills in GOM waters (mainly due to noise sources associated with response and cleanup) would be localized and temporary; therefore, the incremental contribution of expected oil spills (most of which are less than 1,000 bbl) to cumulative noise-related impacts would be **small**. Noise-related impacts associated with an unexpected, low-probability CDE could range from **minor** to **moderate** if it were to occur.
Coastal and Estuarine Habitats		
Barrier Beaches and Dunes	Cumulative impacts result from factors that reduce sediment input to downdrift areas and increase erosion of beaches and dunes. Past actions such as channelization and diversion of Mississippi River flows (through dams and reservoirs) and beach stabilization projects (using groins, jetties, and seawalls) have contributed to sediment deprivation and submergence of coastal lands, and these actions are expected to continue into the foreseeable future. Ongoing and future actions/trends that affect barrier beaches and dunes include those related to oil and gas development in State waters, coastal development (onshore industry and wastewater discharge), marine vessel traffic, recreation, and climate change. Cumulative impacts on barrier beaches and dunes are expected to be **moderate** to **major**.	Routine operations under the Program would result in minor localized impacts primarily due to facility construction, pipeline trenching and landfalls, channel dredging, and vessel traffic. The contribution of the Program to cumulative impacts on beaches and dunes therefore would generally be **small** to **medium**. The incremental impacts of expected accidental oil spills associated with the Program would be **negligible** to **large**, depending on the location, timing, duration, and size of the spill; the proximity of the spill to particular habitats; and the timing and nature of spill containment and cleanup activities. The majority of these spills would be small (less than 50 bbl) and most of them would not likely contact and affect coastal and estuarine habitats.

TABLE 4.6.6-1 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Barrier Beaches and Dunes (Cont.)		Large oil spills (1,000 bbl or greater) or an unexpected, low-probability CDE have the greatest potential to affect extensive areas of shoreline and coastal and estuarine habitats. Although these are rare events, the impacts of such releases on coastal and estuarine habitats could range from **moderate** to **major** if they were to occur.
Wetlands	Cumulative impacts result from direct elimination of wetland habitat by excavation or filling, reduction of sediment inputs, erosion of wetland substrates, and degradation of wetland communities (by reduced water quality or hydrologic changes). Losses of coastal wetlands have been occurring along the GOM coast for decades (especially in Louisiana) and are expected to continue into the foreseeable future. Ongoing and future actions/trends that affect wetlands include those related to oil and gas development in State waters, coastal development (onshore industry and wastewater discharge), marine vessel traffic, dredging/disposal operations, and climate change. Cumulative impacts on coastal wetlands are expected to be **moderate** to **major**.	Same as for barrier beaches and dunes.
Seagrass Beds	Most seagrass beds are in the Eastern GOM where there are no past or present OCS activities and none proposed as part of the Program. The distribution of seagrass beds in coastal waters of Western and Central GOM has diminished in recent decades, possibly due to increased turbidity caused by marine vessel traffic in shallow waters. Ongoing and future actions/trends that affect seagrass habitats include onshore development, commercial and recreational fishing (trawling and anchoring), marine vessel traffic (anchoring), recreation (diving), and climate change. Cumulative impacts on seagrass beds are expected to be **moderate** to **major**.	Same as for barrier beaches and dunes.

TABLE 4.6.6-1 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Benthic and Pelagic Habitats	Cumulative impacts on benthic and pelagic habitats result from activities that disturb ocean bottom or marine habitats, increase sediment suspension (turbidity), degrade water quality, or affect the food supply of biota depending on these resources. Ongoing and future actions/trends that affect these habitats include oil and gas activities in State waters, commercial shipping (including tankers), dredging/disposal operations, anchoring, and climate change. Cumulative impacts on benthic and pelagic habitats are considered to be **moderate** to **major**.	Routine operations under the Program in the GOM could result in mainly temporary and localized impacts from ground disturbance during drilling and pipeline and platform placement, as well as the discharge of drilling muds and cuttings and produced water (sensitive habitats could have long term affects depending on their proximity to these activities). The incremental contribution to cumulative impacts on marine benthic habitats would range from **negligible** to **medium** and would be limited by existing mitigation measures. The incremental impacts of expected accidental oil spills on benthic habitats (most of which are less than 1,000 bbl) would range from **negligible** to **small**, depending on the size, duration, timing, and location of the spill, and the nature (i.e., sensitivity) of the benthic habitat contacted by oil. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could range from **minor** to **moderate** if they were to occur. Major impacts to coral reef habitats could occur if the Flower Gardens Banks are heavily oiled and high mortality occurs.
Essential Fish Habitat	Cumulative impacts on EFH result from any activities that kill managed fish species, disturb ocean bottom habitats, increase sediment suspension (turbidity), degrade water quality, or affect the food supply for fishery resources. Ongoing and future actions/trends that affect EFH include commercial fishing, commercial shipping (and other marine vessel traffic), land development, water quality degradation, dredge/fill and disposal operations, the construction of channel stabilization structures, and climate change. Cumulative impacts on EFH are considered to be **moderate** to **major**.	Routine operations under the Program in the GOM could result in moderate short- and long-term impacts to EFH and managed species, mainly as a result of bottom disturbance during the placement of pipelines and production platforms. The incremental contribution to cumulative impacts on EFH would be **negligible** to **medium** and would be limited by specific lease stipulations. The incremental impacts of expected accidental oil spills on EFH (most of which are less than 1,000 bbl) would range from **negligible** to **medium** depending on the size of the spill, its location, environmental factors, and the uniqueness of the affected EFH. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could result in **moderate** to **major** impacts if they were to occur.

TABLE 4.6.6-1 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Marine and Coastal Fauna		
Marine Mammals	All marine mammals in U.S. waters are protected under the *Marine Mammal Protection Act of 1972*. In the GOM, there are 21 species of cetaceans and one species of Sirenian. Their distribution and abundance is influenced by oceanographic circulation patterns (which is largely wind-driven, but with localized effects from freshwater discharge). Ongoing and future activities or phenomena that affect marine mammals include oil and gas development in State waters, natural phenomena (e.g., hurricanes and diseases), vessel traffic, commercial fishing, pollution, military operations, catastrophes, climate change, and invasive species. Cumulative impacts on marine mammals are considered to be **minor** to **moderate**.	Routine oil and gas-related activities (e.g., seismic surveys, facility construction, normal operations, and, eventually, decommissioning) would result in minor to moderate impacts on marine mammals. Impacts on marine mammals from these activities could include physical injury or death; behavioral disturbances; lethal or sublethal toxic effects; and loss of reproductive, nursery, feeding, and resting habitats. The contribution of Program activities to cumulative impacts on marine mammals would be **negligible** to **medium**. The incremental impacts of expected accidental oil spills (most of which are less than 1,000 bbl) would be **small** to **large**, depending on the location, timing, and volume of the spills; the environmental settings of the spills; and the species exposed to the spills. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from **moderate** to **major** if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to these impacts.
Terrestrial Mammals	The terrestrial mammals considered here are federally endangered GOM coast beach mouse subspecies and the federally endangered Florida salt marsh vole. Present beach mice habitat is no longer of optimal quality because of historical beach erosion, habitat loss and fragmentation from beach front development, and tropical storm damage. Ongoing and future activities or phenomena that affect terrestrial mammals include oil and gas development in State waters, natural phenomena (e.g., hurricanes and tropical storms), industrial and residential development, vehicle traffic, recreation, trash and debris, artificial lighting, climate change (including sea-level rise), and invasive and feral species. Cumulative impacts on terrestrial mammals are considered to be minor to moderate. Cumulative impacts on terrestrial mammals are considered to be **minor** to **moderate**.	Routine oil and gas-related activities (e.g., facility construction, normal operations, and, eventually, decommissioning) are not expected to significantly affect the four federally endangered beach mouse subspecies and the federally endangered Florida salt marsh vole. Negligible to minor impacts may result from consumption of or entanglement in beach trash and debris originating from Program activities. The contribution of the Program activities to cumulative impacts therefore would be **negligible** to **medium**. The incremental impacts of expected accidental oil spills (most of which are less than 1,000 bbl) on these terrestrial mammals would be **small** to **large**, depending on the location, timing, duration, and size of the spill; the proximity of the spill to feeding

TABLE 4.6.6-1 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Terrestrial Mammals (Cont.)		and other important habitats; the timing and nature of spill containment; and the status of the affected animals. An unexpected, low-probability CDE has a greater potential to affect the habitats of beach mice and the Florida salt marsh vole; therefore, impacts could range from **moderate** to **major** if it were to occur. Oil impacts on beach mice would be more likely if a storm surge transports the oil over foredunes.
Marine and Coastal Birds	The GOM is an important pathway for migratory birds. Most migrant birds either directly cross the GOM or move north or south by traversing the GOM or the Florida peninsula. There is a diverse range of habitats that support migratory and resident bird species along the northern GOM coast. Cumulative impacts result from direct injury or mortality of marine and coastal birds due to collisions with onshore and offshore structures, ingestion of trash or debris, or exposure to discharges or emissions; loss or degradation of habitat due to coastal development, climate change, or construction and operations activities; and behavioral disturbance due to commercial and recreational boating and small aircraft traffic. Many bird species are currently experiencing a loss or degradation of habitat due to land development and climate change and these impacts are expected to continue into the foreseeable future. Ongoing and future actions/trends that affect marine and coastal birds include those related to oil and gas development in State waters, coastal development, vessel traffic, dredging operations, and climate change. Cumulative impacts on marine and coastal birds are considered to be **moderate**.	Routine operations may result in localized short-term impacts due to infrastructure construction and marine vessel and aircraft traffic. The contribution of Program activities to cumulative impacts on marine and coastal birds therefore would be **negligible** to **medium**. The incremental contribution of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on marine and coastal birds would be **small** to **large**, depending on the location, timing, duration, and size of the spill; the proximity of the spill to feeding and nesting areas; the timing and nature of spill containment; and the status of the affected birds. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from **moderate** to **major** if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to these impacts.

TABLE 4.6.6-1 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Fish	Fish in the northern GOM live in the water column (pelagic) and on the seafloor or near bottom waters (demersal) along the gradient from the continental shelf to the abyssal plain. Demersal species are much more abundant and diverse in the hard-bottom habitats found in the eastern GOM. Some fish migrate between saltwater and freshwater habitats. For example, anadromous species (such as the Gulf sturgeon and striped bass) spend most of their adulthood in saltwater but spawn in freshwater; catadromous species (such as the American eel) live primarily in freshwater and spawn in saltwater. Cumulative impacts result from OCS and non-OCS activities that generate lethal or sublethal impacts to individuals as well as habitat loss or degradation. Ongoing and future actions/trends that affect fish include oil and gas development in State and Federal waters, commercial and recreational fishing, noise, dredging and trawling operations, explosive platform removal, land loss, and coastal hypoxia. Climate change is also expected to affect fish habitat, productivity, and community structure. Cumulative impacts on fish are considered to be **moderate** to **major**.	The incremental contribution of routine Program activities to these impacts (primarily as a result of disturbance affecting demersal fishes) would be **negligible** to **small**, with the severity of impacts generally decreasing with distance from the disturbance (and a **negligible** contribution to impacts on threatened or endangered fish species). The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on fish would be **negligible** to **medium**, depending on the location, timing, duration, and volume of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range up to **moderate** if it were to occur.
Reptiles	Five species of sea turtles are known to inhabit the GOM. The federally protected American crocodile also lives in the eastern GOM, along Florida's southern coast (in mangrove swamps, brackish bays, and inshore freshwater habitats). Hurricanes in 2005 adversely affected sea turtle nesting sites; and the DWH event caused sea turtle mortality and fouling of habitats. Cumulative impacts on sea turtles result from OCS and non-OCS activities that generate lethal and sublethal impacts that alter or eliminate habitat required for reproduction, feeding, and early life stage development. Ongoing and future actions/trends that affect sea turtles and crocodiles in the GOM include climate change, OCS activities and non-OCS activities such oil and gas development in State and Federal waters, marine vessel traffic, coastal development, dredging, commercial fishing, and land loss. Cumulative impacts on sea turtles are considered to be **moderate** to **major**.	The incremental contribution of routine Program activities to these impacts would be **small** to **medium**, because population-level impacts are not expected. Expected accidental oil spills under the Program (most of which are less than 1,000 bbl) would result in a **negligible** to **medium** incremental increase in the overall impact of exposure to oil from other anthropogenic activities (such as spills from foreign tankers) because such spills are relatively easy to contain and would only affect small areas of habitat (and few individuals). However, large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could potentially result in population-level effects. Although such spills are rare events, impacts could be **major** and long-term if multiple individuals and their habitat (especially nesting habitat) are exposed to oil.

TABLE 4.6.6-1 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Lower Trophic Levels and Invertebrates	Invertebrates (animals without a backbone) occupy multiple habitat types from the intertidal zone to the deep sea. Benthic invertebrates burrow into bottom sediments or move along the sediment surface; pelagic invertebrates either drift with the current or actively swim. In the GOM, invertebrates and lower trophic level organisms include prokaryotes, viruses, protozoa, sponges, jellyfish, worms, mollusks (bivalves, squid, octopi), echinoderms (sea urchins and sea star), and crustaceans (barnacles, crabs, shrimp) among others. Cumulative impacts on invertebrates and lower trophic organisms result from activities that generate lethal or sublethal impacts on individuals as well as habitat loss or degradation. Cumulative impacts result from OCS and non-OCS activities that generate lethal or sublethal impacts to individuals as well as habitat loss or degradation. Ongoing and future actions/trends that affect invertebrates in the GOM include oil and gas development in State and Federal waters, dredging, trawling, land loss, coastal hypoxia, and climate change. Cumulative impacts on invertebrates in the GOM are considered to be **moderate** to **major**.	The contribution of the Program to cumulative impacts (mainly due to bottom-disturbing activities) would be **negligible** to **medium** (with **negligible** impacts to the ESA elkhorn coral), with the severity of the impacts generally decreasing with distance from bottom-disturbing activities. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on invertebrates would be **negligible** to **small**, depending on the location, timing, duration, and size of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could range up to **moderate** if they were to occur.
Areas of Special Concern	In the GOM, Areas of Special Concern are federally managed areas such as marine protected areas, National Marine Sanctuaries, National Parks, and National Wildlife Refuges. A number of other locations have been given special designations by Federal, State, and nongovernmental organizations; these include the National Estuarine Research Reserves, National Estuary Program Sites, and the Military and NASA Use Areas. Cumulative impacts on these resources result from activities that could potentially cause damage to or degradation of fauna or habitats within these areas. Ongoing and future activities or trends that affect these areas in/near the GOM include fishing, diving, dredging operations, marine vessel traffic (and wakes), tankering, trash and debris accumulation (from various sources), onshore infrastructure (e.g., roads and vehicle traffic), and oil and gas development and infrastructure (e.g., pipeline landfalls and onshore facilities). Extreme weather events such as hurricanes and tropical storms also occur regularly in the	Routine operations under the Program could result in a **negligible** to **medium** incremental increase in effects on Areas of Special Concern. Expected oil spills (most of which are less than 1,000 bbl) that may occur during the Program could result in a **negligible** to **small** incremental contribution to cumulative impacts on Areas of Special Concern, depending on spill frequency, location, and volume; the type of product spilled; weather conditions; effectiveness of cleanup operations; and other environmental conditions at the time of the spill. Large spills (1,000 bbl and greater) or an unexpected, low-probability CDE in areas adjacent to the National Parks, NWRs, or National Forests, whether from OCS or non-OCS sources, would also depend on these factors, and could result in **moderate** impacts if they were to occur. Such spills could negatively impact the FGBNMS and coastal habitats and fauna, and could also affect

TABLE 4.6.6-1 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Areas of Special Concern (Cont.)	GOM region and potentially cause damage by increasing shoreline erosion. Climate change has the potential to profoundly affect coral communities within these areas (e.g., in the FGBNMS, the only marine sanctuary in the GOM). Cumulative impacts on Areas of Special Concern in the GOM are considered to be **negligible** to **moderate**.	subsistence uses, commercial or recreational fisheries, and tourism.
Population, Employment, and Income	Population in the GOM coastal region has been steadily increasing since 1980, with the highest growth occurring in Texas. Most of the employment (and earnings) in the region is concentrated in Florida and Texas, with services, retail/wholesale trade, and State and local government being the highest employing sectors. Cumulative economic impacts in the region generally result from direct employment and income created through offshore oil and gas development and the indirect employment/income produced through spending of wages and salaries, and from the procurement of materials and services. Population is affected by the in-migration of workers and their families into the region. The cumulative impacts of ongoing and future OCS program and non-OCS program activities would be considered **beneficial** because these activities would increase employment and earnings in the region over the next 40 to 50 yr.	The Program would add to beneficial impacts, especially in Texas and Louisiana. The incremental contribution of the Program is expected to be **negligible**, however, because the added employment demands are less than 2% of the total GOM coast regional employment. The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be **negligible** to **small** relative to those associated with ongoing and future OCS program and non-OCS program activities. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in **minor** to **moderate** impacts. However, short-term impacts of a CDE could be **major** as a result of lost employment and income, and possible shortages of commodities or services in both coastal and inland areas affected by the spill.
Land Use and Infrastructure	Most of the equipment and facilities supporting offshore oil and gas operations are located in the western and central GOM. Currently, there are hundreds of onshore facilities that support offshore industry. These include ports, refineries, and waste management facilities among others. Cumulative impacts on land use and infrastructure result from demands on roads, utilities, and public services and the need to develop additional onshore facilities to accommodate ongoing and future activities in the GOM. Oil spill response also places stresses on community infrastructure and increases traffic in the affected area. Cumulative impacts on land use and onshore resources could range from **minor** to **major** depending on the nature and location of demands.	The incremental contribution of routine operations under the Program to cumulative impacts would be **negligible** to **small** because the existing infrastructure is considered sufficient to handle the small increases in demands for roads, utilities, and public services related to the Program. Land use–related impacts resulting from expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program include stresses of spill response on community infrastructure, increased traffic in the response area (both onshore and offshore), and temporary restricted access to affected lands (while cleanup is conducted). Such spills would result in a

TABLE 4.6.6-1 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Land Use and Infrastructure (Cont.)		**negligible** to **small** incremental contribution to cumulative impacts on land use and existing infrastructure. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in **minor** to **moderate** impacts if they were to occur.
Commercial and Recreational Fisheries	Commercial fishers are very important to the economies of the GOM coast States. In 2009, commercial fishery landings reached almost 649,000 metric tons, worth more than $629 million. When considering related processor, wholesale, and retail businesses, the GOM seafood industry supports more than 200,000 jobs with related income impacts of $5.5 billion. In 2009, Louisiana led the States in total landings and values, followed by Mississippi, Texas, and Florida. Recreational fishing is also important to the region, with more than 4.5 million people engaged in the activity in 2010. Most of the recreational fish landings in 2010 were in Florida. Cumulative impacts on commercial and recreational fishing result from changes in commercial fishing coasts with offshore oil and gas development, and changes in accessibility of fisheries resources. Ongoing offshore oil and gas development has had both positive and negative effects in the region; the cumulative impacts are considered to be **minor**.	The incremental contribution of routine Program activities to cumulative impacts would be **small**, since these activities would be unlikely to have population- or community-level effects on fishery resources because of the limited timeframe over which most individual activities would occur and because a small proportion of habitat relative to similar available habitat would be affected during a given period. In addition, existing stipulations are in place to prevent or reduce impacts on sensitive habitats such as hard-bottom areas and topographic features. Construction of new platforms could represent a small increase in the availability of desirable recreational fishing locations for recreational anglers. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program would be **medium**, depending on the location, timing, and volumes of spills (among other environmental factors). Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be **moderate** if they were to occur.
Tourism and Recreation	The GOM coastal zone is one of the nation's major recreational regions, with marine fishing and beach-related recreation being top activities. The coast States offer diverse natural and developed landscapes and seascapes, and natural areas are visited by residents and tourists throughout the year. In 2000, Florida along had more than 22 million visitors. Cumulative impacts on tourism and recreation result from changes in accessibility of beach and offshore resources for recreational use and from increases in marine vessel and aircraft traffic in the vicinity of recreational resources. Given the existence of offshore oil and gas development and other ongoing activities in the GOM, cumulative impacts on tourism and recreation are expected to be **minor**.	The incremental contribution of routine operations under the Program to cumulative impacts would be **small**, with potential adverse aesthetic impacts on beach recreation and sightseeing and potential positive impacts on diving and recreational fishing. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on would be **negligible** to **small**, depending on the size, location, and timing of the spill (being greatest if it occurred during the peak recreational season). Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be **minor** to **moderate** if they were to occur.

TABLE 4.6.6-1 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Sociocultural Systems	The counties along the GOM coast are home to a large and heterogeneous population. Within the coastal region, the effects of the offshore oil and gas industry are felt most directly by populations living within the coastal community commuting zone where industry support facilities and the people who work in them are located. Coastal estuaries provide a wealth of wild resources for subsistence harvesting. Though much of the subsistence activities in the GOM region are practiced recreationally, some Native American groups in southern Louisiana depend on fishing, hunting, and gathering for at least part of their domestic subsistence. Commercial Vietnamese fishers also retain a quarter of their catch for family use and barter. Cumulative impacts to sociocultural systems occur when ongoing and future actions (OCS and non-OCS program) cause changes in local populations and social institutions or when jobs are lost or created. Subsistence practices have already been stressed by natural trends associated with climate change (e.g., flood control along the Mississippi River). Given all these factors, cumulative impacts on sociocultural systems are considered to be **moderate**.	The incremental contribution of routine operations under the Program to cumulative impacts would be **small**, since they are more likely to support the existing industry than to create industry growth. Any expansion of deepwater activities will result in jobs that require longer, unbroken periods of work offshore, specialized skills, and potential in-migration of part of the workforce. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program would be **small** to **medium**, especially on localized intertidal resources used by subsistence harvesters. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be **moderate** to **major** if they were to occur, especially if oil from a CDE were to reach the shore. Such spills could lead to long-term closure of fisheries, resulting in social and cultural stress.
Environmental Justice	Environmental justice impacts occur when any activity or trend results in adverse health or environmental impacts that are significantly high and disproportionately affect minority and low-income populations. A large number of minority and low-income individuals are located in the LMA counties along the GOM coast. In this region, the adverse effects of several hurricanes over the past decade are still being felt; these events have been high and disproportionate in their effects on minority and low-income populations, and will likely persist into the foreseeable future. Ongoing and future actions contributing to cumulative impacts in the region include proximity to existing oil and gas infrastructure and any associated health, environmental, and visibility impacts, and climate change (increase in hurricane frequency and intensity). Given all these factors, cumulative impacts on minority and low-income populations are considered to be **moderate** to **major**.	Because of the long-established and well-developed oil and gas industry present in the GOM and the fact that an estimated 75% of activity from the Program would occur in deep and ultra-deep waters, routine operations under the Program are not expected to cause additional environmental justice concerns; their contribution to cumulative impacts on low-income and minority populations therefore would be **negligible**. The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be **negligible** to **medium** because of the movement of oil and gas activities farther away from coastal areas and the demographic pattern of more affluent groups (and fewer low-income and minority populations) living in coastal areas. An unexpected, low probability CDE could result in **moderate** to **major** impacts, depending on the location, size, and timing of the event.

TABLE 4.6.6-1 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Archaeological and Historical Resources	Onshore cultural resources are highly varied in coastal areas of the GOM. Prehistoric cultural resources range from small, temporary use sites to substantial permanent settlements, some from the earliest known human occupation of the areas. Offshore cultural resources mainly consist of shipwrecks dating from as early as the sixteenth century; however, other structures, such as the Ship Shoal Lighthouse, can also be found offshore. Studies indicate that most shipwrecks in the northern GOM are located within a mile of shore; with the highest concentration of ships occurring in areas that experienced high volume marine traffic. Shipwrecks are also thought to be concentrated in the open sea of the eastern GOM. To date, shipwrecks have been found in water depths of up to 1,981 m (6,500 ft). Cumulative impacts to these resources occur when operations involving bottom-disturbing activities come into physical contact with artifacts or their site context, or as a result of waves, currents, and tropical storms. The cumulative impacts of ongoing and future activities (OCS and non-OCS) are not currently known, but could range from **minor** to **moderate**, mainly because activities occurring on the OCS prior to the USDOI's survey requirement, which went into effect in 1973, may already have affected significant sites.	Routine operations could affect significant archaeological and historic resources, especially offshore resources, with construction activities such as platform and pipeline construction, and dredging, potentially damaging or destroying affected resources. Onshore impacts include resource damage or loss, or visual effects and are possible from pipeline landfall, onshore pipeline, and road construction. Anchor drags could adversely affect shipwrecks. The incremental contribution of routine operations under the Program would be **negligible** to **large**, depending on the presence of significant archaeological or historic resources in the area of potential effect. Archaeological surveys that would identify significant cultural resources to be avoided could reduce these impacts. The incremental contribution of oil spills, whether expected oil spills (most of which are less than 1,000 bbl) to cumulative impacts on archaeological and historical resources in Cook Inlet would be **small** to **large**, depending on the presence of significant resources in the area of potential effect and the spill location, timing, duration, and size. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from **minor** to **major** if it were to occur.

TABLE 4.6.6-2 Summary of Cumulative Impacts and Incremental Contributions of the Program – Alaska, Cook Inlet

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Water Quality	Factors affecting the water quality in Cook Inlet include marine vessel traffic, wastewater discharge, dredging and marine disposal, oil and gas production (currently only in State waters), military operations. Water quality is also affected by numerous other factors, including river inflows, urbanization, forest practices, mining, municipal waste discharges, and agriculture. Natural seepage of oil along the west part of the inlet may also be significant. Cumulative impacts on water quality are attributed to a combination of all these factors and, overall, are considered to be **minor** to **moderate**. These impacts may lessen with time since oil and gas production in Cook Inlet is currently in decline.	The incremental contribution of routine operations under the Program would be **small** to **medium**. Compliance with NPDES permits and USCG regulations would reduce the magnitude of most impacts. The effects of expected accidental oil spills (most of which are less than 1,000 bbl) would depend upon weather and sea conditions at the spill site, the type of oil spilled, the depth of the spill event, and the volume and rate of spillage; therefore, the incremental contribution of expected oil spills to cumulative water quality impacts could range from **small** to **large**. Water quality impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from **moderate** to **major** if it were to occur. Spill response and cleanup activities could also contribute to water quality impacts.
Air Quality	Except for a few population centers such as Anchorage, the existing air quality in Alaska is relatively pristine with pollutant levels that are well within the ambient standards. Cumulative impacts on air quality in Cook Inlet are attributed to both offshore and onshore activities. Offshore activities in the region are mainly associated with the oil and gas industry, but also include various marine vessel traffic (shipping, fishing, cruise ships). Onshore emission sources include power generation, industrial plants, mining, commercial and home heating, on-road vehicles, and non-road engines (e.g., aircraft, locomotives, and construction equipment). Overall, cumulative impacts on air quality in Cook Inlet over the next 40 to 50 yr are expected to be **minor** to **moderate**.	The incremental contribution of routine operations under the Program would be **small**, because they would not cause exceedance of the NAAQS in public access areas or affect visibility. The effects of expected accidental oil spills would be localized and temporary due to dispersion; therefore, the incremental contribution of expected oil spills (most of which are less than 1,000 bbl) to cumulative air impacts could range from **small** to **medium**. Air quality impacts associated with an unexpected, low-probability CDE would also be reduced by these factors, and could be **moderate** if it were to occur. Spill response and cleanup activities could also contribute to air quality impacts.

TABLE 4.6.6-2 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Acoustic Environment	Ice, strong tidal fluctuations, and currents all play an important role in the ambient noise levels in Cook Inlet. The main sources of anthropogenic noise are aircraft overflights, marine vessel traffic, oil and gas activities (including seismic surveys and production operations), and other operations such as dredging and pile driving (for new docks). The quality of the acoustic environment in Cook Inlet would continue to be adversely affected by ongoing and future non-OCS program activities and by future OCS program activities (currently there are no existing OCS activities, although seismic studies and exploratory drilling have been conducted in the past). The magnitude of cumulative impacts in the inlet is time- and location-specific and could range from **minor** to **major**, depending on the ambient acoustic conditions and the nature and combination of noise sources from all OCS and non-OCS activities. See also Marine Mammals (this table).	The contribution of routine operations under the Program to cumulative impacts could range from **small** to **medium** and would vary with time and location and would depend on the characteristics of the noise sources present. The incremental increase in adverse acoustic environmental impacts from expected accidental oil spills in Cook Inlet waters (mainly due to noise sources associated with response and cleanup) would be localized and temporary; therefore, the incremental contribution of expected oil spills (most of which are less than 1,000 bbl) to cumulative noise-related impacts would be **small**. Noise-related impacts associated with an unexpected, low-probability CDE could range from **minor** to **moderate** if it were to occur.
Coastal and Estuarine Habitats		
Barrier Beaches and Dunes	Coastal habitats along Cook Inlet are influenced by dynamic tidal currents. Sensitive shoreline habitats in the lower Cook Inlet include marshes, sheltered tidal flats, sheltered rocky shores, and exposed tidal flats. The affects of climate change on coastal habitats in Cook Inlet are also significant. These include sea level rise, which could inundate low-lying coastal habitats, and increase in the incidence of pests and diseases, which could result in increased forest tree mortality. Cumulative impacts on coastal beaches and dunes in Cook Inlet are considered to be **moderate**.	Routine operations under the Program would result in minor localized impacts primarily due to facility construction, pipeline trenching and landfalls, channel dredging, and vessel traffic. The contribution of the Program to cumulative impacts on beaches and dunes therefore would generally be **small** to **medium**. The incremental impacts of expected accidental oil spills associated with the Program would be **negligible** to **large**, depending on the location, timing, duration, and size of the spill; the proximity of the spill to particular habitats; and the timing and nature of spill containment and cleanup activities. The majority of these spills would be small (less than 50 bbl) and most of them would not likely contact and affect coastal and estuarine habitats. Large oil spills (1,000 bbl or greater) or an unexpected, low-probability CDE have the greatest potential to affect extensive areas of shoreline and coastal and estuarine habitats. Although these are rare events, the impacts of such releases on coastal habitats could range from **moderate** to **major** if they were to occur.

TABLE 4.6.6-2 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Wetlands	Cumulative impacts on coastal and estuarine habitats result from the loss of beach and wetland habitat in Cook Inlet. While there are no past or ongoing OCS activities in the Cook Inlet Planning Area, other ongoing and future actions/trends that affect these resources include those related to State oil and gas development, commercial shipping (and other marine vessel traffic), coastal development, discharge of municipal wastes and other effluents, domestic transportation of oil and gas, logging, and climate change. These activities can be reasonably expected to continue into the future. Cumulative impacts on coastal and estuarine habitats in Cook Inlet are considered to be **moderate**.	Same as for barrier beaches and dunes.
Benthic and Pelagic Habitats	Cumulative impacts on marine benthic and pelagic habitats in Cook Inlet result of from any activities that disturb ocean bottom or marine habitats, increase sediment suspension (turbidity), degrade water quality, or affect the food supply of biota depending on these resources. Ongoing and future actions/trends that affect these resources include oil and gas activities in State waters, commercial shipping (including tankers), dredging and disposal of dredging spoils in OCS waters, and anchoring. State oil and gas activities (in upper Cook Inlet) and future OCS activities could affect seafloor and pelagic habitats; these include the generation of noise, well drilling, pipeline placement, subsea production well and platform placement, and routine discharges. Accidental oil spills are also among these actions. Cumulative impacts on benthic and pelagic habitats in Cook Inlet are considered to be **moderate** to **major**.	Routine operations under the Program in Cook Inlet could result in negligible to moderate impacts from ground disturbance during drilling and pipeline and platform placement, as well as the discharge of drilling muds and cuttings and produced water. The incremental contribution to cumulative impacts on marine benthic habitats would range from **negligible** to **medium** and would be limited by existing mitigation measures. The incremental impacts of expected accidental oil spills on benthic habitats (most of which are less than 1,000 bbl) would range from **negligible** to **small**, depending on the size, duration, timing, and location of the spill, and the nature (i.e., sensitivity) of the benthic habitat contacted by oil. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could result in **minor** to **moderate** impacts if they were to occur.

TABLE 4.6.6-2 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Essential Fish Habitat	Cumulative impacts on EFH in Cook Inlet result of from any activities that kill of managed fish species, disturb ocean bottom habitats, increase sediment suspension (turbidity), degrade water quality, or affect the food supply for fishery resources. Ongoing and future actions/trends that affect these resources include land use practices (e.g., logging), point and non-point source pollution, dredging and disposal operations, anchoring, fishing (commercial, subsistence, personal use, and sportfishing), and commercial shipping (including imported oil). Subsistence fishing is subject to harvest limits that reduce the potential for overfishing; and much of Cook Inlet is defined as a nonsubsistence area where subsistence fishing is not authorized. For this reason, the impacts related to subsistence are considered minor. State oil and gas activities (in upper Cook Inlet) and future OCS activities could affect EFH (there are no ongoing OCS activities in the inlet); these include the generation of noise, well drilling, pipeline placement, subsea production well and platform placement, and routine discharges. Accidental oil spills are also among these actions. Cumulative impacts on EFH in the Cook Inlet are considered to be **minor** to **moderate**.	Routine operations under the Program in Cook Inlet could result in moderate short- and long-term impacts to EFH and managed species, mainly as a result of bottom disturbance during the placement of pipelines and production platforms. The incremental contribution to cumulative impacts on EFH would be **negligible** to **medium** and would be limited by specific lease stipulations. The incremental impacts of expected accidental oil spills on EFH (most of which are less than 1,000 bbl) would range from **negligible** to **medium** depending on the size of the spill, its location, environmental factors, and the uniqueness of the affected EFH. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could result in **moderate** to **major** impacts if they were to occur.
Marine and Coastal Fauna		
Marine Mammals	All marine mammals in U.S. waters are protected under the Marine Mammal Protection Act of 1972. There are 17 marine mammal species that occur in Cook Inlet or nearby waters of the Gulf of Alaska; nine of these species are threatened or endangered. Ongoing and future activities or phenomena that affect marine mammals include oil and gas development in State waters, vessel traffic; commercial, recreational, and subsistence fishing; subsistence marine mammal harvests; pollution (and marine debris), military operations, development, climate change, and invasive	Routine oil and gas-related activities (e.g., seismic surveys, facility construction, normal operations, and, eventually, decommissioning) would result in minor to moderate impacts on marine mammals. Impacts on marine mammals from these activities could include physical injury or death; behavioral disturbances; lethal or sublethal toxic effects; and loss of reproductive, nursery, feeding, and resting habitats. The contribution of Program activities to cumulative impacts on marine mammals would be **negligible** to **small**.

TABLE 4.6.6-2 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Marine Mammals (Cont.)	species. Cumulative impacts on marine mammals in the Cook Inlet are considered to be **minor** to **moderate**.	The incremental impacts of expected accidental oil spills (most of which are less than 1,000 bbl) would be **negligible** to **small**, depending on the location, timing, and volume of the spills; the environmental settings of the spills; and the species exposed to the spills. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from **minor** to **major** if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to these impacts.
Terrestrial Mammals	There are about 40 species of terrestrial mammals in south-central Alaska, including brown bears, moose, and river otters. Ongoing and future activities or phenomena that affect terrestrial mammals in the Cook Inlet region include State oil and gas development, aircrafts and vehicle traffic; coastal and community development, timber harvests, hunting; pollution, climate change, and natural catastrophes. Cumulative impacts on terrestrial mammals in the Cook Inlet are considered to be **minor** to **moderate**.	Routine oil and gas-related activities (e.g., facility construction including onshore pipelines, normal operations including aircraft and marine vessel traffic, and, eventually, decommissioning) would result in minor impacts on terrestrial mammals. Impacts on terrestrial mammals from these activities could include physical injury or death; behavioral disturbances; lethal or sublethal toxic effects; and loss of reproductive, nursery, feeding, and resting habitats. The contribution of Program activities to cumulative impacts would be **negligible** to **small**. The incremental impacts of expected accidental oil spills (most of which are less than 1,000 bbl) on terrestrial mammals would be **negligible** to **small**, depending on the location, timing, duration, and size of the spill; the proximity of the spill to feeding and other important habitats; the timing and nature of spill containment; and the status of the affected animals. An unexpected, low-probability CDE has a greater potential to affect the terrestrial habitats; therefore, impacts could range from **minor** to **major** if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to these impacts.

TABLE 4.6.6-2 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Marine and Coastal Birds	There are more than 492 naturally occurring bird species in Alaska. Annual use patterns of Cook Inlet are characterized by the sudden and rapid occurrence of very large numbers of birds in early may followed by a sudden and rapid departure in mid- to late-May. Cumulative impacts result from direct injury or mortality of marine and coastal birds due to collisions with onshore and offshore structures, ingestion of trash or debris, or exposure to discharges or emissions; loss or degradation of habitat due to coastal development, climate change, or construction and operations activities; and behavioral disturbance due to commercial and recreational boating and small aircraft traffic. Many bird species are currently experiencing a loss or degradation of habitat due to land development and climate change and these impacts are expected to continue into the foreseeable future. Ongoing and future actions/trends that affect marine and coastal birds include those related to oil and gas development in State waters, coastal development, vessel traffic, dredging operations, and climate change. Cumulative impacts on marine and coastal birds are considered to be **minor** to **moderate**.	Routine operations may result in localized short-term impacts due to infrastructure construction and marine vessel and aircraft traffic. The contribution of the Program to cumulative impacts on marine and coastal birds therefore would be **negligible** to **medium**. The incremental contribution of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on marine and coastal birds would be **small** to **large**, depending on the location, timing, duration, and size of the spill; the proximity of the spill to feeding and nesting areas; the timing and nature of spill containment; and the status of the affected birds. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from **moderate** to **major** if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to these impacts.
Fish	Cumulative impacts result from OCS and non-OCS activities that generate lethal or sublethal impacts to individuals as well as the loss or degradation of fish habitat. Ongoing and future actions/trends that affect fish in Cook Inlet include oil and gas development in State and Federal waters, commercial and recreational fishing, noise, dredging operations, and wastewater discharge. Climate change is also expected to affect fish habitat, productivity, and community structure. Cumulative impacts on fish in Cook Inlet are considered to be **moderate** to **major**.	The incremental contribution of routine Program activities to these impacts (primarily as a result of disturbance affecting demersal fishes) would be **negligible** to **small**, with the severity of impacts generally decreasing with distance from the disturbance (and a **negligible** contribution to impacts on threatened or endangered fish species). The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on fish would be **negligible** to **medium**, depending on the location, timing, duration, and volume of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range up to **moderate** if it were to occur. Impacts would be greatest if oil were to reach intertidal habitats.

TABLE 4.6.6-2 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Lower Trophic Levels and Invertebrates	Invertebrates (animals without a backbone) occupy the rocky and sandy substrates in the intertidal and subtidal zones. Water column invertebrates in Cook Inlet are composed of a mix of oceanic and coastal species. Several species of copepods (small crustaceans) dominate the macrozooplankton assemblage, peaking in late spring and summer. In lower Cook Inlet, benthic invertebrate communities vary spatially as a result of differences in ice formation, with Arctic species being more common on the western side of the inlet and temperate species being more common on the eastern side. Invertebrates and lower trophic level organisms in the rocky and sandy intertidal zone include echinoderms (sea urchins and sea stars), mollusks (bivalves, limpets, and snails), polychaetes (worms), and crustaceans (barnacles, crabs, and amphipods); clams and polychaetes are predominant in subtidal sandy and muddy sediments. Cumulative impacts result from OCS and non-OCS activities that generate lethal or sublethal impacts to individuals as well as habitat loss or degradation. Ongoing and future actions/trends that affect invertebrates in Cook Inlet include oil and gas development in State and Federal waters, dredging, trawling, and wastewater discharge. Climate change is also expected to affect fish habitat, productivity, and community structure. Cumulative impacts on invertebrates in Cook Inlet are considered to be **moderate** to **major**.	The contribution of the Program to cumulative impacts (mainly due to bottom-disturbing activities) would be **negligible** to **medium**, with the severity of the impacts generally decreasing with distance from bottom-disturbing activities. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on invertebrates would be **negligible** to **small**, depending on the location, timing, duration, and size of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could range up to **moderate** if they were to occur.

TABLE 4.6.6-2 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Areas of Special Concern	The Alaska National Interest Lands Conservation Act of 1980 designated certain public lands in Alaska as National Parks, Wildlife Refuges, Wild and Scenic Rivers, and for the National Wilderness Preservation and National Forest Systems. Many of these occur in the Cook Inlet region. Other Areas of Special Concern include MPAs, National Estuarine Research Reserves, National Estuary Program Areas, MUAs, and NOAA-designated HCAs. In addition, there are several State parks and recreation areas bordering Cook Inlet. Cumulative impacts on these resources result from activities that could potentially cause damage to or degradation of fauna or habitats within these areas. Ongoing and future activities or trends that affect Areas of Special Concern in or near Cook Inlet include fishing, diving, dredging operations, marine vessel traffic (and wakes), tankering, trash and debris accumulation (from various sources), onshore infrastructure (e.g., roads and vehicle traffic), and oil and gas development and infrastructure (e.g., pipeline landfalls and onshore facilities). Cumulative impacts on Areas of Special Concern in the Cook Inlet are considered to be **negligible** to **moderate**.	Routine operations under the Program could result in **negligible** to **medium** incremental increases in effects on national sanctuaries, parks, refuges, and estuarine research reserves. Expected oil spills (most of which are less than 1,000 bbl) that occur during the Program could result in a **negligible** to **small** incremental contribution to cumulative impacts on Areas of Special Concern, depending on spill frequency, location, and volume; the type of product spilled; weather conditions; effectiveness of cleanup operations; and other environmental conditions at the time of the spill. Large spills (1,000 bbl and greater) or an unexpected, low-probability CDE in areas adjacent to the national parks, NWRs, or national forests, whether from OCS or non-OCS sources, would also depend on these factors, and could result in **moderate** impacts if they were to occur. Such spills could negatively impact coastal habitats and fauna, and could also affect subsistence uses, commercial or recreational fisheries, and tourism.
Population, Employment, and Income	Between 2005 and 2009, the Municipality of Anchorage had a population of 280,389, about 45% of the total population in Alaska. Employment is concentrated in Anchorage, which provides about 83% of employment in the region. The largest employing sectors in 2008 were in services, wholesale and retail trade, and State and local government. Oil and gas employment is concentrated in Anchorage, with a total of 8,636 workers employed directly in oil and gas extraction activities, pipeline and refinery activities, and support activities in 2007. Cumulative economic impacts result from direct employment and income created through the development of offshore oil and gas resources and the indirect employment and income produced through the spending of wages and salaries and from the procurement of materials and services in the region. The cumulative impacts of future OCS program and ongoing and future non-OCS program activities would be considered **beneficial** because these activities would increase employment and earnings in the region over the next 40 to 50 yr.	The Program would add to beneficial impacts, especially on the Kenai Peninsula and in Anchorage. The incremental contribution of the Program is expected to be **small**, however, because the added employment demands are less than 5% of baseline levels in Alaska. The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be **negligible** to **small** relative to those associated with future OCS program and ongoing and future non-OCS program activities. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in **minor** to **moderate** impacts. However, in the short-term, impacts of a CDE could be **major** as a result of lost employment, income, and property value; increased traffic congestion; increased cost of service provision; and possible shortages of commodities or services.

TABLE 4.6.6-2 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Land Use and Infrastructure	Anchorage is the State center for scheduled aircraft and the regional center for chartered aircraft. It has a cargo facility served by a railroad connecting it to Alaska's interior and the port of Seward and two military bases (Joint Base Elmendorf-Richards on). It is also the center for the State's overall road network. Much of the on-land infrastructure around Cook Inlet supports offshore oil and gas development; facilities/complexes include the Trading Bay production facility, the Tesoro Refinery, the Drift River Terminal, and the Nikiski complex (Agrium and ConocoPhillips LNG). Cumulative impacts on land use and infrastructure result from demands on roads, utilities, and public services and the need to develop additional onshore facilities to accommodate ongoing and future activities in the inlet. Oil spill response also places stresses on community infrastructure and increases traffic in the affected area. Cumulative impacts on land use and onshore resources could range from **minor** to **major**, depending on the nature and location of demands.	The incremental contribution of routine operations of the Program to cumulative impacts in the GOM would be **negligible** to **small** because the Program would not introduce new kinds of activities that would alter existing land uses. Land use–related impacts resulting from expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program include stresses of spill response on community infrastructure, increased traffic in the response area (both onshore and offshore), and temporary restricted access to affected lands (while cleanup is conducted). Such spills would result in a **small** incremental contribution to cumulative impacts on land use and existing infrastructure. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in **moderate** impacts if they were to occur.
Commercial and Recreational Fisheries	Commercial fisheries of Cook Inlet and the Gulf of Alaska target groundfish, Pacific halibut, Pacific salmon, herring, crab, shrimp, clams, scallops, sea urchins, and sea cucumbers. The groundfish fisheries accounted for the largest share ($640 million, or about 48%) of the ex-vessel value of all commercial fisheries in Alaska in 2009. Recreational fishing in the Cook Inlet region includes marine sport fishing, freshwater fishing, and shellfish gathering activities, which contribute substantially to the area's economy. On the western bank of upper Cook Inlet, there are recreational fisheries for razor clams, several species of hardshell clams, and crab. Cumulative impacts on commercial and recreational fishing result from changes in commercial fishing costs with offshore oil and gas development and changes in accessibility of fishery resources. The cumulative impacts on commercial and recreational fisheries in Cook Inlet are considered to be **minor**.	The incremental contribution of routine operations under the Program to cumulative impacts in Cook Inlet would be **small**, since these activities would be unlikely to have population-level effects on fishery resources or result in long-term loss of fishery resources. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on would be **negligible** to **medium**, depending on the location, timing, and volumes of spills (among other environmental factors). Small spills are unlikely to affect a large number of fish or have a substantial effect on recreational fishing before dilution and weathering reduced concentrations of oil in the water. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be **moderate** if they were to occur.

TABLE 4.6.6-2 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Tourism and Recreation	Opportunities for recreational activities such as hunting, hiking, boating, wildlife viewing, and sightseeing are abundant in the Cook Inlet region. Visitors reach the area via tour ships and ferries, as well as helicopters, small aircraft, and fishing charters. The Kenai Peninsula and Prince William Sound receive the heaviest recreational use by residents and nonresidents, and are in close proximity to Cook Inlet and Anchorage. The Chugach National Forest attracts hikers, campers, and other users. Cumulative impacts on tourism and recreation result from changes in accessibility of beach and offshore resources for recreational use, and from increases in marine vessel and aircraft traffic in the vicinity of recreational resources; these impacts are expected to be **minor**.	The incremental contribution of routine operations under the Program to cumulative impacts in Cook Inlet would be **small**, with potential adverse aesthetic impacts on sightseeing, boating, fishing, and hiking activities in the inlet. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program would be **negligible** to **small**, depending on the size, location, and timing of the spill (being greatest if it occurred during the peak recreational season). Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be **minor** to **moderate** if they were to occur.
Sociocultural Systems	The region surrounding Cook Inlet includes economically complex cities such as Anchorage and its suburbs, the largest urban community in the State; towns such as Kenai, Soldotna, and Nikiski that are centers of the oil and gas industry; smaller towns such as Port Lions that depend on commercial fishing; and small predominantly Alaska Native communities. Subsistence harvesting plays some role in communities of all types. Cumulative impacts to sociocultural systems occur when ongoing and future actions (OCS and non-OCS programs) cause changes in local populations and social institutions or when jobs are lost or created. Subsistence harvesting could also be affected by activities that affect marine fauna, such as increases in airborne or subsea noise (e.g., aircraft or marine vessel traffic, seismic surveys, drilling) or degradation of water quality (e.g., fuel or oil spills, chemical releases, or dredging operations that increase turbidity), or that necessitate changes in subsistence fishing practices. Cumulative impacts on sociocultural systems in Cook Inlet as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be **minor** to **moderate** over the next 40 to 50 yr.	The incremental contribution of routine operations under the Program to cumulative impacts would be **small**, since they would not introduce new kinds of activities that would alter existing socioeconomic systems. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on would be **small** to **large**, especially in intertidal and estuarine zones used by subsistence harvesters. Impacts associated with an unexpected, low-probability CDE could be **major** if it were to occur, especially if resources important to subsistence harvesters, including intertidal resources, migrating fishes, and fishes with strong ties to the shore, were affected.

TABLE 4.6.6-2 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Environmental Justice	Environmental justice impacts occur when any activity or trend (OCS program or non-OCS program related) results in adverse health or environmental impacts that are significantly high and disproportionately affect minority and low-income populations. A large number of minority and low-income individuals live in the south-central Alaska region; however, the number of minority individuals in each of the local boroughs does not exceed 50% of the population or the State average by 20 percentage points or more in any of the boroughs. Thus, there is no minority population in south-central Alaska. Likewise, there are no low-income populations in any of the local boroughs. Subsistence hunting and fishing are an important part of the economies in rural communities. Although there are no environmental justice concerns here, cumulative impacts on local communities could result from changes in the proximity of onshore oil and gas infrastructure and to marine vessel and aircraft traffic. Ongoing and future oil and gas development would continue to affect populations in some regions of Cook Inlet by increasing the proximity to existing oil and gas infrastructure and associated health, environmental, and visibility impacts. Given these factors, cumulative impacts on local populations are considered to be **moderate** to **major**.	The incremental contribution of routine operations under the Program would be small, depending on the proximity of onshore pipelines and offshore infrastructure to communities and their subsistence harvest areas, but are not expected to cause additional environmental justice concerns; their contribution to cumulative impacts on low-income and minority populations therefore would be **small**. The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be **negligible** to **small**. Large spills (1,000 bbl or greater) or an unexpected CDE could result in **moderate** to **major** impacts on the Alaska Native population, especially if subsistence resources were diminished or tainted as a result of the spill. Mitigation measures, cooperative agreements between Native and industry groups, and government-to-government consultations are designed to limit the effects from oil spills and routine operations.
Archaeological and Historical Resources	Onshore archaeological and historic resources occur along the shoreline surrounding Cook Inlet; the predominant types of prehistoric features are house pits containing household and subsistence artifacts like stone lamps, sinkers, and arrowheads. Historic sites onshore consist of early Russian houses, churches, roadway inns, fish camps, and mining camps. Little research has been done to characterize prehistoric resources in the offshore waters of Cook Inlet; however, it is likely that high-energy tidal movement has removed at least some resources from their original resting place. The best preserved shipwrecks are likely to be found on the OCS, because wave action and ice are less likely to contribute to the breakup of ships in deeper waters. Cumulative impacts to these resources occur when operations involving	Routine operations could affect significant archaeological and historic resources, especially offshore resources, with construction activities such as platform and pipeline construction potentially damaging or destroying affected resources. Onshore impacts include resource damage or loss, or visual effects and are possible from pipeline landfall, onshore pipeline, and road construction. Anchor drags could adversely affect shipwrecks. The incremental contribution of routine operations under the Program is expected to be **negligible** to **large**, depending on the presence of significant archaeological or historic resources in the area of potential effect. Archaeological surveys that would identify significant cultural resources to be avoided could reduce these impacts.

TABLE 4.6.6-2 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Archaeological and Historical Resources (Cont.)	bottom-disturbing activities (e.g., channel dredging) come into physical contact with artifacts or their site context, or as a result of natural phenomena such as high-energy waves and currents, ice gouging, and thermokarst collapse. The cumulative impacts of future OCS and ongoing and future non-OCS activities are not currently known, but could range from **minor** to **moderate**, mainly because activities occurring on the OCS prior to the USDOI's survey requirement, which went into effect in 1973, may already have affected (i.e., damaged or destroyed) significant sites.	The incremental contribution of oil spills, whether expected oil spills (most of which are less than 1,000 bbl) to cumulative impacts on archaeological and historical resources in Cook Inlet would be **small** to **large**, depending on the presence of significant resources in the area of potential effect and the spill location, timing, duration, and size. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from **minor** to **major** if it were to occur.

TABLE 4.6.6-3 Summary of Cumulative Impacts and Incremental Contributions of the Program – Alaska, Arctic Region

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Water Quality	Factors affecting the water quality in the Beaufort and Chukchi Seas include marine vessel traffic, wastewater discharge, oil and gas production (currently only in State waters), military operations. Water quality is also affected by numerous other factors, including river inflows, mining, and municipal waste discharges. Cumulative impacts on water quality are attributed to a combination of all these factors and, overall, are considered to be **moderate**. Impacts related to marine vessel traffic in the Beaufort and Chukchi Seas (especially shipping and research vessels, icebreakers, and cruise ships) would likely increase in the coming decades as the open water season begins earlier and ends later (an effect of climate change).	The incremental contribution of routine operations under the Program would be **small** to **medium.** Compliance with NPDES permits and USCG regulations would reduce the magnitude of most impacts. The effects of expected accidental oil spills (most of which are less than 1,000 bbl) would depend upon weather and sea conditions at the spill site, the type of oil spilled, the depth of the spill event, and the volume and rate of spillage; therefore, the incremental contribution of expected oil spills to cumulative water quality impacts could range from **small** to **large**. Water quality impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from **moderate** to **major** if it were to occur. Spill response and cleanup activities could also contribute to water quality impacts.
Air Quality	The Arctic region has a low population. Barrow is the largest city in the North Slope Borough with a population (in 2010) of just 4,600. The primary industrial emissions in the region are associated with the oil and gas industry, power generation, small refineries, paper mills, and mining. Currently, the North Slope Borough is designated as an unclassified/attainment area for all criteria pollutants. The region does experience air pollution problems (e.g., Arctic haze), however, due to long-range transport of air pollutants from industrial parts of northern Eurasia and North America. Overall, cumulative impacts on air quality in the Arctic over the next 40 to 50 yr are expected to be **minor** to **moderate**.	The incremental contribution of routine operations under the Program would be **small** because they would not significantly increase onshore airborne pollutants or affect visibility. The effects of expected accidental oil spills (most of which are less than 1,000 bbl) would be localized and temporary due to dispersion; therefore, the incremental contribution of expected oil spills to cumulative air impacts could range from **small** to **medium**. Air quality impacts associated with an unexpected, low-probability CDE would also be reduced by these factors (depending on the season), and could be **moderate** if it were to occur. Spill response and cleanup activities could also contribute to air quality impacts.

TABLE 4.6.6-3 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Acoustic Environment	Arctic waters are a unique acoustic environment mainly because of the presence of ice, which can contribute significantly to ambient sound levels (e.g., ice cracking generates noise; ice deformation generates low-frequency noise). Ambient levels of natural sound can vary dramatically between and within seasons. During open water season, wind and waves are important sources of ambient sounds. The main sources of anthropogenic noise are aircraft overflights, marine vessel traffic, oil and gas activities (including seismic surveys and production operations), human settlements, and military activities. The quality of the acoustic environment in the Beaufort and Chukchi Seas would continue to be adversely affected by ongoing and future non-OCS program activities and by future OCS program activities (currently there are no existing OCS activities, although seismic studies and exploratory drilling have been conducted in the past). The magnitude of cumulative impacts in the Beaufort and Chukchi Seas is time- and location-specific and could range from **minor** to **major**, depending on the ambient acoustic conditions and the nature and combination of noise sources from all OCS and non-OCS activities.	The contribution of routine operations under the Program to cumulative impacts could range from **small** to **medium** and would vary with time and location and would depend on the characteristics of the noise sources present. The incremental increase in adverse acoustic environmental impacts from expected accidental oil spills in Arctic waters (mainly due to noise sources associated with response and cleanup) would be localized and temporary; therefore, the incremental contribution of expected oil spills (most of which are less than 1,000 bbl) to cumulative noise-related impacts would be **small**. Impacts associated with an unexpected, low-probability CDE could range from **minor** to **moderate** if it were to occur.
Coastal and Estuarine Habitats		
Barrier Beaches and Dunes	Arctic coastal habitats are greatly influenced by a short growing season and extremely cold winters; onshore sediments are underlain by permanently frozen soil (permafrost). They are also greatly affected by the dynamics of sea ice, which dominates coastal habitats during most of the year. The Arctic coastline is highly disturbed due to the movement of sea ice that frequently is pushed onshore, scouring and scraping the coastline. The affects of climate change on Arctic habitats are also significant. These include decreases in sea ice cover, warming of permafrost, a longer growing season, and changes in precipitation. Portions of the coast have experienced considerable erosive losses (up to 457 m [1,500 ft]) over the past few decades; the erosion rate in areas of the Beaufort Sea coast more than doubled between 1955 and 2005. Projections for future climate change indicate that these changes are expected to continue.	Routine operations under the Program would result in minor localized impacts primarily due to facility construction, pipeline trenching and landfalls, channel dredging, and marine vessel traffic. The contribution of the Program to cumulative impacts on beaches and dunes therefore would generally be **small** to **medium**. The incremental impacts of expected accidental oil spills associated with the Program would be **negligible** to **large**, depending on the location, timing, duration, and size of the spill; the proximity of the spill to particular habitats; and the timing and nature of spill containment and cleanup activities. The majority of these spills would be small (less than 50 bbl) and most of them would not likely contact and affect coastal and estuarine habitats. Large oil spills (1,000 bbl or greater) or an unexpected, low-probability CDE have

TABLE 4.6.6-3 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Barrier Beaches and Dunes (Cont.)	Cumulative impacts on barrier beaches and dunes result from factors that increase erosion of beach and dunes, such as disturbance of dune vegetation or beach and dune substrates. Increases in wave action also contribute to the erosion of beaches. Accidental oil spills may also affect these resources. While there are no past or ongoing OCS activities in the Beaufort Sea and Chukchi Sea Planning Areas (other than exploratory drilling), other ongoing and future actions/trends that affect beaches and sand dunes include those related to State oil and gas development, commercial shipping (and other marine vessel traffic), coastal development, and climate change. These activities can be reasonably expected to continue into the future. Cumulative impacts on coastal and estuarine habitats in the Arctic region are considered to be **moderate**.	the greatest potential to affect extensive areas of shoreline and coastal and estuarine habitats. Although these are rare events, the impacts of such releases on coastal habitats could range from **moderate** to **major** if they were to occur.
Benthic and Pelagic Habitats	Cumulative impacts on marine benthic and pelagic habitats in the Arctic region result of from any activities that disturb ocean bottom or marine habitats, increase sediment suspension (turbidity), degrade water quality, or affect the food supply of biota depending on these resources. Ongoing and future actions/trends that affect these resources include oil and gas activities in State waters, commercial shipping (including tankers), dredging and disposal of dredging spoils in OCS waters, and anchoring. State oil and gas activities (especially along the Beaufort Sea coastline) and future OCS activities could affect seafloor and pelagic habitats; these include the generation of noise, well drilling, pipeline placement, subsea production well and platform placement, and routine discharges. Accidental oil spills are also among these actions. Cumulative impacts on benthic and pelagic habitats in the Arctic region are considered to be **moderate** to **major**.	Routine operations under the Program in the Arctic region could result in impacts from ground disturbance during drilling and pipeline and platform placement, as well as the discharge of drilling muds and cuttings and produced water (sensitive habitats could have long term affects depending on their proximity to these activities). The incremental contribution to cumulative impacts on marine benthic habitats would range from **negligible** to **medium** and would be limited by existing mitigation measures. The incremental impacts of expected accidental oil spills on benthic habitats (most of which are less than 1,000 bbl) would range from **negligible** to **small**, depending on the size, duration, timing, and location of the spill, and the nature (i.e., sensitivity) of the benthic habitat contacted by oil. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could result in **minor** to **moderate** impacts if they were to occur.

TABLE 4.6.6-3 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Essential Fish Habitat	Cumulative impacts on EFH in the Arctic region result of from any activities that kill of managed fish species, disturb ocean bottom habitats, increase sediment suspension (turbidity), degrade water quality, or affect the food supply for fishery resources. Ongoing and future actions/trends that affect these resources include subsistence fishing, commercial shipping (including tankers and other marine vessels), coastal modifications, hardrock mining, dredging and disposal operations, anchoring, and climate change. Commercial fishing does not occur in the Beaufort Sea and Chukchi Sea Planning Areas. Sportfishing in the Arctic region is currently a minor activity, but could increase if regulations change and warming temperatures allow an increase in marine vessel traffic. State oil and gas activities (especially along the Beaufort Sea coastline) and future OCS activities could affect EFH; these include the generation of noise, well drilling, pipeline placement, subsea production well and platform placement, and routine discharges. Accidental oil spills are also among these actions. Cumulative impacts on EFH in the Arctic region are considered to be **moderate** to **major**.	Routine operations under the Program in the Arctic region could result in moderate short- and long-term impacts to EFH and managed species, mainly as a result of bottom disturbance during the placement of pipelines and production platforms. The incremental contribution to cumulative impacts on EFH would be **negligible** to **medium** and would be limited by specific lease stipulations. The incremental impacts of expected accidental oil spills on EFH (most of which are less than 1,000 bbl) would range from **negligible** to **medium** depending on the size of the spill, its location, environmental factors, and the uniqueness of the affected EFH. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could result in **moderate** to **major** impacts if they were to occur.
Marine and Coastal Fauna		
Marine Mammals	There are 15 species of marine mammals in the Arctic Region, four of which are listed as threatened or endangered. Ongoing and future activities or phenomena that affect marine mammals include oil and gas development in State waters; vessel traffic; commercial, recreational, and subsistence fishing; marine mammal subsistence harvests; pollution (and marine debris); development; climate change (including temporal and spatial changes in sea ice); diseases; and natural catastrophes. The contribution of the Program activities to cumulative impacts would be small; however, the incremental impacts of accidental oil spills would be small to large, depending on spill location, timing, duration, and size. Cumulative impacts on marine mammals in the Arctic region are considered to be **minor** to **moderate**.	Routine oil and gas-related activities (e.g., seismic surveys, facility construction, normal operations, and, eventually, decommissioning) would result in minor to moderate impacts on marine mammals. Impacts on marine mammals from these activities could include physical injury or death; behavioral disturbances; lethal or sublethal toxic effects; and loss of reproductive, nursery, feeding, and resting habitats. The contribution of Program activities to cumulative impacts would be **negligible** to **small**. The incremental impacts of expected accidental oil spills (most of which are less than 1,000 bbl) would be **negligible** to **large**, depending on the location, timing, and volume of the spills; the environmental settings of the spills; and the species exposed to the

TABLE 4.6.6-3 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Marine Mammals (Cont.)		spills. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from **minor** to **major** if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to these impacts.
Terrestrial Mammals	There are about 30 species of terrestrial mammals in the Arctic region. These include the brown bear, caribou, muskox, the Arctic fox, brown lemming, and wolverine, among others. Ongoing and future activities or phenomena that affect terrestrial mammals include State oil and gas development, aircrafts and vehicle traffic; coastal and community development, timber harvests, hunting; pollution, climate change, and natural catastrophes. Cumulative impacts on terrestrial mammals in the Arctic region are considered to be **minor** to **moderate**.	Routine oil and gas-related activities (e.g., facility construction including onshore pipelines, normal operations including vehicle and aircraft traffic, and, eventually, decommissioning) would result in minor impacts on terrestrial mammals. Impacts on terrestrial mammals from these activities could include physical injury or death; behavioral disturbances; lethal or sublethal toxic effects; and loss of reproductive, nursery, feeding, and resting habitats. The contribution of Program activities to cumulative impacts would be **negligible** to **small**. The incremental impacts of expected accidental oil spills (most of which are less than 1,000 bbl) on terrestrial mammals would be **negligible** to **large**, depending on the location, timing, duration, and size of the spill; the proximity of the spill to feeding and other important habitats; the timing and nature of spill containment; and the status of the affected animals. An unexpected, low-probability CDE has a greater potential to affect the terrestrial habitats; therefore, impacts could range from **minor** to **major** if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to these impacts.
Marine and Coastal Birds	There are more than 492 naturally occurring bird species in Alaska. Because of the limited seasonal nature of open water and snow-free conditions, the Beaufort and Chukchi Seas support a much smaller number of birds than lower parts of Alaska. Most of the birds occurring in the Arctic region are migratory, being present for all or part of the period between May and early November. Cumulative impacts result from direct injury or mortality of marine and coastal birds due to collisions with onshore and offshore structures,	Routine operations may result in localized short-term impacts due to infrastructure construction and marine vessel and aircraft traffic. The contribution of the Program to cumulative impacts on marine and coastal birds therefore would be **negligible** to **medium**. The incremental contribution of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on marine and coastal birds would be **small** to **large**, depending on the

TABLE 4.6.6-3 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Marine and Coastal Birds (Cont.)	ingestion of trash or debris, or exposure to discharges or emissions; loss or degradation of habitat due to coastal development, climate change, or construction and operations activities; and behavioral disturbance due to commercial and recreational boating and small aircraft traffic. Many bird species are currently experiencing a loss or degradation of habitat due to land development and climate change and these impacts are expected to continue into the foreseeable future. Ongoing and future actions/trends that affect marine and coastal birds include those related to oil and gas development in State waters, coastal development, vessel traffic, and climate change. Cumulative impacts on marine and coastal birds are considered to be **minor** to **moderate**.	location, timing, duration, and size of the spill; the proximity of the spill to feeding and nesting areas; the timing and nature of spill containment; and the status of the affected birds. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from **moderate** to **major** if it were to occur. Spill response activities (e.g., vessel traffic, *in situ* burning, and the use of dispersants) could add to these impacts.
Fish	The Beaufort and Chukchi Seas support at least 98 fish species, with the greatest number found in Chukchi Sea. Fish in the Arctic region must survive extended seasonal periods of frigid and harsh conditions such as reduced light, seasonal darkness, prolonged low temperatures, and ice cover. Food resources tend to be scare during winter months, so most of a fish's yearly food supply must be acquired during the brief Arctic summer. Many species found in the Beaufort and Chukchi Seas are at the northern limits of their range. Subsistence fishing has a long history in the region (commercial fishing occurred infrequently in the past). Cumulative impacts result from activities that generate lethal or sublethal impacts to individuals as well as the loss or degradation of fish habitat. Cumulative impacts result from OCS and non-OCS activities that generate lethal or sublethal impacts to individuals as well as the loss or degradation of fish habitat. Ongoing and future actions/trends that affect fish include oil and gas development in State and Federal waters, noise, dredging operations, and the potential effects of climate change such as the loss of sea ice, habitat alteration, and changes in fish productivity and community structure. Cumulative impacts on fish in Arctic waters are considered to be **moderate** to **major**.	The incremental contribution of routine Program activities to these impacts (primarily as a result of disturbance affecting demersal fishes) would be **negligible** to **small**, with the severity of impacts generally decreasing with distance from the disturbance (and a **negligible** contribution to impacts on threatened or endangered fish species). The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on fish would be **negligible** to **medium**, depending on the location, timing, duration, and volume of spills; the proximity of spills to particular habitats; and the timing and nature of spill containment and cleanup activities. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range up to **moderate** if it were to occur. Impacts would be greatest if oil were to reach intertidal habitats.

TABLE 4.6.6-3 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Lower Trophic Levels and Invertebrates	Invertebrates (animals without a backbone) occur in various intertidal and deepwater habitats in the Beaufort and Chukchi Seas. Benthic invertebrates are predominantly echinoderms, polychaetes, sponges, anemones, bivalves, gastropods, and bryozoans. The most common water column macroinvertebrates in the Arctic region are the copepods. Larger invertebrates tend to be sparse in much of the Beaufort Sea relative to the Chukchi Sea, where echinoderms, crabs, and shrimp are more abundant. Zooplankton productivity is highly seasonal. At the lowest trophic levels, microbes such as bacteria and protists are important in Arctic waters for breaking down and recycling nutrients and organic matter. Cumulative impacts on invertebrates and lower trophic organisms result from activities that generate lethal or sublethal impacts to individuals as well as habitat loss or degradation. Cumulative impacts result from OCS and non-OCS activities that generate lethal or sublethal impacts to individuals as well as habitat loss or degradation. Ongoing and future actions/trends that affect invertebrates include oil and gas development in State and Federal waters, dredging, trawling, and the potential effects of climate change such as the loss of sea ice, changes in invertebrate habitat and changes in invertebrate productivity and community structure. Cumulative impacts on invertebrates in Arctic waters are considered to be **moderate** to **major**.	The contribution of the Program to cumulative impacts (mainly due to bottom-disturbing activities) would be **negligible** to **medium**, with the severity of the impacts generally decreasing with distance from bottom-disturbing activities. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on invertebrates would be **negligible** to **small**, depending on the location of the spill and the season in which the spill occurred. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE would also depend on these factors, and could range up to **moderate** if they were to occur.

TABLE 4.6.6-3 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Areas of Special Concern	The Alaska National Interest Lands Conservation Act of 1980 designated certain public lands in Alaska as National Parks, Wildlife Refuges, Wild and Scenic Rivers, and as designated for the National Wilderness Preservation and National Forest Systems. Some of these occur in the Arctic region. Other Areas of Special Concern include MPAs; there are no MUAs, National Estuarine Research Reserves, National Estuary Program Areas, or NOAA-designated HCAs in or adjacent to the Beaufort Sea or Chukchi Sea Planning Area. Cumulative impacts on these resources result from activities that could potentially cause damage to or degradation of fauna or habitats within these areas. Ongoing and future activities or trends that affect Areas of Special Concern in or near Arctic waters include fishing, diving, dredging operations, marine vessel traffic (and wakes), tankering, trash and debris accumulation (from various sources), onshore infrastructure (e.g., roads and vehicle traffic), and oil and gas development and infrastructure (e.g., pipeline landfalls and onshore facilities). Cumulative impacts on Areas of Special Concern in Arctic waters are considered to be **negligible** to **moderate**. The impacts of activities taking place within the Areas of Special Concern located onshore, such as National Parks and National Forests, are regulated through permitting processes.	Routine operations Routine operations under the Program could result in **negligible** to **medium** incremental increases in effects on national parks and wildlife refuges. Expected oil spills (most of which are less than 1,000 bbl) that occur during the Program could result in a **negligible** to **small** incremental contribution to cumulative impacts on Areas of Special Concern, depending on spill frequency, location, and volume; the type of product spilled; weather conditions; effectiveness of cleanup operations; and other environmental conditions at the time of the spill. Large spills (1,000 bbl and greater) or an unexpected, low-probability CDE in areas adjacent to the National Parks and NWRs, whether from OCS or non-OCS sources, would also depend on these factors, and could result in **moderate** impacts if they were to occur. Such spills could negatively impact coastal habitats and fauna, and could also affect subsistence uses.
Population, Employment, and Income	The population in the Beaufort Sea and Chukchi Sea Planning Areas is concentrated in Barrow. It increased at an average annual rate of 3.6% between 1980 and 1990, and 2.1% between 1990 and 2000; it decreased by 1.0% between 2000 and 2009. The components of population increase include the natural increase due to births and net positive domestic migration; the population trend is uncertain over the next 50 yr and will likely depend on the availability of jobs. Most communities in the borough have a high percentage of American Indian or Alaska Natives. Cumulative impacts of future OCS program and ongoing and future non-OCS program activities	The Program would add to beneficial impacts. The incremental contribution of routine operations under the Program is expected to be **small**, however, because the added employment demands are less than 10% of total Alaska employment. The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be **negligible** to **small** relative to those associated with future OCS program and ongoing and future non-OCS program activities. Large spills (1,000 bbl or greater) or an unexpected CDE could result in

TABLE 4.6.6-3 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Population, Employment, and Income (Cont.)	would be considered **beneficial** because these activities would increase employment and earnings in the region over the next 40 to 50 yr (although rural Alaskan employment in the petroleum industry, especially among Alaska Natives, would likely remain relatively low).	**minor** to **moderate** impacts. In the short-term, impacts of a CDE could be major as a result of lost employment, income, and property value; increased traffic congestion; increased cost of service provision; and possible shortages of commodities or services.
Land Use and Infrastructure	Land use in much of the Arctic region is not intense, with oil and gas-related development (onshore and offshore in State waters) and subsistence being the predominant uses. There are only a few small communities in the area, the largest of which is Barrow. Barrow is the economic, transportation, and administrative center for the North Slope Borough. Transportation-related infrastructure is minimal, but concentrated in the Prudhoe Bay oil field area. Marine shipping to North Slope communities is by barge and by lightering of cargo to shore because of the shallow coastal waters and the lack of dredging and heavy-lift equipment. Paved and unpaved roads are generally limited to the area within communities. During the winter, many residents travel by snowmobile. Airports and related service facilities are also limited. Most of the oil and gas-related infrastructure in the Arctic region is along the Beaufort Sea coastline. The Prudhoe Bay/Kuparuk oil field infrastructure is served by about 480 km (300 mi) of interconnected gravel roads, 640 km (400 mi) of pipeline routes, and related processing and distribution facilities. Cumulative impacts on land use and infrastructure result from demands on roads, utilities, and public services and the need to develop additional onshore facilities to accommodate ongoing and future activities in the region. Oil spill response also places stresses on community infrastructure and increases traffic in the affected area. Cumulative impacts on land use and onshore resources could range from **minor** to **major**, depending on the nature and location of demands.	The incremental contribution of routine operations under the Program to cumulative impacts in the Arctic region would be **small** to **medium** because of land use changes needed for new onshore pipeline construction and transportation network. Land use–related impacts resulting from expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program include stresses of spill response on community infrastructure, increased traffic in the response area (both onshore and offshore), and temporary restricted access to affected lands (while cleanup is conducted). Such spills would result in a **small** incremental contribution to cumulative impacts on land use and existing infrastructure. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in **moderate** to **major** impacts if they were to occur.

TABLE 4.6.6-3 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Commercial and Recreational Fisheries	There currently is no commercial fishing and little data on recreational fishing in the Beaufort or Chukchi Seas (although the North Pacific Fishery Management Council has concluded that there are few recreational fisheries in these waters). Sport fishing likely occurs in coastal areas of larger population centers such as Barrow. Subsistence fishing is widespread in coastal areas of the Arctic; fisherman target Pacific herring, Dolly Varden char, whitefish, Arctic cod, and sculpin. Given the importance of fishing to local communities in the Arctic region, the most important cumulative impacts would result from any activities that cause a decline in fish availability for subsistence harvest. The cumulative impacts on recreational (and subsistence) fisheries in Arctic waters are considered to be **moderate** to **major**.	The incremental contribution of routine Program activities to cumulative impacts would be **small**, since routine operations under the Program would not occur in the immediate area where fisheries are located. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on would be **medium**, depending on the location, timing, and volumes of spills (among other environmental factors). Small spills are unlikely to affect a large number of fish or have a substantial effect on fishing before dilution and weathering reduced concentrations of oil in the water. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be **moderate** if they were to occur.
Tourism and Recreation	Tour groups to the North Slope Borough make up most of the nonresidential recreational activity. Most visitors stay in Barrow or Deadhorse. Travel to these areas is primarily by air, although bus tours occasionally arrive via the Dalton Highway. Hikers and river rafters also visit the Arctic National Wildlife Refuge and other areas using scheduled or chartered airplanes for access. An increasing number of cruise ships are entering the Chukchi and Beaufort Seas. Cumulative impacts on tourism and recreation result from disruptions to land-based activities, increases in the trash and debris accumulation, and competition between workers and tourists for local services, such as air transport and hotel accommodations; these impacts are expected to be **moderate** to **major**.	The incremental contribution of routine operations under the Program to cumulative impacts would be **small**, with potential adverse aesthetic impacts on sightseeing, hiking, and rafting activities. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on would be **negligible** to **small**, depending on the size, location, and timing of the spill (being greatest if it occurred during the peak recreational season). Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could range from **minor** to **moderate** if they were to occur.

TABLE 4.6.6-3 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Sociocultural Systems	Most of the sparsely populated rural lands in the Arctic region are inhabited by indigenous Alaskans. Barrow is the largest permanent community on the North Slope and serves as the administrative and commercial hub of the region. The Alaska Natives living in communities along the coast of the Beaufort and Chukchi Seas are primarily Iñupiaq Eskimo. Alaska Native communities along the Arctic coast are heavily dependent on subsistence harvesting of sea mammals, fish, and terrestrial fauna. Enclaves of workers at Prudhoe Bay and nearby oil fields are employed by the oil and gas industry. They commute from mostly south central Alaska, Fairbanks, and States outside of Alaska. For the most part, these two communities (Alaska Native communities and worker enclaves) have had little interaction because of the physical distance that separates them. Cumulative impacts to sociocultural systems occur when ongoing and future actions (OCS and non-OCS program) cause changes in local populations and social institutions or when jobs are lost or created. Subsistence harvesting could also be affected by activities that affect marine fauna, such as increases in airborne or subsea noise (e.g., aircraft or marine vessel traffic, seismic surveys, drilling) or degradation of water quality (e.g., fuel or oil spills, chemical releases, or dredging operations that increase turbidity), or that necessitate changes in subsistence fishing practices. Cumulative impacts on sociocultural systems in the Arctic Planning Areas as a result of ongoing and future OCS and non-OCS activities and natural phenomena could be **moderate** over the next 40 to 50 yr.	The incremental contribution of routine operations under the Program to cumulative impacts would range from small to medium, especially if subsistence-related activities, central to the well-being of Alaska Natives who inhabit the area, are affected. Many of these potential effects are mitigatable. Onshore linear features (e.g., pipelines and roads) affect the migration patterns of terrestrial mammals. Because of the high level of dependence on subsistence harvesting, the incremental contribution of the Program to cumulative impacts on subsistence activities near the Beaufort and Chukchi Seas would be expected to be **small** to **medium**. Design stipulations and operational procedures could reduce the impact of onshore development. The incremental impacts of expected accidental spills (most of which are less than 1,000 bbl) associated with the Program on would be **small** to **medium**, depending on the location, volume, and timing (i.e., season) of the spill. Impacts associated with large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could be **major** if they were to occur, especially if they disrupt sea mammal harvest or resulted in the IWC reducing or eliminating whale quotas in the Alaska Arctic.
Environmental Justice	Environmental justice impacts occur when any activity or trend (OCS program or non-OCS program related) results in adverse health or environmental impacts that are significantly high and disproportionately affect minority and low-income populations. A large number of minority and low-income individuals are located in the Arctic region, although the number of low-income individuals does not exceed 50% of the total population (thus there is no low-income population in the region). Subsistence hunting and fishing	The incremental contribution of routine operations under the Program would be small, depending on the proximity of onshore pipelines and offshore infrastructure to communities and their subsistence harvest areas, but are not expected to cause additional environmental justice concerns; their contribution to cumulative impacts on low-income and minority populations therefore would be **small**.

TABLE 4.6.6-3 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Environmental Justice (Cont.)	are an important part of the economies in Arctic communities. Cumulative impacts on local communities could result from changes in the proximity of onshore oil and gas infrastructure and to marine vessel and aircraft traffic. Ongoing and future oil and gas development would continue to affect populations in some regions along the Beaufort and Chukchi Seas by increasing the proximity to existing oil and gas infrastructure and associated health, environmental, and visibility impacts. Given these factors, cumulative impacts on local populations are considered to be **moderate** to **major**.	The incremental contribution of expected accidental oil spills (most of which are less than 1,000 bbl) associated with the Program would be **negligible** to **small**. Large spills (1,000 bbl or greater) or an unexpected, low-probability CDE could result in **moderate** to **major** impacts on the Alaska Native population, especially if subsistence resources were diminished or tainted as a result of the spill. Mitigation measures, cooperative agreements between Native and industry groups, and government-to-government consultations are designed to limit the effects from oil spills and routine operations.
Archaeological and Historical Resources	At the height of the late Wisconsinan glacial advance, about 19,000 years ago, the global sea level was much lower than at present and created land bridges between the North American and Asian continents. During this time, large expanses of the OCS were exposed as dry land and shorelines shifted depending on the location of ice. These relict shorelines (and other relevant landforms) are currently inundated. Some studies indicate that ice gouging may have altered the seafloor in the Arctic region, removing all archaeological evidence of the first peoples; however, the extent of the disturbance is not known. To date, more studies have been done in the Beaufort Sea, but more will be needed to fully understand the potential for significant artifacts to be present. Numerous shipwrecks have been documented in the Beaufort and Chukchi Seas. Most of these were associated with commercial whaling which occurred in the region between 1849 to 1921 and are likely to be in State waters. There are significant onshore historic sites in the Arctic region; these include Cold War era outposts, radar stations, and missile sites, and the Ipiutak Site National Historic Landmark at Point Hope among others. Cumulative impacts to these resources	Routine operations could affect significant archaeological and historic resources, especially offshore resources, with construction activities such as platform and pipeline construction potentially damaging or destroying affected resources. Onshore impacts include resource damage or loss, or visual effects and are possible from pipeline landfall, onshore pipeline, and road construction. Anchor drags could adversely affect shipwrecks. The incremental contribution of routine operations under the Program could be **negligible** to **large**, depending on the presence of significant archaeological or historic resources in the area of potential effect. Archaeological surveys that would identify significant cultural resources to be avoided could reduce these impacts. The incremental contribution of oil spills, whether expected oil spills (most of which are less than 1,000 bbl) to cumulative impacts on archaeological and historical resources in the Arctic region would be **small** to **large**, depending on the presence of significant resources in the area of potential effect and the spill location, timing, duration, and size. Impacts associated with an unexpected, low-probability CDE would also depend on these factors, and could range from **minor** to **major** if it were to occur.

TABLE 4.6.6-3 (Cont.)

	Anticipated Trends and Cumulative Impacts	Contributions of Program to Cumulative Impacts
Archaeological and Historical Resources (Cont.)	occur when operations involving bottom-disturbing activities (e.g., channel dredging) come into physical contact with artifacts or their site context, or as a result of natural phenomena such as high-energy waves and currents, ice gouging, and thermokarst collapse. The cumulative impacts of future OCS and ongoing and future non-OCS activities are not currently known, but could range from **minor** to **moderate**, mainly because activities occurring on the OCS prior to USDOI's survey requirement, which went into effect in 1973, may already have affected (i.e., damaged or destroyed) significant sites.

5 UNAVOIDABLE ADVERSE ENVIRONMENTAL EFFECTS

5.1 IMPACTS ON PHYSICAL RESOURCES

Some unavoidable adverse effects on water and sediment quality would be expected to occur as a result of routine operations under the proposed action. Operational discharges of drilling muds and cuttings, produced water, and small amounts of hydrocarbons into the water column during routine offshore oil and gas operations would lower local water and sediment quality. These discharges could temporarily raise the levels of some water quality and sediment parameters above normal within 100 to 2,000 m (328 to 6,562 ft) of the discharge point during drilling, and intermittently/continuously during the production period.

An increase in emissions of air pollutants would be expected to occur, particularly in areas that do not already have extensive oil and gas activities. Emissions of nitrogen oxides and reactive hydrocarbons would increase ozone concentrations in the immediate vicinity of the offshore operations for intermittent periods during the term of the proposal.

Seismic surveys, infrastructure construction and removal, and support vehicle traffic would result in unavoidable but short-term increases in ambient noise levels in the survey areas, project locations, and vessel and helicopter routes. More long-term increases in ambient noise levels would occur during normal operations; the duration of increased ambient noise levels would correspond directly to the duration of production operations.

5.2 IMPACTS ON ECOLOGICAL RESOURCES

Marine mammals would be adversely affected by noise and disturbances associated with routine offshore activities (seismic surveys, vessels, aircraft, drilling, and dredging) during relatively brief periods of time. Some marine mammals would exhibit short-term responses to noises and disturbance, such as confusion or avoidance. Bowhead whales, for example, will exhibit avoidance behavior to noise-producing activities. Should an oil spill contact marine mammals, some individuals would experience short-term effects, while a small number could die. An oil spill would also adversely affect local marine mammal prey resources in small areas affected by a spill.

Disturbances of terrestrial mammals by offshore related aircraft, vehicles, facilities, human presence, and habitat alteration from construction activities are unavoidable. Disturbance of caribou, bears, and other animals in Alaska would be temporary and would not affect their overall distribution and abundance.

Marine and coastal birds would be adversely affected by noise and disturbances associated with routine offshore and onshore activities. Habitat alteration from the construction of onshore facilities would affect a small portion of the available habitat. Should an oil spill contact marine and coastal bird habitat, some birds would experience short-term effects, while some birds that feed in or rest on the water could be coated with oil and die. An oil spill could also adversely affect local marine and coastal bird prey resources.

Wetland and estuarine habitat alteration resulting from pipeline and other related coastal construction could have an unavoidable adverse impact on fish nursery areas and terrestrial mammals; however, regulations are in place to minimize these impacts. An oil spill contacting fish habitat would have an adverse effect on local fishery stocks and food webs.

Although individual sea turtles may be injured or killed by support vessel collisions, population-level effects would be minimal. The most likely impacts from noise would be short-term behavioral changes such as diving and evasive swimming. If an oil spill were to contact sea turtles, some individuals might not recover from exposure, but sea turtle populations as a whole would not be threatened.

Unavoidable adverse effects on seafloor habitats and associated organisms could occur from anchoring, drilling discharges, structure emplacement and removal, and pipeline emplacement.

5.3 IMPACTS ON SOCIAL, CULTURAL, AND ECONOMIC RESOURCES

Commercial and, to a lesser extent, recreational fisheries will be adversely affected by loss of fishing areas occupied by offshore vessels, platforms, and exposed pipelines, particularly in areas where oil and gas activities have not previously occurred. Oil spills could contaminate, injure, or kill shellfish, finfish, eggs, and larvae in the vicinity.

Unavoidable adverse effects could be expected to occur to tourism and recreation areas from floating debris and oil spills that contact beach areas. Effects on scenic quality could also be expected to occur.

The proposed action with its ancillary activities will place increased demands on coastal communities, particularly in areas where oil and gas activities are not currently occurring. Offshore operations may result in the deposition of floating debris on beaches, precluding their use for recreation, and platform placement could also affect commercial fishing costs. Beaches may be affected temporarily by oil spills, which could also restrict commercial and recreational fishing. Impacts on beach recreation and on recreational and commercial fishing could disrupt coastal economies. Some unavoidable adverse effects on subsistence harvests in the Alaska region may result from routine offshore oil and gas activities. These offshore and onshore activities could cause localized displacement or loss of small numbers of subsistence resources. If oil spills were to contact bowhead and beluga whales and walruses, there could be a reduction of total annual harvests of these species. In such a case, short-term loss of some subsistence resources and potential repercussions on the culturally significant sharing system would be unavoidable.

Unavoidable adverse effects to archaeological resources could occur as a result of the proposed action. Construction and siting of offshore and onshore oil and natural gas facilities such as platforms, pipelines, or processing facilities could displace, damage, or destroy archaeological resources.

6 RELATIONSHIP BETWEEN SHORT-TERM USES OF MAN'S ENVIRONMENT AND THE MAINTENANCE AND ENHANCEMENT OF LONG-TERM PRODUCTIVITY

The short-term uses of man's environment in relation to the 2012-2017 Outer Continental Shelf (OCS) Leasing Program (the Program) are the offshore and onshore activities needed to develop oil and gas resources to meet the energy needs of the United States. The Bureau of Ocean Energy Management (BOEM) makes every attempt to minimize the environmental effects from these uses. By adopting mitigating measures for OCS operations, BOEM attempts to minimize long-term impacts and maintain or enhance the long-term productivity of areas in which oil and gas have been exploited. With proper removal of offshore oil and gas facilities, or their disposal in areas designed to enhance recreational fishing, offshore areas will continue to maintain fish resources and provide habitat for marine mammals, birds, and reptiles long after oil and gas operations have ceased. After the completion of oil and gas production, the marine environment that may be affected by routine operations under the Program is generally expected to remain at or return to its anticipated long-term productivity levels. The long-term productivity of the marine environment in GOM and Alaskan waters is affected by a wide variety of factors, many unrelated to OCS oil and gas activities, and it is speculative to suggest what productivity levels in these OCS waters may be in 40 to 50 years when the Program oil and gas activities would be completed. The onshore effects of the OCS program and the proposed action will contribute to the continuing alteration of nearby coastal areas from natural environments to urbanized and industrialized environments.

One confounding factor that may affect long-term productivity of the areas included in the Program is climate change. Even in the absence of the oil and gas activities that would occur under the Program and the proposed action, baseline environmental conditions (such as sea level and ocean acidification) are changing as a consequence of climate change; this is especially true in the Arctic (see Section 3.3 for a discussion of climate change and baseline conditions). As climate-driven changes occur, productivity may be expected to change as well, and any changes in long-term productivity that could occur as a result of the Program would be in addition to any climate-related changes.

Short-term use of the environment in the vicinity of OCS activities includes the exploration and development of OCS oil and gas resources during the period of activity needed for the completion of the proposed action. The overall life of the proposed action is estimated to be about 40–50 years, with about 10-15 years of oil and gas exploration and delineation activity and about 30–35 years of resource development and production activity. Many of the effects of routine operations discussed in Chapter 4 are the result of short-term uses and are greatest during the exploration, development, and early production phases. These effects may be reduced by mitigation measures required by BOEM, and are not expected to adversely affect long-term productivity of affected areas or resources.

Extraction and consumption of offshore oil and natural gas would be a long-term depletion of nonrenewable resources. Economic, political, and social benefits would accrue from the use of these natural resources. Most benefits would be short-term and would delay the increase in the dependency of the United States on oil imports. The production of offshore oil and natural gas from the proposed action would provide short-term energy sources and perhaps additional time for the development of long-term alternative energy sources or substitutes for these nonrenewable resources.

In the event of a catastrophic discharge event (CDE), such as the Deepwater Horizon (DWH) event or the *Exxon Valdez* spill in Alaska, some natural resources may incur long-term effects on productivity. Studies on the effects of the *Exxon Valdez* spill on biota and habitats in Prince William Sound show some resources to have recovered, others to still be showing possible spill effects, and yet for others that is no clear indication of the presence or absence of long-term effects (see discussions in Chapter 4). It is too early to ascertain whether the 2010 DWH event will cause long-term changes in productivity of affected resources. Long-term impacts of large oil spills to local economies and sociocultural systems may also be expected, especially in the Alaska planning areas.

Onshore facility construction (e.g., pipelines, processing facilities, service bases, etc.) causes definite short- and long-term changes, with localized long-term effects on coastal habitats along onshore pipeline corridors. Some biological resources, such as nesting birds, may have difficulty repopulating altered habitats and could be permanently displaced from the local construction area. Short-term biological productivity would be reduced or lost in the immediate onshore areas where construction takes place; however, areas where long-term effects may be incurred would be very limited in spatial extent and the long-term productivity in some of these areas could be mitigated with habitat reclamation. After the completion of oil and gas production, the marine environment is generally expected to remain at or return to its normal long-term productivity levels.

In the Alaska region, habitat disturbance associated with routine activities could cause local impacts to subsistence resources, which could threaten subsistence as a way of life. Road construction resulting from the proposed action would improve accessibility to primitive areas in the region. The wilderness values of the coast and along pipeline routes and associated access roads would decrease with increased human activity in these areas, particularly in areas that do not already have extensive oil and gas activities. Land use changes would be noticeable at onshore facility sites and along pipeline routes. Short-term changes may include a shift in land use from subsistence-based activities to industrial activities during the life of the proposed action. Areas adjacent to onshore facilities and pipeline corridors would probably be subject to hunting regulations and restrictions. Land use in some localized areas would change from conservation to resource development. Long-term effects on land use may result if the infrastructure or facilities continued to be used after the lifetime of the proposed action.

Increased population and minor gains in revenues have the potential for disrupting coastal communities in the short term. In Alaska, an added incentive to shift from a subsistence-based economy to a cash-based economy, a reduction in subsistence resources, a decrease in subsistence activities, and other changes brought about by the proposed action could be factors in long-term consequences for Native social and cultural systems. In the event of an oil spill, sociocultural systems and subsistence of local communities and populations may incur short-term consequences, while a large spill such as a CDE may have long-term consequences to affected communities and populations.

Archaeological and historic finds discovered during development would enhance long-term knowledge. Overall, finds may help to locate other sites, but destruction of artifacts or damage to sites would represent long-term losses.

This page intentionally left blank.

7 IRREVERSIBLE AND IRRETRIEVABLE COMMITMENTS OF RESOURCES

Section 102(2)(c)(ii) of the National Environmental Policy Act (NEPA) requires that an environmental impact statement (EIS) include information on any adverse environmental effects that cannot be avoided, should the proposed action be implemented. A commitment of a resource is considered *irreversible* when the primary or secondary impacts from its use limit the future options for its use. An *irretrievable* commitment refers to the use or consumption of a resource that is neither renewable nor recoverable for use by future generations.

7.1 MINERAL RESOURCES

The development of oil and gas production facilities, as well as all exploration and project support activities, would result in the consumption of ship and aircraft fuel, structural steel, and other materials. Upon decommissioning, some of these materials would be available for reuse. The consumption of fuels during exploration, construction, production, and decommissioning would represent an irreversible and irretrievable commitment. The offshore oil and natural gas resources recovered as a result of the proposed action would be irretrievable once they are consumed.

7.2 BIOLOGICAL RESOURCES

In general, the impact of routine operations would not constitute an irreversible and irretrievable commitment of resources. During exploration, construction, production, and decommissioning, some biota would be affected, and for most species population-level effects (which could result in irreversible and irretrievable commitment of biological resources) would not be expected. Offshore and onshore oil and gas activities, such as facility construction; platform removal; and aircraft, vessel, and vehicle traffic could result in direct habitat loss in some limited areas and displace some fauna and flora species from favorable habitats to unfavorable habitats. Displacement and habitat loss may result in the reduction of some local populations and become irretrievable if alterations to the environment were permanently maintained. However, the degree of displacement and amount of irretrievable habitat loss should represent a transitory and negligible effect on the overall populations of most species.

An irreversible and irretrievable commitment of biological resources may occur where habitats (such as wetlands and corals) are impacted by dredging, construction activities, or oil spills. Dredging and construction activities can destroy coastal wetland vegetation, which results in soil erosion and wetland loss. Dredging and construction in offshore areas could similarly destroy marine benthic habitats and sessile biota inhabiting the disturbed areas. These types of losses would be greatest in areas where oil and gas activities are currently not occurring. However, implementation of habitat restoration measures may limit the amount of habitat that could be permanently lost.

An irretrievable and irreversible commitment of biological resources may also be incurred if one or more individuals of a species listed under the Endangered Species Act is injured or killed, or important habitats such as nesting sites are disturbed. However, consultation and coordination with the U.S. Fish and Wildlife Service (USFWS) and the National Oceanic and Atmospheric Administration (NOAA) prior to initiation of any oil and gas development activities would identify mitigation measures to reduce or eliminate potential impacts to listed species, and implementation of such measures would act to reduce the potential for an irreversible and irretrievable commitment of these biotic resources.

7.3 LAND USE

In general, land used for support of oil and gas development and processing would not revert to its predevelopment characteristics; however, the land may become favorable to other urban or industrial uses. Some areas of land disturbance may be returned to predevelopment characteristics with active restoration.

7.4 ARCHAEOLOGICAL RESOURCES

Irretrievable prehistoric archaeological sites and cultural materials may be lost through indiscriminate or accidental activity on known and unknown sites such as placement of a pipeline across a shipwreck. Archaeological protection requirements should mitigate some losses.

8 CONSULTATION AND COORDINATION

8.1 PROCESS FOR THE PREPARATION OF THE 2012-2017 OCS OIL AND GAS LEASING PROGRAMMATIC ENVIRONMENTAL IMPACT STATEMENT

8.1.1 Draft Proposed Program and Draft PEIS

Preparation and review of the draft programmatic environmental impact statement (PEIS) closely paralleled that of the 2012-2017 Outer Continental Shelf (OCS) Oil and Gas Leasing Program (the Program) decision documents. Comments received on the program decision documents were also reviewed for consideration in the preparation of the PEIS.

In January 2009, the previous Administration published a Draft Proposed Program (DPP) and a Notice of Intent (NOI) to prepare a programmatic environmental impact statement (PEIS) that requested comments from States, local governments, Native groups, federally recognized tribes, the oil and gas industry, Federal agencies, and other interested individuals and groups and set out a schedule for scoping meetings in the areas of the DPP. In February 2009, the Secretary of the Interior extended the comment period on the DPP and postponed the scoping meetings to allow time to consider further public comment before determining which areas in the DPP should be scoped and analyzed for consideration in subsequent program proposals. A preliminary revised Program was proposed on March 31, 2010.

8.1.2 Scoping for the Draft PEIS

An NOI to prepare and scope the Program PEIS was published in the *Federal Register* (75 FR 16828) on April 2, 2010. That NOI invited the public to provide comments on the scope and content of the PEIS and identified as many as 14 locations where public scoping meetings might be held.

On June 30, 2010, Secretary of the Interior Salazar announced that the public scoping meetings would be postponed in response to the Deepwater Horizon (DWH) incident. The additional time would be used to evaluate safety and environmental requirements of offshore drilling. On December 1, 2010, Secretary Salazar announced an updated oil and gas strategy for the OCS. The new strategy continued a moratorium for areas in the Eastern Gulf of Mexico (GOM) and eliminated the Mid-Atlantic and South Atlantic Planning Areas from consideration for potential sales and development through the 2017 planning horizon. The Western GOM, Central GOM, Cook Inlet, Chukchi Sea, and Beaufort Sea OCS Planning Areas would continue to be considered in the PEIS. Subsequently, on January 4, 2011, a Notice of Scoping Meetings for the proposed 2012-2017 OCS oil and gas leasing program PEIS was published in the *Federal Register* (76 FR 376) and a second scoping period was conducted from January 6, 2011, through March 31, 2011. During this scoping period, public scoping meetings were scheduled for 12 locations in the GOM (three locations), Alaska (eight locations), and Washington, D.C. The scheduled Alaska meetings for Point Hope and Point Lay were not held because of inclement weather and subsequently could not be rescheduled because of ongoing schedule conflicts (e.g., whaling season). The public scoping meetings were held to garner significant issues and public concerns for inclusion in the PEIS. In addition, the Bureau of Ocean Energy Management (BOEM) received comments through the mail and maintained a public website to accept scoping comments electronically.

BOEM established cooperating agency status with the U.S. Department of Commerce National Oceanic and Atmospheric Administration (NOAA), the State of Alaska, and the Alaska North Slope Borough. They reviewed preliminary versions of the Draft and Final PEIS.

8.1.3 Commenting on the Proposed Program and Draft PEIS

Comments were requested during a 90-day period on the proposed Program and during a 60-day period on the associated Draft PEIS. The comments received were evaluated and considered in the preparation of the Proposed Final Program and Draft PEIS. The Proposed Final Program will be submitted to the President and to the Congress along with an explanation from the U.S. Department of the Interior (USDOI) concerning the reasons for the decision.

8.2 PUBLIC COMMENT ON THE DRAFT PEIS

A Notice of Availability (NOA) for the public release of the Draft PEIS was published in the *Federal Register* on November 10, 2011. The notice announced a 60-day public comment period from November 10, 2011 until January 9, 2012. All comments received during the public comment period were impartially considered and given equal weight by BOEM. Section 8.4.4 of this Final PEIS presents the responses to these comments prepared by BOEM. The stakeholders providing comments are listed in Tables 8.4-1 and 8.4-2.

During the public comment period, BOEM provided the public with three methods for delivering comments on the Draft PEIS:

- Electronically, using a Web-based form accessible on the Internet at http://www.boem.gov/5-year/2012-2017,
- Regular mail to BOEM Headquarters, and
- Public meetings.

Thirteen public hearings were held on the following dates and at the following locations:

- December 5, 2011 — Wainright, Alaska
- December 6, 2011 — Nuiqsut, Alaska
- December 6, 2011 — Washington, D.C.

- December 6, 2011 — Houston, Texas
- December 7, 2011 — Kaktovik, Alaska
- December 7, 2011 — Mobile, Alabama
- December 8, 2011 — New Orleans, Louisiana
- December 9, 2011 — Anchorage, Alaska
- December 12, 2011 — Kotzebue, Alaska
- December 13, 2011 — Point Hope, Alaska
- December 14, 2011 — Point Lay, Alaska
- December 16, 2011 — Barrow, Alaska

Two meetings to receive public comments were held on the same day in Houston, Mobile, and New Orleans, with single meetings at all other hearing locations. All meetings except the one held in Washington, D.C., were advertised in local newspapers and through local press releases.

Comments were received from State and local officials; Federal, State, and local agencies; environmental and nongovernmental organizations; the oil and gas energy sector; and individuals. Per CEQ NEPA Regulations, 40 CFR 1503.4, BOEM prepared responses to all substantive comments (see Section 8.4.4) and revised portions of the Final PEIS to incorporate some of the changes suggested by commenters.

8.3 DISTRIBUTION OF THE FINAL PEIS

The Final PEIS was distributed to Federal, State, and local agencies; to interested groups and individuals who had been involved in the preparation of the Program and the PEIS process; and to stakeholder and project area libraries.

FEDERAL AGENCIES: Copies of the PEIS were provided to the following Federal agencies:

- Federal Energy Regulatory Commission
- Marine Mammal Commission
- U.S. Department of Commerce
  - National Oceanic and Atmospheric Administration (NOAA)
  - NOAA National Marine Fisheries Service

- U.S. Department of Defense
  - U.S. Air Force
  - U.S. Army Corps of Engineers
  - U.S. Navy

- U.S. Department of Energy

- U.S. Department of the Interior (USDOI)
  - U.S. Fish and Wildlife Service
  - Bureau of Indian Affairs
  - Bureau of Mines
  - Bureau of Safety and Environmental Enforcement
  - National Park Service

- U.S. Department of Transportation

- U.S. Department of Homeland Security
  - U.S. Coast Guard

- U.S. Department of State

- U.S. Department of Justice

- U.S. Environmental Protection Agency (USEPA)

- U.S. Geological Survey

CONGRESS: Copies of the PEIS were provided to the following Congressional offices:

- House of Representatives Committee on Resources

- United States Senate Committee on Energy and Natural Resources

TRIBES/TRIBAL ORGANIZATIONS: Copies of the PEIS were provided to the following tribes and tribal organizations:

ALASKA

Afognak Native Corporation
Agdaagux Tribe of King Cove
Alaska Area Native Health Service
Alaska Eskimo Whaling Commission
Alaska Federation Of Natives
Alaska Intertribal Council
Alaska Inter-Tribal Council
Alaska Native Harbor Seal Commission

8.4 PUBLIC COMMENTS ON THE DRAFT PROGRAMMATIC EIS

8.4.1 Introduction

A Notice of Availability (NOA) for the public release of the Draft PEIS was published in the *Federal Register* on November 10, 2011. The notice announced a 60-day public comment period from November 10, 2011, until January 9, 2012. All comments received during the public comment period were impartially considered and given equal weight by BOEM. Comments were received from State and local officials; Federal, State, and local agencies; environmental and nongovernmental organizations; the oil and gas energy sector; and individuals.

A total of 342 comment documents[1] were received from Federal, State, and local governments and agencies, nongovernmental organizations, and individuals. Members of several of the nongovernmental organizations submitted comments using a ‘standard’ form letter for their constituents. For example, the Sierra Club submitted a compact disc with 24,000 form letters (or versions of the form letter) from organization members across the country. While this represents 24,000 submittals, the vast majority of these are identical to the form letter. Other groups submitting largely standardized form letters included the Institute for Energy Research (890 letters) and CREDO (71,626 letters).

As comment documents were received during the public comment period, they were assigned a 5-digit document number. Within each document, individual comments were further numbered. All comment documents received during the public comment period were cataloged in this manner and considered in the preparation of the Final PEIS. Evaluation of the 342 comment documents yielded a total of 1,992 unique comments.

8.4.2 Summary of Major Issues Raised by Commenters on the Draft PEIS

As comments documents were being evaluated and individual comments identified, comments with similar themes were grouped into categories based on the overall nature of the comment. Analysis of comments received on the Draft PEIS identified nine major topics of concern: (1) National Environmental Policy Act (NEPA) process and public involvement; (2) NEPA analysis; (3) alternatives; (4) environmental issues and concerns; (5) cumulative impacts; (6) oil spills; (7) mitigation; (8) regulations and safety; and (9) statutory compliance. These topics covered a wide range of issues, including, but not limited to, compliance and adequacy pertaining to NEPA and the Endangered Species Act (ESA), development of alternatives and selection of planning areas for program consideration, resource impact concerns, impacts on subsistence, oil spills and response, and public outreach.

---

[1] A ‘comment document’ refers to the entire submittal provided by a commenter, whether in writing or verbally during one of the public hearings that was held on the Draft PEIS. Each comment document, in turn, may have one or more individual comments on one or more different topics. In some cases, the submitted document contained only a single substantive comment.

NEPA Process and Public Involvement. Some commenters called for BOEM to prepare site-specific EISs for each planning area and to not defer resource specific analyses and regulatory compliance activities to the leasing stage or later, but conduct those analyses as part of the 2012-2017 Program PEIS. Concerns related to public involvement included uncertainty over how the public comments received during scoping were used to prepare the PEIS, and displeasure with the overlap of the public comment period for the 2012-2017 Program PEIS with NEPA comment periods for other NEPA projects in the affected areas.

NEPA Analysis. Some commenters felt that BOEM underestimated risks and impacts of oil spills, did not identify spill responses plans or procedures, and overestimated the benefits of OCS oil and gas development. Several commenters called for the PEIS to include an evaluation of a 'worst case' oil spill scenario. Some commenters called for BOEM to adopt the recommendations of the Council on Environmental Quality (CEQ) and the National Commission on the Deepwater Horizon Oil Spill and Offshore Drilling (the National Commission) and reform its NEPA compliance procedures. Some commenters felt that BOEM did not take a hard look and adequately assess differences in impacts across alternatives, nor adequately consider important impacting factors, such as climate change, on the nature of those impacts. A number of commenters raised concerns regarding insufficient or incomplete information, calling for BOEM to conduct more studies before adopting any new leasing program.

Alternatives. Some commenters called for the addition of more planning areas, while others suggested limiting leasing to only certain areas within the planning areas. Several commenters felt that BOEM did not adequately evaluate the environmental impacts of the alternatives or the benefits of the No Action Alternative, while others felt there was insufficient consideration of alternate/renewable energy sources. Concerns were raised about including alternatives with Arctic leasing given the current industry and governmental capability to contain and clean up possible spills in the Arctic.

Environmental Issues and Concerns. A number of comments were received expressing concerns about how OCS oil and gas development would affect both natural and socioeconomic resources and conditions, including, but not limited to, impacts on air and water quality, biota, socioeconomics, public health, subsistence, and environmental justice. Many commenters were concerned about the impacts of both routine operations and accidental oil spills on one or more resources. Some comments expressed concern about how OCS oil and gas activities may affect human health and subsistence (especially in the Arctic).

Cumulative Impacts. Some commenters felt that the cumulative analyses did not sufficiently consider reasonably foreseeable future actions, climate change, and impacts on resources. Some commenters felt that the analyses did not adequately evaluate the Arctic and impacts on Arctic resources. Some commenters expressed concerns that the cumulative analyses did not adequately consider the full effects of oil spills, including the DWH event.

Oil Spills. Some commenters felt that the risk characterization of a catastrophic discharge event (CDE) presented in the Draft PEIS was insufficient, while others felt that the risks of deepwater drilling were overstated. A concern was also identified that the Draft PEIS did not sufficiently address the persistence of environmental impacts of oil spills on natural resources. Many commenters expressed concerns about the ability of industry and BOEM to respond to oil spills, especially if they occur under ice cover and in Arctic winter conditions. Some commenters requested a greater discussion of the use and impacts of dispersants, and more discussion of the reforms enacted by industry following the DWH event.

Mitigation. Some commenters felt that the Draft PEIS provided only minimal and generic information on required mitigation. Commenters felt that the PEIS should identify both planning area- and resource-specific mitigation measures and requirements.

Regulation and Safety. Some commenters requested that BOEM and the Bureau of Safety and Environment Enforcement (BSEE) reform their regulations and practices to reflect the findings and recommendations of the National Commission on the Deepwater Horizon Oil Spill and Offshore Drilling. Other commenters called for the PEIS to better identify safety changes implemented by industry since the DWH event. One commenter requested that the PEIS include a risk assessment of drilling. Several commenters identified a concern that BOEM, BSEE, the U.S. Coast Guard, and industry do not have adequate oil spill response measures in place to support OCS oil and gas leasing, especially in the Arctic.

Statutory Compliance. Some commenters noted that some major Federal laws and Executive Orders were missing from Appendix C (Federal Laws and Executive Orders), and that the Draft PEIS was not in compliance with, nor adequately explained, provisions of various environmental statutes. A number of commenters expressed concerns regarding BOEM's position with regard to the ESA, the Marine Mammal Protection Act (MMPA), and the Magnuson-Stevens Fishery Conservation and Management Act (FCMA). Commenters requested that the PEIS include U.S. Fish and Wildlife Service (USFWS) requirements for protecting polar bear dens, and identify industry practices for compliance with the USFWS requirements. Some commenters expressed concerns that the Executive Order instituting the National Ocean Policy and Coastal and Marine Spatial Planning directly conflicts with the Outer Continental Shelf Lands Act.

Other Comments. In addition to specific comments on the major issues summarized above, BOEM also received a variety of comments that were either not applicable to the PEIS, were general in nature, did not request or require changes to the Draft PEIS, or addressed topics other than the 2012-2017 OCS Leasing Program. These comments discussed topics such as general concerns about climate change, opposition to or support of oil and gas development and fossil fuel use, a need for basic services and human rights, the value of traditional knowledge, and displeasure with industry activities in the Arctic.

8.4.3 Summary of the Changes Made to the Draft PEIS

Following the closure of the public comment period on the Draft PEIS, BOEM reviewed and considered all of the comments received on the draft and made revisions to the PEIS as appropriate. Factual or editorial errors identified in the comments were corrected, and text was clarified or expanded to provide additional information on the proposed action and alternatives, the exploration and development scenarios, baseline environmental conditions, climate change, oil spills, potential environmental impacts, or other concerns. In addition, a cost-benefit analysis of the alternatives was added, and the discussion of issues of programmatic concern was expanded to provide a new discussion of programmatic deferrals and mitigation. Several of the figures were revised to clarify areas of confusion or correct errors identified by some commenters, and some new figures were developed.

8.4.4 Response to Comments

Presented below are the major issues that capture the substantive concerns raised in the comments received on the Draft PEIS. BOEM has prepared responses to the concerns associated with these issues, which are provided below. Table 8.4-1 identifies stakeholders providing comments on each issue.

8.4.4.1 Issue 1 NEPA Process and Public Involvement

1. Each planning area is unique. Combining the Gulf of Mexico, Cook Inlet, and Chukchi and Beaufort Seas in the PEIS is confusing and potentially problematic for the reader to understand the many distinctions between these areas. The regions are remarkably different with respect to location, climate, seasonal variations, as well as the level of activity anticipated from offshore energy exploration and development. Therefore, BOEM should create a separate site-specific, detailed EIS for each at the planning stage, especially in areas with complex geology, in deepwater, and in the Arctic and other frontier areas.

   Response: BOEM is cognizant of and sensitive to the unique environmental conditions that exist across the various OCS Planning Areas. The purpose of and need for preparing a schedule of potential OCS oil and gas lease sales is to “best meet national energy needs for the 5-year period following its approval” (43 USC 1344) by balancing the potential for adverse environmental and societal impacts with the beneficial impacts of the discovery and development of oil and gas. In developing the 5-year leasing schedule, BOEM considers regional and national energy needs; leasing interests as expressed by possible oil and gas producers; applicable laws, goals, and policies of affected States, local governments, and tribes; competing uses of the OCS; relative environmental sensitivity and marine productivity among OCS regions; public input; and the equitable sharing of benefits and risks among stakeholders. Therefore, to handle each OCS planning area separately, as the comment is suggesting, would be contrary to the purpose and need of the proposed action analyzed. The PEIS evaluates the potential effects to all planning areas that the Secretary of the Interior (Secretary) is considering in this PEIS, in order to adequately balance the factors described above. Including all of the OCS areas that the Secretary has already identified for consideration will ultimately lead to a more informed decision with regard to the program as a whole.

   In regard to the specific suggestion that BOEM create a separate site-specific analysis for each planning area, it is especially important to note here that BOEM uses a tiered analytical approach in its NEPA documents. When a broad NEPA document such as a PEIS has been prepared, any subsequent site-specific assessment or evaluation can summarize (and include by reference) the issues discussed in the broader document, and thus, the site-specific assessment can focus its analyses on project-specific issues of the particular proposed action (40 CFR 1502.20). Following selection of the Program, any subsequent lease sale-specific NEPA analyses and documentation may tier off the PEIS for the Program. This PEIS is the first of many NEPA analyses that will be done for the activities that occur as a result of the Program. The NEPA assessments, including EISs and environmental assessments (EAs) associated with various stages of OCS oil and gas development, are shown in Table 1-1 of the PEIS.

2. BOEM has exhibited a pattern of postponing its decisions on protected areas, mitigation measures, deferrals, health impact assessments, etc. until later stages in the tiered leasing program. After delaying these decisions, there is concern that BOEM fails to adequately address these issues in the subsequent stages. In particular, when these decisions are postponed until the exploration plan stage, there is concern that the timeframe of this phase prevents preparation of an adequately detailed site-specific analysis. To address these concerns, the impacts should be addressed at the programmatic phase. Barring that, EISs should be required for specific lease sales, especially for lease blocks in deep water, in areas with complicated geology, in the Arctic, and in frontier locations. At this programmatic stage, BOEM should conduct better science in order to more narrowly target lease sales.

   Response: The use of the tiering framework, from the 5-year Program through plan approval, allows BOEM to consider reasonable alternatives and integrate new environmental information during program implementation when the issues of concern are most ripe. BOEM does prepare NEPA documents for specific lease sales, but tiering encourages BOEM to first address a broad general program, such as the 2012-2017 OCS Oil and Gas Program, in an initial environmental impact statement, and then analyze narrower lease sale and project-specific proposals under the initial program in subsequent, more focused NEPA analyses. In fact, CEQ encourages the use of programmatic NEPA and tiering in these situations as evident in the NEPA Task Force report, Modernizing NEPA Implementation (CEQ 2003). This PEIS does not analyze additional deferrals and mitigations as alternatives.

   A useful approach for addressing the issues raised in comments is to strengthen the program's tiering process so that it is more effective and transparent, rather than attempting to develop specific mitigations and spatial/temporal deferrals at the preliminary planning stage of the program when information needed for an informed decision may not be available, needed consultation and coordination may not have occurred, and the analytic granularity is generally too coarse for site-specific or resource-specific decisions. BOEM has included a new section in the Issues of Programmatic Concern to facilitate the process of considering and evaluating different deferral and mitigation strategies that may need to be applied at appropriate program decision points. Consistent with the NEPA Task Force recommendation, the PEIS provides a roadmap, explaining where and when deferred issues raised by the public and/or regulatory agencies will be addressed. Chapters 1 and 2 of the PEIS explain how more detailed analyses should follow that will evaluate the need for specific mitigations in different program areas. Section 4.3.2 describes the process BOEM will follow during program implementation to foster focused leasing, deferral and mitigation strategies will be tracked and evaluated during the program, along with mechanisms for stakeholders to engage in and contribute to the lease sale alternative evaluation and development process.

With regard to conducting better science, BOEM has a robust research program in its Environmental Studies Program. Many of the studies funded and completed for the Environmental Studies Program directly support and inform the analyses presented in BOEM NEPA documents. In many instances, these studies assist BOEM in developing and improving upon mitigation strategies that ultimately may help identify and protect sensitive environmental areas. BOEM has found that leasing and plans can be tailored to protect resources, the details for which come most appropriately at those stages.

3. The PEIS acknowledged NOAA's concerns about sensitive hard-bottom habitat in the GOM, but deferred serious consideration of specific exclusion areas until later NEPA analyses for specific lease areas. NOAA would prefer to see the exclusion of these areas considered during the 5-year Program stage, rather than waiting for the lease sale phase. NOAA encourages BOEM to exclude these sensitive areas under the Outer Continental Shelf Lands Act Section 18 requirement to consider the ecological characteristics, environmental sensitivity, and other anticipated uses of the area in determining the timing and location of the leasing program.

   Response: Exclusion areas are generally determined at the lease sale stage. However, the Assumed Mitigation that is described in Appendix B does explain mitigation that BOEM assumes would be included. This includes mitigation relative to chemosynthetic communities, topographic features, Pinnacle Trend, and the Flower Gardens. Section 2.9.5 of the PEIS addresses the addition of areal and temporal exclusion areas, as well as the rationale for deferring the designation of new exclusions to lease sale and plan stages of the Program. In addition, a new section (Section 4.3.2) discussing programmatic deferrals and mitigation can be found in Section 4.3 Issues of Programmatic Concern.

4. BOEM should incorporate the "worst-case discharge" calculations from oil spill response plans into its NEPA documents.

   Response: Pursuant to BSEE OCS Regulations (30 CFR 254.47), operators are required to submit worst-case discharge (WCD) scenarios to BSEE for all OCS facilities. Furthermore, pursuant to 30 CFR 550.219 and 550.250, all plans must also be accompanied by information regarding oil spills, including calculations of the WCD scenario; this is further clarified by notices to lessee (NTL) No. 2010-N06. The WCD scenario is currently used to evaluate the adequacy of the assets in an oil spill response plan (OSRP), which is a required mitigation measure. Total calculation for the volume of oil that could be released in a WCD scenario is determined by the type of facility in question.

5. BSEE does take into consideration WCD calculations submitted by industry; however, the incorporation of WCD calculations for wells submitted by industry are not appropriate to incorporate at the programmatic level of NEPA analysis, as these numbers are submitted by industry and reviewed by BOEM and BSEE, where appropriate, at subsequent stages in the

leasing process, per relevant OCS regulations. By continuing to call events like the Macondo event phrases like “catastrophic oil spill”, the Federal Government is perpetuating a misunderstanding that is inherent to that phrase. A spill cannot be catastrophic. An eruption or a volcano of oil can be. It was recommended that any reference in the PEIS to such volumes of lost oil from operations not be called spill, but be called by a more accurate descriptive name.

Response: BOEM has used an appropriate term to describe this unprecedented oil spill and other low-probability events with catastrophic consequences. BOEM’s official term in the PEIS for this type of very large oil spill is a catastrophic discharge event (CDE). In the case of the April 2010 CDE, BOEM’s official term is the DWH event.

6. It is unclear how public comments from the scoping meetings have been incorporated into the PEIS. These important comments should be addressed in the PEIS so that the public can best understand the evolution of BOEM’s work on the leasing program.

   Response: On January 4, 2011, a Notice of Scoping Meetings for the proposed 2012-2017 OCS Oil and Gas Leasing Program PEIS was published in the *Federal Register* (76 FR 376) and a scoping period was conducted from January 6, 2011, through March 31, 2011. During this scoping period, public scoping meetings were held in 10 locations in Alaska, Texas, Louisiana, Alabama, and Washington, D.C. In addition, BOEM received comments through the mail and maintained a public website to accept scoping comments electronically.

   As evidenced in the scoping comments received, there was a wide range of interest in, and opinions expressed about, the 2012-2017 OCS Oil and Gas Leasing Program PEIS, and the comments summarized in Section 1.4.3 of the PEIS illustrate the varied and, at times, contradictory issues, concerns, and desired future conditions expressed by individuals, organizations, industry, and public agencies. This PEIS determined whether issues raised during the scoping period were relevant enough to be considered and analyzed further; any issues raised that were deemed irrelevant or beyond the scope of this PEIS were not further analyzed. Section 1.4.3 is intended to categorize and summarize the substance of the scoping comments, not reproduce the exact wording of individual comments. A number of analytical issues, many of which are addressed in this PEIS, were identified during scoping. These include the geographic scope of the PEIS, the analytical scope of the PEIS, the impacting factors to be considered in the analyses, and the resources that may be affected by the Program. These analytical issues are fully discussed in Section 1.5 of this PEIS. Also, issues that arose during the scoping process may be found addressed throughout the PEIS, as appropriate.

7. BOEM should take into account the burden on Alaska Native communities that are buried in overlapping public comment periods for very technical documents. To have different ending dates for the PEIS and the proposed Program served only to increase confusion and undermine the public process. BOEM should strive to release documents with sufficient time to review by communities and should coordinate internally with sister agencies to reduce confusion and simultaneous comment periods. Submitted comments were not made accessible during the comment period. BOEM should extend the comment period to allow

additional time for review. BOEM should ensure that it conveys the importance and purpose of their public hearings in advance. Public meetings held on Friday evenings during the holiday season are not convenient and have a low turnout. Meetings during the week from 3:00 p.m. to 7:00 p.m. are ideal.

Response: BOEM announced its intent to hold public hearings for the Draft PEIS for the Proposed 5-Year OCS Oil and Gas Leasing Program for 2012-2017 in a *Federal Register* Notice that was published on November 11, 2011 (https://www.federalregister.gov/articles/2011/11/10/2011-29152/draft-programmatic-environmental-impact-study-peis-for-proposed-5-year-outer-continental-shelf-ocs). The PEIS document was posted the same day of the Secretary's announcement of the proposed 2012-2017 Program on November 8, 2011. Hard copies of the PEIS were also sent to Alaska libraries (including universities, colleges, and public libraries) prior to filing the PEIS with the U.S. Environmental Protection Agency (USEPA). A complete distribution list can be found in Section 8.3.

The list of libraries that were sent a hard copy is presented in Section 8.3, and is posted here: http://www.boem.gov/uploadedFiles/BOEM/5-Year/2012-2017/PEIS/2012-2017_Draft_PEIS_library_list.pdf.

Public meetings were scheduled and held in full consideration of the Christmas holidays, with the first meeting beginning on December 5, 2011, in Wainright, Alaska. Eight more public meetings were held in Alaska, with the last one taking place on December 16 in Barrow, Alaska, at the Inupiat Heritage Center one week before the Christmas holidays. BOEM regrets that the 7-10 p.m. timeframe was inconvenient for some, although it was taken into consideration that meetings scheduled in the evenings are generally more convenient for most people because of other obligations during the day.

8. BOEM should develop and take public comment on a NEPA handbook designed to guide the agency's environmental analysis of OCS oil and gas issues. In a review of the Alaska Region office, the Government Accountability Office noted that "the lack of a comprehensive NEPA guidance handbook, combined with high staff turnover, leaves the process for meeting NEPA requirements ill-defined for the analysts charged with developing NEPA documents." The National Commission on the BP Deepwater Horizon Oil Spill and Offshore Drilling recommended that BOEM, in consultation with the Council on Environmental Quality (CEQ), "develop and make public a formal NEPA handbook." The National Commission recommended that the handbook "provide guidelines for applying NEPA in a consistent, transparent, and appropriate manner to decisions affecting OCS oil and gas activities." Before BOEM undertakes any additional action in the Arctic that requires environmental analysis under NEPA, the agency should commit to developing and making available for public comment a NEPA handbook as recommended by the National Commission. The National Commission recommends that BOEM address the issue of tiering in the proposed NEPA handbook noted. (Ref: Government Accountability Office, GAO-10-276, *Offshore Oil and Gas Development: Additional Guidance Would Help Strengthen the Minerals Management Service's Assessment of Environmental Impacts in the North Aleutian Basin* (March 2010); National Commission on the BP Deepwater Horizon Oil

Spill and Offshore Drilling, *Deep Water: The Gulf Oil Disaster and The Future of Offshore Drilling* (Jan. 2011)).

Response: BOEM issued NEPA Guidance in September 2011 in response to a recommendation from the 2010 Government Accountability Office (GAO) report, in which it recommended that USDOI develop and set a deadline for issuing a comprehensive NEPA handbook providing guidance on how to implement NEPA and periodically update and revise this guidance as needed. BOEM regional offices are continuing to develop internal guidance that is more appropriately tailored to their specific geographical jurisdiction.

9. In July 2011, the President established the Interagency Working Group on Coordination of Domestic Energy Development and Permitting in Alaska ("Working Group") to, among other things, "engage in long-term planning," facilitate sharing of scientific and cultural knowledge and traditional information, and coordinate scheduling of regulatory and permitting activities in the Arctic. The Proposed Final Program should clarify how BOEM will engage with the Working Group. Good faith participation in the National Ocean Council (NOC) process would facilitate improved communication and coordination among different agencies with respect to decisions about oil and gas. BOEM should provide the public with more information about how BOEM will use the "Working Group" to coordinate with other Federal agencies, share information, and inform management decisions about leasing activities in the Arctic. BOEM is encouraged to use the "Working Group" process.

   Response: The Interagency Working Group on Coordination of Domestic Energy Development and Permitting in Alaska was established by Executive Order 13580 in 2011 and seeks to coordinate the efforts of Federal agencies responsible for overseeing the safe and responsible development of onshore and offshore energy resources and associated infrastructure in Alaska and to help reduce the Nation's dependence on foreign oil. An entirely separate Executive Order (E.O. 13547 — Stewardship of the Ocean, Our Coasts, and the Great Lakes) issued in 2010 establishes a national policy to ensure the protection, maintenance, and restoration of the health of ocean, coastal, and Great Lakes ecosystems and resources, enhance the sustainability of ocean and coastal economies, preserve the Nation's maritime heritage, support sustainable uses and access, provide for adaptive management to enhance understanding of and capacity to respond to climate change and ocean acidification, and coordinate with the Nation's national security and foreign policy interests.

   Executive Order 13547 also provides for the development of coastal and marine spatial plans that build upon and improve existing Federal, State, tribal, local, and regional decision-making and planning processes. These regional plans will enable a more integrated, comprehensive, ecosystem-based, flexible, and proactive approach to planning and managing sustainable multiple uses across sectors and improve the conservation of the ocean, coasts, and the Great Lakes. Please refer to Section 4.3.1 of the PEIS for further discussion of BOEM's compliance with Executive Order 13547.

   Therefore, these two initiatives are distinct and driven by separate directives, even though there are some overlaps in the issues that are being covered by each. Notwithstanding the foregoing, BOEM supports the implementation of E.O. 13580 by participating in the Alaska

"Working Group" as well as any future efforts on public outreach regarding this engagement, however, further discussion of this topic is outside the scope of this PEIS.

8.4.4.2 Issue 2 NEPA Analysis

1. The PEIS underestimates the risks and overstates the potential benefits of oil and gas OCS activity.

   Response: The purpose of this PEIS is to identify and document the potential impacts of the proposed action and alternatives to the proposed action. In Chapter 4 of this PEIS, the effects of routine activities and cumulative effects associated with the proposed action are analyzed. BOEM also analyzes the potential impacts of a CDE.

   The discussion of the potential benefits of oil and gas activity has been clarified in this PEIS. As a complement to the impact analysis and conclusions in this PEIS, Section 2.12 summarizes the conclusions of the cost-benefit analysis of the Program. The cost-benefit analysis compares the net economic value with the net social value, the latter of which includes environmental costs. The full cost-benefit analysis discussion can be found in the Proposed Final Program document. In addition, Section 4.5, Other Alternatives, has been expanded to include a more robust tradeoff discussion, including possibly foregone socioeconomic benefits.

2. BOEM should adopt the recommendations of CEQ and the National Commission on the Deepwater Horizon (DWH) event, including: reforming its NEPA compliance procedures and incorporating 'worst-case scenario' calculations from oil spill response plans into its NEPA documents. BOEM has not addressed NEPA actions with regard to lessons learned.

   Response: BOEM prepares EISs when deemed appropriate, such as with this PEIS and multi-sale EISs. CEQ regulations require low-probability, catastrophic events to be analyzed if reasonably foreseeable. BOEM follows the CEQ regulations at 40 CFR 1502.22 in this regard. BOEM has made changes to its NEPA procedures and provides for wider use of EAs with opportunity for public comment on post-lease activities than prior to the DWH event. The PEIS has an expanded Section 4.3.3 to include not only past, but also current and likely future reforms by BOEM and BSEE that have come frequently from various independent investigations such as the National Commission on the BP Deepwater Horizon Oil Spill and Offshore Drilling. See Section 4.3.3.3.4 and response to Comment 3 in NEPA Process and Comment 1 in NEPA Analysis above.

3. BOEM should ensure that the 2012-2017 Program is part of a planning effort that acknowledges connections between marine, coastal, and terrestrial areas in the Arctic and balances energy extraction with conservation.

   Response: BOEM agrees that the 2012-2017 Program should be integrated with connections between marine, coastal, and terrestrial areas in the Arctic and all of its planning areas; therefore, BOEM coordinates with other Federal, State, local, and tribal governments and other groups and individuals that utilize various resources and geographic areas. See Section 4.3.3 for recent regulatory reforms implemented to reduce risk. BOEM must implement its programs in concert with USDOI leadership, which seeks to minimize environmental impact and maintain a robust research program with its Environmental Studies Program.

4. What if there are drastic changes within five years?

   Response: The Secretary of the Interior is empowered to cancel or postpone a lease sale, each of which was done in the GOM after the DWH event. The Secretary can also defer a lease sale area. The Secretary must also undertake annual reviews of the program per Section 18(e) of the Outer Continental Shelf Lands Act (OCSLA). That could be a mechanism to revise the program (i.e., delay or cancel sale) or reapprove a program. Enhanced Section 18(e) reviews will be done as a way to increase clarity. See Section 4.3.2 and the Proposed Final Program document for additional information.

5. While the PEIS indicates potential intensity of environmental harm from oil and gas exploration and drilling activities, it avoids concluding whether an impact will be "significant," which is the main purpose of an EIS under NEPA. Instead, the PEIS provides over-simplified charts noting whether population-level impacts for biological and physical resources are expected to be "negligible, minor, moderate, or major" and whether the incremental contribution is expected to be "small, medium, or large." Some explanation as to what these terms mean are found in the PEIS, but it is unclear how the terms are to be interpreted in relation to whether there will be a "significant impact," which is the threshold requirement for preparation of a subsequent EIS. This is troubling given the history of using tiered analysis for offshore oil and gas to achieve categorical exclusions, which circumvent adequate safety and mitigation measures to protect against oil spills and other impacts. Further, the absence of a determination at the programmatic level as to whether activities could have a "significant impact" carries the potential for DWH event, the General Accounting Office "found considerable variation among MMS's OCS regions in how they determine what constitutes a 'significant' environmental impact" (Ref: 177 See 40 CFR 1502.1 ("The primary purpose of an environmental impact statement is to serve as an action-forcing device…it shall provide a full and fair discussion of significant environmental impacts…").

   Response: NEPA's significance threshold is of most importance when deciding how to analyze a proposed action. In the case of the 5-year Program, it was determined that significant impacts could occur to various resource areas. Therefore, an environmental impact statement was prepared instead of an environmental assessment. See Section 1.3.1 for a general discussion on the scope of this PEIS. The PEIS identifies the nature, extent, and magnitude of impacts that may be incurred by natural, physical, socioeconomic, and cultural resources and systems from routine OCS Program activities as well as from accidental oil spills. The assessment approach used for the analyses presented in the PEIS, as well as definitions of impact levels, are presented in Section 4.1.3, and the impact levels are identified on a resource-by-resource basis in the Chapter 4 of the PEIS. The assessment approach as well as the impact levels used in this PEIS are fully consistent with the NEPA-required considerations of both context and intensity for determining significance (40 CFR 1508.27). There are many impacts that could be significant depending on many factors, including a possible unexpected CDE for which the impacts could be quite variable. BOEM has always recognized that a CDE has impacts that could be significant in any of its planning areas. A CDE is not part of the proposed action, but it is recognized and analyzed as a low probability catastrophic discharge event. BOEM regions have very different environments and types and levels of activities so it should be expected that there would be variation in how significant impacts are determined and why subsequent EIS's are prepared at later stages such as the lease sale stage. The fact that this PEIS was prepared is recognition of the fact that impacts from the proposed action could be "significant," but exactly when and where the impacts rising to the level of "significant" will occur cannot be determined until a later stage of OCS development.

6. The PEIS fails to meet NEPA requirements for the analysis of alternatives. BOEM failed to rigorously explore and objectively evaluate all reasonable alternatives to the Proposed Action, failed to do a thorough, comparative analysis of potential impacts at the programmatic level, and failed to include temporal or spatial deferral alternatives within a given planning area. The Department can and should do a more thorough and robust analysis of potential impacts and alternatives at the programmatic level. NEPA requires the Department to consider whether the agency can carry out proposed actions in a manner less environmentally damaging, and whether alternatives exist that make the action unnecessary.

   Response: BOEM believes that analysis presented in the PEIS meets the standards of analysis prescribed by the CEQ and that the alternatives analyzed in this PEIS represent a range of reasonable alternatives; the activities corresponding to each alternative are analyzed in view of current environmental standards, and the alternatives meet the purpose and need identified at the beginning of Chapter 1. Chapter 2 discusses the range of alternatives considered in this PEIS and includes those alternatives which are fully analyzed in this PEIS as well as those considered but eliminated from further analysis at this programmatic stage for various reasons. Alternatives not analyzed at this stage may be appropriate for re-consideration at the lease sale stage.

   Considering alternatives suggesting specific spatial or temporal deferrals, it should be emphasized that portions of planning areas (subareas) can be deferred either at the outset of, or later during, a 5-year leasing program, at the Secretary's discretion. The Secretary may "carve out" deferral areas that are based on specific, established need and supported by adequate information, such as deferral areas selected in previous 5-year program alternatives and needed to continue protection of bowhead whale migration in the Beaufort Sea and coastal subsistence uses in the Chukchi Sea.

   Detailed analyses of the large number of proposed exclusions in different planning areas, which vary widely in spatial definition and the completeness of supporting scientific information, can be more meaningfully accomplished at the lease sale stage. The determination of other areal and temporal exclusions and restrictions will depend on the location of specific lease sale areas and whether exploration and further analysis of resource potential, environmental concerns, and potential effects on other uses such as subsistence and fishing. New scientific information may become available or public input may be provided later in the Program in advance of actual lease sales that help inform such exclusion decision-making. The exclusion of specific areas or blocks within a planning area is generally considered at the lease sale stage of the Program or when specific OCS projects are being evaluated.

During scoping and the public comment period on the PEIS BOEM also received numerous comments about including an alternative that would delay both Arctic and Gulf proposed lease sales to the later years of an approved 5-year Program. Based on the Secretary's balancing decision of OCSLA factors, BOEM has already delayed Arctic sales and proposes to conduct those sales late in the Proposed Program; however, BOEM has not delayed sales in the GOM. The Secretary maintains the discretion to delay and/or cancel any lease sales in any OCS Planning Areas that are part of an approved program if he deems it prudent. Therefore, the concept and possibility of delaying lease sales is implicit in the alternatives presented in this PEIS.

Before a lease sale can occur, an additional NEPA document would need to be prepared for each of the OCS lease sale areas included in the proposed 5-year Program. These subsequent NEPA documents would focus in greater detail on local conditions in the lease sale area. During Program implementation, decisions on additional deferrals specific to that particular sale would be made. But it is generally premature to make those decisions now, particularly because if conditions described and evaluated in a 5-year PEIS changed during the Program as a result of new information, technologies, or other developments that mitigated the issues responsible for the deferral of a subarea, it would not be possible to restore the subarea for leasing during the existing Program if it were not included in the Program at the outset.

7. The PEIS should not assume that Alaskan oil and natural gas will only be transported via onshore pipelines. Tanker transport and a subsea pipeline should be considered and evaluated. The PEIS should include a discussion of the existing natural gas infrastructure and marketplace in North America.

Response: Section 1.2 has information on demand for oil and gas. Discussing all possible infrastructure and marketplace conditions is beyond the scope of this PEIS.

Onshore pipelines are the preferred transportation system for both oil and gas for engineering, economic and safety reasons. The analyses in the PEIS focus on the most likely and reasonably foreseeable activities. Additional discussions of all possible development strategies are beyond the scope of this general PEIS analysis. After leasing and exploration has resulted in the discovery of commercial size oil or gas pools, all aspects of development proposals would be analyzed before these plans are approved. At this time, BOEM does not know the location or characteristics of future commercial projects, so although the Bureau cannot categorically exclude any alternatives for development, it also must focus on the most reasonably foreseeable alternatives.

Several possible marine transportation scenarios were considered, including oil and liquid natural gas (LNG) tankering, but pipeline systems are clearly the most feasible for logistical, regulatory and economic reasons. Logistically, in the Arctic, sea ice conditions will continue to inhibit marine traffic for the majority of the year — regardless of recent trends in summer open-water conditions. Shallow water areas near shore will restrict the size of tankers, so dozens of ships would be required to carry the same volume as a large diameter overland pipeline. Therefore, pipelines are anticipated to be used for Alaska operations instead of other marine transportation options. Economically, pipelines are a more efficient delivery system for both oil and gas, and marine transport is only used when conditions preclude pipelines. Our pipeline scenario represents the most reasonably foreseeable scenario for purposes of analysis. Many other scenarios are possible, although less likely, and it is not practical to analyze less-likely alternatives for transporting oil and gas from Arctic Alaska.

Either natural gas will remain stranded or it will be delivered to market through a future transportation system. To cover the range of possibilities, BOEM included three scenarios related to a range in oil and gas prices. Under current conditions (low gas prices and no transportation system), the more likely scenario is that gas remains stranded in northern Alaska. Assuming a transportation system is built, BOEM includes natural gas production for the mid- and high-price scenarios. Of the possible systems to transport gas, a large-capacity pipeline is the most feasible for logistical, regulatory, and economic reasons. LNG transport is a possible, but less likely, alternative than a large overland pipeline system.

In 2003, a new 40-year right-of-way was approved for the Trans-Alaska Pipeline System (TAPS). Shortly thereafter, an upgrade of the system's pump stations was completed. In 2009, a study was completed to analyze problems and possible solutions associated with low flow rates. The goal of these projects is to extend the economic life of TAPS while maintaining operational efficiencies and safety. This means that there is no fixed life expectancy, and a properly configured and maintained TAPS could continue to transport oil for many decades into the future. A detailed engineering review of the corrosion status and maintenance program for the entire pipeline infrastructure on the North Slope is far beyond the scope of this general PEIS, and BOEM believes the current analytical assumptions are reasonable.

Concerning references about elevated onshore pipelines to connect to TAPS, these general assumptions are part of the reasonably foreseeable scenario and are not taken from a published engineering feasibility study. Therefore, no reference can be supplied. However, before any new pipeline systems are built, detailed studies will be done to define optimum locations and designs to minimize environmental impacts. At this time, before commercial discoveries have occurred, it is premature to speculate on the site specific details or impacts of future pipeline systems across the North Slope.

8. There should not be numerical limits or pre-determined restrictions on the number of pipeline landfalls or the potential development of oil and gas resources in Alaska.

   Response: BOEM determines the scenario based on past use and best available projections. The scenario is specifically designed in the PEIS to give the subject matter experts enough information to evaluate the general impacts from the proposed action. The Alaska-Arctic scenario described in Chapter 4.4.1.3 explains why no new pipeline landfalls or support bases are expected to occur in the Chukchi region. It is assumed that the required infrastructure would have already been constructed as a result of Lease Sale 193 activities.

9. The PEIS does not adequately take into account the effects of climate change and incorrectly claims that missing information pertaining to climate change impacts is not essential to a reasoned choice among alternatives. The PEIS wrongly claims that missing information pertaining to the impacts of climate change on marine and coastal birds is not essential to a reasoned choice among alternatives. BOEM's rationale for reaching this conclusion is that, because the information is missing for all alternatives, it is irrelevant in choosing among them (4-594). That suggestion is flawed for one simple reason: the Proposed Action and alternatives would affect climate change differently and so lead to different impacts on resources.

   The effects of climate change may not be entirely clear, but the impacts of climate change would be different under the different alternatives considered in the PEIS. Better information on the effects of climate change on resource areas, which does exist in the literature, would allow for a more accurate understanding of the differential impacts of the alternatives, and thus allow for a more reasoned choice among alternatives. BOEM should correct its erroneous statement that missing information pertaining to the impacts of climate change is not essential to a reasoned choice among alternatives, and modify its PEIS to reflect this correction accordingly.

   Response: The PEIS includes analyses of climate change as part of the baseline condition for several resource areas. Climate change is also analyzed and highlighted as an impacting factor in the cumulative impacts section for several resource areas. Scientifically credible information available at the time the PEIS was written was used, including updates between the Draft and Final PEIS. BOEM follows the CEQ regulations at 40 CFR 1502.22 regarding incomplete and unavailable information. BOEM disagrees that a clear distinction could be made among the alternatives for their impact on climate change. Instead, it is BOEM's finding that the alternatives, including the No Action Alternative, would not have a substantially different impact on climate change. Oil and gas are worldwide commodities controlled by complex economic markets and the lack of a lease sale or sales would not noticeably affect the global demand for or production of oil and gas. Climate change is a global issue that must be globally managed.

   The PEIS considers how climate change, based on the observed changes that have been occurring during the past several decades, may affect baseline conditions of resources over the 40- to 50-year period during which oil and gas production could occur following lease sales under the Program. The effects of climate change on ecosystems are complex and non-uniform across the globe and vary among atmospheric, terrestrial, and oceanic systems. Considerations of climate change effects in OCS Planning Areas focus on marine and coastal system impacts, where environmental sensitivities are typically associated with increasing atmospheric and ocean temperatures, sea-level rise, and ocean acidification. These general categories of climate change responses are occurring in addition to human-induced pressures related to coastal population densities (e.g., land use changes, pollution, overfishing) and trends of increasing human use of coastal areas. The PEIS presents resource-specific discussions of the affected environment with discussions of the effects of ongoing, observable climate changes on those resources. In addition, the impacts of the continuing trend in climate change during the life of the Program are evaluated as well. Section 3.3 of the PEIS contains a discussion of climate-change effects and baseline conditions, as do each of the resource sections.

10. Comments suggested that inadequate baseline science or information was currently available for some resources on the OCS, and moreover, without that information, potential impacts to those resources were difficult to evaluate. The PEIS does not properly deal with the fact that baseline information is missing and incomplete. BOEM has a duty to gather research when information is lacking.

    Response: BOEM uses scientifically credible information that is available at the time the PEIS is written, including updates between the Draft and Final PEIS. BOEM follows the CEQ regulations at 40 CFR 1502.22 regarding incomplete and unavailable information. There is often uncertainty with respect to the context and intensity of impacts at the programmatic level of analysis. In instances of missing information related to resource impacts and mitigation for this PEIS, it was determined that the information was not essential to the Secretary's reasoned choice among alternatives at this broad, programmatic stage. If missing or unavailable information were to be arguably necessary to a reasoned choice among alternatives, the Secretary would treat this information as directed by the CEQ regulations implementing NEPA. Even in the face of unavailable information, the Secretary must maintain an oil and gas leasing program, but, at the lease sale stage, the Secretary does have the discretion to delay and cancel lease sales that are part of an approved 5-year Program. For example, if missing information is identified and it is deemed essential to a lease sale decision, the Secretary can cancel or delay the sale.

    BOEM asserts that there is adequate scientific baseline knowledge of the OCS for the decision at hand, which is establishing a schedule of potential lease sales and framing the geographic scope for which OCS development can occur. If exploration and development occur as a result of the lease sale, each ensuing project would undergo additional environmental review and analysis that focuses on a smaller area, as mentioned above. Should the proposed 5-year Program be approved, subsequent NEPA documents would focus in greater detail on local conditions and identify additional mitigation measures relevant to the lease sale area. Therefore, in view of the increasing focus and specificity of NEPA documents that would occur if an approved 5-year program progresses to further stages, BOEM believes that the analysis in this PEIS is appropriate at this preliminary planning stage of the proposed 2012-2017 Program.

11. It would be helpful for the PEIS to provide more information on how BOEM will determine the appropriate level of NEPA documentation for actions "tiered" from this PEIS.

    Response: Table 1-1 in the PEIS shows the various tiering stages. BOEM has clarified its commitments and procedures in the PEIS with regard to deferrals (see Section 4.3.2). The regional offices determine what level of NEPA documentation is needed based on many factors (e.g., see 40 CFR 1502.9(c)). BOEM follows CEQ regulations and guidance in determining the appropriate level of NEPA documentation for all Bureau actions. Generally, in the BOEM GOM Regional Office, the NEPA document would be an environmental impact statement (EIS) at the lease sale stage and an environmental assessment (EA) or categorical exclusion review (CER) at the plan stage. Generally, in the BOEM Alaska Regional Office, the NEPA document would be an EIS for at the lease sale and EIS or EA at the plan stages due to the frontier nature of oil and gas activity in the Alaska region.

12. Section 1.3.1.1, Incomplete and Unavailable Information: The PEIS states that "CEQ regulations require an agency to obtain, or explain why it cannot obtain, relevant information about reasonably foreseeable significant adverse impacts that is essential to a reasoned choice among the alternatives presented in an EIS (40 CFR 1502.22)." However, the actual instructions concerning how to analyze incomplete or unavailable information in regulation 1502.22 have more detail than the quoted sentence suggests. We recommend revising this statement to better reflect the CEQ regulations.

    Response: The discussion of incomplete and unavailable information, now found in Section 1.4.2 of the PEIS, presents a salient excerpt and points the reader to the full regulatory citation.

13. BOEM claims that deferring deepwater leasing would not be reasonable because allowing deepwater leasing strikes the right balance between potential benefits (specifically, helping to meet the Nation's need for oil and gas) and adverse impacts, such as environmental damage to the ocean and coastal zone. How the PEIS arrives at this conclusion is not at all clear. Indeed, no analysis in support of this statement is conducted; it is simply stated as a self-evident truth. That approach is exactly backward. The purpose of an EIS is to evaluate the "comparative merits" of the Proposed Action and reasonable alternatives (40 CFR 1502.14) and then determine which action is most appropriate in light of the environmental impacts of each. In the PEIS, however, BOEM simply presumes that maximum oil and gas production — including deepwater leases — is more appropriate than an option that excludes deepwater leases. BOEM's approach ignores the purpose of NEPA review by rejecting out of hand a reasonable alternative that would "avoid or minimize" the adverse environmental impacts of the 5-year Program (40 CFR 1502.1).

    Response: Without new deepwater activity in the GOM for the Program, 93% of the expected oil production from the Program would become unavailable, essentially removing GOM oil production from the 2012-2017 Program (see Table 4.4.1-2 for depth-related scenario information). As discussed in Section 4.3.3, water depth is only one of many factors that control oil-spill risk (see Table 4.3.3-2 for a listing of these complex risk factors). While there may be greater logistical difficulties associated with containing a catastrophic discharge event in deepwater, the risk to environmental resources from shallow-water drilling in some circumstances could be greater because of the proximity to and greater likelihood of oil contact with many of those resources. Therefore, excluding deepwater from the Program does not necessarily equate to avoiding or minimizing adverse environmental impacts. In addition, excluding deepwater activity in the GOM for this Program does not stop any associated adverse environmental impacts that could occur from currently leased oil and gas activity in deepwater areas of GOM. BOEM's rationale for not fully analyzing a GOM deepwater deferral has been expanded (see Section 2.9.7).

14. With the exception of the Central and Western GOM Planning Areas, all OCS Planning Areas would benefit from the addition of new geophysical seismic data. Doing so would help us understand what resources are subject to administrative withdrawals or moratoria, would better inform the decision making process for administrative withdrawals or moratoria during the length of the program, and would encourage interest in those areas if and when they are opened.

    Response: The collection of geophysical data in OCS areas outside Program areas is beyond the scope of this PEIS. The PEIS considers the environmental effects of geophysical operations in the six planning areas under consideration.

15. A comprehensive, stakeholder-driven scientific research and monitoring program should be in place before BOEM decides whether and where leases should be offered on the OCS.

    Response: BOEM has a robust research program with its Environmental Studies Program (ESP), which was initiated in 1973. BOEM's ESP in the Alaska Region alone has funded over 400 biological, physical oceanographic, contaminants, and socioeconomic studies for a total of over $300 million and currently has 50 studies underway, 90% having to do with the Arctic offshore.

    BOEM implements a concerted effort to find and fund relevant research in all of the regions where it is involved. The research is comprehensive, covering physical oceanography, atmospheric sciences, biology, protected species, social sciences and economics, submerged cultural resources and environmental fates and effects. The Environmental Studies Program Information System (ESPIS) is a searchable database of all completed ESP reports (http://www.boem.gov/Environmental-Stewardship/Environmental-Studies-Program-Information-System.aspx). It includes technical summaries of more than 700 BOEM-sponsored environmental research projects, and more than 2,000 full research reports. BSEE's Technology Assessment and Research (TAR) Program and Environmental Studies Program work in concert by conducting interdisciplinary cooperative research projects. These joint efforts allow for a broader research scope and help to maximize the efficient use of the funds available for studies. The TAR Program supports research associated with operational safety and pollution prevention as well as oil-spill response and cleanup capabilities. The TAR program was established in the 1970s to ensure that industry operations on the OCS incorporated the use of the best available and safest technologies.

    See also comment responses in Issues 4 (Environmental Concerns), 5 (Cumulative Impacts), and 6 (Oil Spills) for more information on how the PEIS has been further expanded to address these concerns.

16. The PEIS does not contain a sufficient analysis of the impacts of the DWH event in the GOM in order to make a decision. The full impacts of the DWH event on the GOM are not yet understood. The ecological baseline in the Gulf has changed and the PEIS should be updated to include this information as well as lessons learned from the event.

Response: The purpose of the PEIS is to look at environmental impacts associated with a decision on a schedule of potential OCS oil and gas lease sales from 2012–2017. The full impact of the DWH event on the GOM probably will not be understood for many years to come and may never be understood. However, BOEM used the best available, scientifically credible information to update the Final PEIS. Chapters 3 and 4 of the PEIS have been updated with numerous references to peer-reviewed scientific information about the status of the GOM environmental baseline and the nature of the effects from the DWH event. In addition, the PEIS includes a much expanded Section 4.3.3 on risk that did not appear in the EIS for the 2007-2012 Program and within that Section, 4.3.3.3.4 discusses BOEM regulatory reforms as a result of the DWH event. Lessons learned and regulatory reforms will be an ongoing process.

BOEM implements a concerted effort to find and fund relevant research in all the regions where it is involved. Research covers physical oceanography, atmospheric sciences, biology, protected species, social sciences and economics, submerged cultural resources, and environmental fates and effects. The ESPIS is a searchable database of all completed ESP reports. It includes technical summaries of more than 700 BOEM-sponsored environmental research projects, and more than 2,000 full research reports. BSEE's TAR Program and ESP work in concert by conducting interdisciplinary cooperative research projects. These joint efforts allow for a broader research scope and help to maximize the efficient use of the funds available for studies. The TAR Program supports research associated with operational safety and pollution prevention as well as oil spill response and cleanup capabilities. The TAR program was established in the 1970s to ensure that industry operations on the OCS incorporated the use of the best available and safest technologies.

There is often uncertainty with respect to the context and intensity of impacts at the programmatic level of analysis. In instances of missing information related to resource impacts and mitigation for this PEIS, it was determined that the information was not essential to the Secretary's reasoned choice among alternatives at this broad, programmatic stage. If missing or unavailable information were to be arguably necessary to a reasoned choice among alternatives, the Secretary would treat this information as directed by the CEQ regulations implementing NEPA. Per OCSLA, the Secretary is not at liberty to delay the issuance of the entire 5-year Program due to the unavailability of the information, but at the lease sale stage the Secretary does have the discretion to delay and cancel lease sales that are part of an approved 5-year Program. For example, if missing information is identified and it is deemed essential to a lease sale decision, the Secretary can cancel or delay the sale.

At this stage, the Secretary is only establishing a schedule of potential lease sales and framing the geographic scope for which OCS development can occur. If exploration and development occur as a result of the lease sale, each ensuing project would undergo additional environmental review and analysis that focuses on a smaller area, as mentioned above. Should the proposed 5-year Program be approved, subsequent NEPA documents would focus in greater detail on local conditions and identify additional mitigation measures relevant to the lease sale area. Therefore, in view of the increasing focus and specificity of NEPA documents that would occur if an approved 5-year Program progresses to further stages, the Bureau believes that the analysis in this PEIS is appropriate at this preliminary planning stage of the proposed 2012-2017 Program.

17. Ecosystem-based models are needed to predict how expanded offshore oil and gas drilling in the GOM would impact the marine environment and resources. Fulton et al. (2011) demonstrates an ecosystem-based model called the Atlantis modeling framework, which has been used for decades for marine management decision making. This modeling framework is being coupled to climate, biophysical and economic models to help consider climate change impacts, monitoring schemes and multiple use management. This model could be utilized in the PEIS to give a comprehensive view of the impacts of oil and gas activities on water quality, air quality, greenhouse gas emissions, oil spill risk, affected habitats, subsistence communities and other resources. Using this model would greatly improve the PEIS by giving it a more encompassing view of oil and gas activities weighed against affected environments and the multiple long-term uses that have been described within the lease sale areas in the 5-year Program.

    Another good example of an applied environmental sensitivity index is Grilli et al. (2011), which was used for offshore wind site assessment in the Rhode Island Special Area Management Plan. This model incorporates fisheries, recreation, and biodiversity to weigh the impacts of siting offshore wind in certain locations off Rhode Island. This model could be further scaled up to give an impact index for the 5-year Program's proposed oil and gas activities in the GOM Large Marine Ecosystem by incorporating multiple uses and biodiversity. These modeling studies will require consultation from NOAA and FWS about endangered species and commercially important species. In light of such a large stressor like the DWH event, it is even more imperative that the PEIS adequately model how the GOM has changed and how it could be further impacted by offshore oil and gas activities in the 5-year Program in order to make a reasoned decision amongst the alternatives.

    Response: An ecosystem model is an abstract representation of an ecosystem which is developed to help understand how the actual ecosystem functions. It integrates known biological and physical data to help make predictions about how the ecosystem may react under different conditions. Ecosystems themselves are complex, with many interacting variables. Ecosystem models have to simplify these interactions using a limited number of variables that are well-understood. Ecosystem models are, by their nature, limited by the quality and completeness of the data used to develop them and by the scope of the objectives of the model design. Ecosystem models developed for a specific geographic area (such as Atlantis) may not easily transfer to other areas, because of the lack of comparable data inputs or differences in the importance of various ecosystem components to ecosystem structure and function. Specifically, the Atlantis model and methodologies like the Rhode Island Special Area Management Plan (SAMP) have only been implemented in a few small areas to address specific non-energy management concerns. The effort involved to scale these methodologies to the entire U.S.OCS would be a substantial, multi-year process limited by the intense data requirements noted above. BOEM is currently evaluating multiple potential methodologies to address the potential impacts of OCS energy development (including Atlantis and the Rhode Island SAMP) as the agency strengthens its analysis of relative environmental sensitivity, but it disagrees that a large-scale ecosystem model is essential to making a reasoned choice among the alternatives presented in the PEIS.

BOEM recognizes models can be useful tools to help understand what outcomes are expected under various conditions and uses models in the analysis of impacts for the 5-year Program and subsequent lease sales and plans. BOEM includes conceptual models for a wide range of individual resources in the 5-year PEIS (see Figures 4.4.7.1- 4.4.10.3) and incorporated NOAA's Environmental Sensitivity Index and coastal vulnerability indexes into its analyses. BOEM did not develop large-scale ecosystem models as part of the 5-year EIS process; such models might have value, but they would also have limitations, particularly at such a broad scale. The PEIS does, however, thoroughly evaluate the potential for impacts on individual resources within a broader ecosystem context.

18. Due to the extent of potential adverse impacts from offshore facility lighting with regards to protected birds and other species, and the options for reducing these impacts, we believe that a supplemental Draft PEIS must be prepared to ensure these issues are adequate to meet NEPA requirements for the Draft PEIS. While we recognize this can delay completion of the PEIS, the impacts that are not adequately addressed are significant as are BOEM's relevant legal obligations under Federal law.

    Response: BOEM asserts that the PEIS currently addresses facility lighting issues sufficiently in the PEIS for the programmatic stage of the oil and gas leasing process. At this stage, the Secretary is only establishing a schedule of potential lease sales and framing the geographic scope for which OCS development can occur. If exploration and development occur as a result of the lease sale, each ensuing project would undergo additional environmental review and analysis that focuses on a smaller area. Should the proposed Program be approved, subsequent NEPA documents would focus in greater detail on local conditions and identify additional mitigation measures relevant to the lease sale area. Therefore, in view of the increasing focus and specificity of NEPA documents that would occur if an approved 5-year Program progresses to further stages, BOEM asserts that the analysis in this PEIS is appropriate at this preliminary planning stage of the Program.

19. The effects of hydrocarbon consumption that would be produced or not produced in the Proposed Alternative should have a direct bearing on the decisions regarding the proposed leasing program. This would assess the full footprint of the Proposed Alternative and must be included. The PEIS violates NEPA by failing to quantify greenhouse gas emissions within the scope of the 5-year Program.

    Response: Consistent with judicial guidance, the USDOI does not analyze the global environmental impact of oil and gas consumption in its NEPA documents as analyzing the entire gamut of activities that entail the use of the byproducts derived from OCS extraction would be considered too remote and speculative to permit any meaningful analysis.

20. It was suggested that the PEIS clarify that, in addition to re-gasifying LNG for import, an emerging trend in GOM LNG development is to liquefy the gas for export.

    Response: The trend in exporting domestically produced LNG has been clarified in the PEIS in Section 4.6.1.2. Most natural gas is exported to Mexico or Canada; however, as an overall trend, relatively more natural gas is imported. Authorization to export LNG is provided by the U.S. Department of Energy Office of Oil and Gas Global Security and Supply, Office of Natural Gas Regulatory Activities.

21. A national energy strategy should stress conservation, efficiency, alternative transit, and the development of diverse energy supplies due to concerns about climate change and other environmental impacts from fossil fuels. Alternatively, there were suggestions that a national energy strategy should incorporate responsible oil and gas development in addition to energy conservation and renewable energy. Instead of oil and gas development, BOEM should consider a national energy strategy that shifts away from fossil fuels and promotes investments in various renewable energies and conservation strategies. This strategy would mitigate climate change and promote green jobs and energy security/independence.

    Response: The purpose of the proposed action is to prepare a schedule of potential OCS oil and gas lease sales to best meet national energy needs for the 5-year period following its approval. While we may agree that a national energy strategy is important, BOEM works within statutory and policy bounds and is not in a position to start developing a new national energy strategy.

    BOEM believes that the alternatives analyzed in this PEIS present a range of reasonable alternatives to meet the purpose and need identified at the beginning of Chapter 1, and the activities corresponding to each alternative are analyzed in view of current environmental standards.

    The role of energy conservation and renewable energy sources in meeting the energy demands of this country continues to grow. Such sources, however, could not replace the energy supplied by oil and gas from OCS sources in the near term. A more detailed discussion of alternative forms of energy and other energy substitutes for oil and gas appears in Section 4.5.7, which considers the environmental effects of the No Action Alternative. BOEM has an offshore renewable energy program committed to orderly, safe, and environmentally responsible renewable energy development activities, such as the siting and construction of offshore wind farms on the OCS, as well as other forms of renewable energy, such as wave, current, and solar. For more information about this Program, BOEM recommends that you visit the following bureau Web page: http://www.boem.gov/Renewable-Energy-Program/index.aspx.

    While the Bureau's offshore renewable energy program seeks to expand and diversify the national energy portfolio, OCLSA mandates that the management of the OCS be conducted in a manner which considers economic, social, and environmental values of both the renewable and nonrenewable resources contained in the outer Continental Shelf. Notwithstanding the valuable contributions of renewable energy sources, OCSLA specifically mandates the development of an OCS oil and gas program every five years and renewable energy development is not yet a substitute for oil and gas development.

8.4.4.3 Issue 3 Alternatives

1. The inclusion of additional areas in the leasing program would encourage new investment in offshore exploration and eventually development - an investment that would create new jobs, generate billions of dollars in economic activity, and allow for the delivery of much-needed energy to American consumers, while continuing to reduce U.S. dependence on foreign energy resources. We encourage BOEM to continue to look for opportunities to bring potentially promising areas into the leasing program.

   Response: There are 26 planning areas on the OCS, and 6 of these have been identified for leasing consideration as part of the Program (Figure 1-1). Twenty planning areas located along the Atlantic, Pacific, Florida, and Alaska coasts are neither part of the proposed action nor analyzed in any alternative considered in this PEIS. There is no requirement to include all OCS planning areas in the PEIS. On December 1, 2010, Secretary Salazar announced an updated oil and gas strategy for the OCS that recognizes a continuing Congressional moratorium in place for most of the Eastern GOM (Figure 1-2) and eliminates the Mid-Atlantic and South Atlantic Planning Areas from consideration for potential sales and development through the 2017 planning horizon. The Western GOM, Central GOM, Eastern GOM (only a very small portion thereof), Cook Inlet, Chukchi Sea, and Beaufort Sea OCS Planning Areas (Figure 1-1) are considered in the proposed Program and consequently analyzed in this PEIS. Although additional OCS areas were included in the Draft Proposed Program, the Secretary decided to exclude them from the proposed 2012-2017 Program after giving further consideration to the potential for environmental damage, the potential for the discovery of oil and gas, and the potential for adverse impact on the coastal zone in all OCS areas. The Secretary also decided to focus, in the Program, on areas with already-established leasing programs, although this could change in future 5-year programs.

2. Alternative 1 should be modified to delay GOM lease sales for 2012 or 2013 to allow time to analyze impacts of the DWH event. The PEIS violates NEPA and OCSLA by failing to consider an alternative that would forego any lease sales in the GOM Planning Areas during 2012 and 2013 so that additional data on the impacts of the DWH event can be gathered. The alternatives analysis is integral to an EIS and should ensure that decision-makers can consider "all possible approaches to a particular project (including total abandonment of the project) which would alter the environmental impact and the cost-benefit balance." BOEM's ability to cancel scheduled lease sales does not preclude its duty to conduct this environmental analysis. And while BOEM could analyze the impacts of canceling individual lease sales in subsequent EISs at the lease sale stage, that in no way negates BOEM's duty to analyze, in this EIS, the environmental impacts of a programmatic alternative in which GOM lease sales are not scheduled at all in 2012 and 2013. This alternative would be reasonable and crucial to a reasoned choice among alternatives. In fact, by not considering the alternative, the PEIS is less able to achieve one of its stated purposes. If lease sales in the GOM were canceled for 2012 and 2013, oil and gas companies could still explore for oil and gas on thousands of preexisting leases; oil and gas companies currently hold 4,251 leases in the GOM that are inactive, meaning they have no approved exploration or development plan, roughly double the number of active leases in the Gulf (*U.S. Department of the Interior Oil and Gas Lease Utilization – Onshore and Offshore*, Report to the President, Mar. 2011,

pg. 4). These inactive leases, according to the Department of the Interior, contain approximately 70% of the Undiscovered Technically Recoverable Resources in the GOM, totaling 11.6 billion barrels of oil and 59.2 tcf of natural gas. The Secretary also decided to focus, in the 2012-2017 Program, on areas with already-established leasing programs, although this could change in future 5-year programs.

Response: The OCSLA mandates that the Secretary prepare a schedule of proposed lease sales every five years. OCSLA also mandates that the Secretary select the timing and location of leasing in consideration of a proper balance among the potential for environmental damage, potential for the discovery of oil and gas, and the potential for adverse impact on the coastal zone. The Secretary must see that lease sales are conducted in an expeditious manner. These tenets clearly define the purpose and need of the proposed action. This PEIS was prepared to meet that obligation and help inform the Secretary's decision as to where and when those lease sales may be held. The consequences of approving the proposed program would be to establish a schedule for one or more lease sales within the areas included in the program, but that does not guarantee that any particular sale will occur; a scheduled lease sale can be canceled if deemed necessary in the future. Before any lease sale can occur, additional NEPA documents would be prepared for the OCS lease sale areas included in the 5-year Program, as is currently being prepared in the GOM for potential Western and Central Planning Area lease sales.

The PEIS does not include a specific alternative to delay lease sales in the GOM to allow for more time to analyze the impacts of the DWH event or allow the Gulf ecosystem to recover from oil spill effects. A different but practical equivalent of this alternative (i.e., delaying sales until oil spill response and drilling safety reform is complete), was considered, but eliminated from further evaluation as an alternative. Section 2.9.3 has been revised to address the recommendation to delay lease sales until more information is gathered regarding the DWH event.

BOEM does not analyze the suggested alternative to delay leases in the GOM until more information about the post-spill baseline condition is available because this is a decision that can best be made at the lease sale phase and is largely already embodied in the No Action Alternative considered for each individual lease sale. In previous 5-year EISs, BOEM's predecessor, the Minerals Management Service, evaluated alternatives to slow the pace of leasing with the stated objective of giving affected governments and communities more time to plan for and address sale-related impacts. However, an option to hold fewer or delay lease sales was limited to areas where leasing was not already occurring.

In the GOM, where annual lease sales are anticipated, holding relatively fewer or delaying a few lease sales does not necessarily equate to significantly less cumulative OCS activity in the present or next few years. Under a fewer or delayed Gulf lease sales scenario, BOEM still expects that most of the OCS activity that could occur over the next few years will occur under leases issued pursuant to previously approved 5-year Programs, already approved or imminently approval plans, new geophysical and geological permit applications, etc. These activities can even occur in the absence of a new 2012-2017 Program with or without another lease sale, that corresponding level of activity may influence the recovery of the GOM ecosystem. However, deferring an entire 5-year Program of lease sales in the GOM, or in either the Central or Western Planning Areas, could have an important effect in reducing the level of OCS activity at some point in the future; therefore, those alternatives are considered in the PEIS.

Holding fewer Gulf lease sales later in the 2012-2017 Program may result in a relatively minor incremental decrease or delay in the number of seismic surveys occurring in support of a new lease sale and, potentially, fewer exploration operations may proceed through the Exploration Plan, OSRP, and Application for Permit to Drill (APD) approval process following the first lease sales in the Western and Central Planning Areas. The context is fundamentally different from the Arctic, where a delay is proposed because of lack of ongoing activity and that delay will allow BOEM and BSEE to collect new data related to proposed exploration activities under previous lease sales. Even in the absence of new lease sales in 2012 and 2013 in the GOM, it is possible that industry would elect to develop existing leases, resulting in no net change in the level of overall activity. Similarly, in the longer-term reasonably foreseeable future, it is possible that holding fewer lease sales in this 5-year Program may or may not affect the overall cumulative activity in the GOM over the 40–50 year life of the program. If OCS activities remain confined to acreage currently under active lease at the start of the program, OCS operators would likely proceed on leased acreage while exploration, delineation, and development strategies would be re-evaluated in consideration of restricted access to acreage that, if acquired, could have served to improve the delineation of their oil and gas prospects. New lease terms were put into place for Lease Sale 218 and combined Lease Sales 216/222 during the last sales under the 2007-2012 Program to in part incentivize industry to re-evaluate its portfolios of leases and develop leases more quickly. Industry may perceive these policy changes as a signal of future access restrictions and may react by increasing its bidding activity on tracts in available areas under later 2012-2017 lease sales in order to improve its acreage position. Restricting access to acreage available for lease in space or time will challenge industry to reallocate and re-prioritize assets; however, the nature of this re-distribution is somewhat speculative and will not be carried out only within the confines of the U.S. OCS.

If the 1989 Valdez incident in Prince William Sound is a corollary, a definitive scientific understanding of the environmental impacts of the DWH event may take a very long time to achieve through the pre-assessment and injury-assessment phases of the Natural Resources Damage Assessment (NRDA) process (i.e., well beyond a 2-year horizon). Under the provisions of the Oil Pollution Act, the NRDA Trustees are collecting valuable scientific data to help define the extent of impacts and loss of public resources realized during and following the DWH event. This also necessitates consideration of the extent to which the Gulf ecosystem is resilient and has inherent capacity to recover. BOEM is a cooperating agency on the NRDA Programmatic EIS currently being developed to evaluate a range of restoration alternatives to compensate the public and the environment for loss of natural resources and services due to the DWH event.

This PEIS was prepared to provide the Secretary of the Interior with best-available environmental information to consider when developing a national schedule of OCS oil and gas lease sales for the 2012–2017 timeframe. Again, the Secretary maintains the discretion to postpone or cancel lease sales at any time, or suspend operations if scientific evidence indicates it is prudent to do so.

To make sure that this issue is memorialized in the PEIS, BOEM has included a new section (Section 4.3.2) in the Issues of Programmatic Concern in order to facilitate the process of considering and evaluating different alternatives and mitigation strategies that may need to be applied at appropriate program decision points. Consistent with the NEPA Task Force recommendation, the PEIS provides a roadmap, explaining where and when deferred issues raised by the public and/or regulatory agencies will be addressed. Chapters 1 and 2 of the PEIS explain how more detailed analyses in subsequent lease sale NEPA documents will evaluate the need for specific mitigation in different program areas. Section 4.3.2 also describes the process BOEM will follow during program implementation to ensure focused leasing alternatives will be tracked and evaluated during the program, along with mechanisms for stakeholders to engage in and contribute to the lease sale alternative evaluation and development process.

3. BOEM should have made allowances for partial leasing of each of the OCS planning areas.

   Response: Portions of planning areas (subareas) can be deferred either at the outset of, or later during, a 5-year leasing program, at the Secretary's discretion. The Secretary may "carve out" deferral areas that are based on specific, established need and supported by adequate information, such as deferral areas analyzed and selected in previous 5-year program alternatives and needed to continue protection of bowhead whale migration in the Beaufort Sea and coastal subsistence uses in the Chukchi Sea. Detailed analyses of the large number of proposed exclusions in different planning areas, which vary widely in spatial definition and the completeness of supporting scientific information, can be more meaningfully accomplished at the lease sale stage. The determination of other areal and temporal exclusions and restrictions will depend on the location of specific lease sale areas and whether exploration and further analysis of resource potential, environmental concerns, and potential effects on other uses such as subsistence and fishing. New scientific information may become available or public input may be provided later in the Program in advance of actual lease sales that help inform such exclusion decision-making. The exclusion of specific areas or blocks within a planning area is generally considered at the lease sale stage of the Program or when specific OCS projects are being evaluated. Please refer to Section 4.3.2 for a description of the process BOEM has committed to during program implementation to ensure focused leasing alternatives will be tracked and evaluated during the Program, along with mechanisms for stakeholders to engage in and contribute to the lease sale alternative evaluation and development process.

4. The PEIS includes minimal discussion of Alternative 5 to exclude the Beaufort Sea Planning Area and Alternative 6 to exclude the Chukchi Sea Planning area for the duration of the program. The discussion is limited to one short paragraph for each alternative, concluding only that "the potentially available resources" that would "not be made available" under these alternatives include: "as much as 0.4 Bbbl of oil and as much as 2.2 Tcf of natural gas" for the Beaufort Sea Planning Area and "as much as 2.1 Bbbl of oil and as much as 8.0 Tcf of natural gas." The PEIS lacks a discussion of the advantages of excluding these regions from lease sales — such as avoiding the numerous potential significant impacts to the ecological and economic health of the region that could result from oil and gas drilling. Without this

evaluation, it is impossible for the PEIS to provide "a clear basis for making a reasoned choice among the alternatives by the decision-maker."

Response: Section 4.5 of the PEIS describes the potential effects associated with each of the action alternatives considered. Sections 4.5.4 and 4.5.5 generally considered adverse effects avoided by not pursuing oil and gas exploration and development activities in the Beaufort Sea and Chukchi Sea Planning Areas, respectively. The PEIS has been revised to better characterize the possible beneficial effects of pursuing those alternatives, which are inherently related to avoided adverse effects. The potential for different economic effects under those exclusion alternatives is also presented in Section 4.5 and Section 2.12.

5. BOEM must revisit its analysis of the "No Action Alternative" in order to more fully depict the potential benefits of no action, ensuring that costs are depicted appropriately for the Arctic region, appropriately incorporate conservation and efficiency, and include a discussion of an option value. Once it corrects those failings, BOEM must use this information in the PEIS to more accurately reflect the costs and benefits of alternatives relevant to the Arctic Ocean.

Response: BOEM has revised the effects analysis of the "No Action" Alternative (Alternative 8; see Section 4.5.7). BOEM has incorporated by reference the Energy Alternatives and the Environment Report (OCS Study BOEM 2011-051), which provides the underlying energy substitution scenario, including estimates of substitutions across energy sectors that may be reasonably expected under that alternative. A redacted, preliminary version of the draft report formed the basis of the discussion of the No Action Alternative in the PEIS. BOEM has revised the Energy Alternatives and the Environment Report to address relevant comments received on the PEIS and Proposed Program. In turn, the No Action Alternative content has been revised in the PEIS. In addition, the PEIS incorporates by reference and summarizes the cost-benefit analysis prepared under the Section 18 requirements of the OCSLA. The cost-benefit summary can be found in Section 2.12.12 of the PEIS. The underlying methodologies for economic analysis are described in a series of related reports (e.g., Economic Analysis Methodology for the 5-year OCS Oil and Gas Leasing Program 2012-2017 (OCS Study BOEM-2011-050) and Description of the Cost and Benefit Calculations in the Offshore Environmental Cost Model (no publication number is available).

The PEIS discloses potential adverse and beneficial impacts associated with the No Action Alternative, such as the potential for increased spill impacts from tankering in non-Arctic U.S. waters and avoided adverse impacts from no OCS oil and gas development and tankering in the Arctic. The Proposed Final Program depicts the monetized cost of pursuing the No Action Alternative in the Arctic Planning Areas. The PEIS and Proposed Final Program documents treat the potential for conservation and efficiency substitution, which were estimated as a 6% reduction in demand over the life of the program. The PEIS and supporting analytical documents have been revised to further clarify the nature of impacts under the No Action Alternative, incorporate the cost-benefit analysis per the CEQ requirements in 30 CFR 1502.23, and more fully discuss adverse and beneficial effects of the No Action Alternative, including potential economic ramifications. Note that the CEQ requirement does not provide any instruction about the methodology and/or content of the cost-benefit analysis, but rather, simply states that if a cost-benefit analysis, in whatever form, is prepared, that analysis should be used to help aid in evaluating the environmental consequences of alternatives.

Option value is the sum of individuals' willingness to pay for maintaining or preserving a public good now for later or different use, even if there is little or no likelihood of actually ever using it, which has not historically been considered in BOEM's Section 18 cost-benefit analyses. It is discussed within the framework of the Fair Market Value analysis in the context of hurdle prices (p. 70-72 of Proposed Program). In the Proposed Final Program, BOEM has clarified that discussion addressing option value, which in turn has been incorporated by reference into Chapter 2 of this PEIS.

6. By not considering the potential for increased research and development and deployment of alternate/renewable energy sources, spurred by a reduced emphasis on oil and gas production, the PEIS fails to adequately characterize the potential for those alternatives to displace the oil and gas that would be produced under the Proposed Action. For example, the PEIS does not include assumptions about additional government investment in potential of electric vehicles (EVs) and plug-in hybrid electric vehicles (PHEVs). This shortcoming does not apply only to the PEIS's discussion of EVs, but to its discussion of oil and gas action alternatives as a whole. Thus, the PEIS fails to properly substantiate its claim that alternate/renewable energy sources could not replace some or all oil and gas that would be produced under the Proposed Action. The Energy Information Agency's (EIA) energy projection is only one of many trusted sources that provide energy projections. The PEIS seems to ignore other trusted sources for energy consumption projections.

   Response: The substitution effects anticipated by pursuing the No Action Alternative can be found in BOEM's Energy Alternatives and Environment report. The report has been incorporated into the discussion of the impacts of the No Action Alternative presented in the PEIS (Section 4.5.7) to provide BOEM's most current evaluations of energy substitutions for oil and gas and their near- and long-term market outlooks. As explained in another associated report, Economic Analysis Methodology for the 5-year OCS Oil and Gas Leasing Program 2012-2017 (OCS Study BOEM 2012-022, BOEM uses the MarketSim model to estimate the substitutions for offshore oil and gas production in the absence of lease sales in each of the areas. MarketSim calculates the energy market substitutions of additional imports, onshore production, and fuel switching, as well as reduced demand and consumption of oil and gas that could potentially replace OCS production. MarketSim models oil, gas, coal, and electricity markets under a special energy projection baseline run by the EIA's National Energy Modeling System (NEMS). The exploration and development scenarios from each Planning Area, summarized in Section 4.4 of the PEIS, are then introduced into the model as a shock to this special baseline, triggering a series of simulated price changes until each fuel market reaches equilibrium or supply equals demand. The MarketSim uses elasticities derived from the special EIA NEMS runs and elasticities from other credible elasticity studies to estimate the changes that would occur to prices and energy production and consumption through 2064.

BOEM maintains that the EIA information is an authoritative source where the underlying assumptions regarding each energy sector are clearly specified in source documentation. In this specific analysis, MarketSim incorporates a modified NEMS version of the EIA's 2009 Annual Energy Outlook (AEO) reference case (updated to reflect the American Recovery and Reinvestment Act). The AEO reference case is normally based on baseline assumptions for future OCS oil and gas leasing, but has been modified to assume no OCS leasing. The modified version is prepared by EIA at BOEM's request. Each energy sector is modeled separately for residential, commercial, industrial, and transportation demand with the own-price and cross-price elasticity specific to each submarket and fuel. NEMS also includes macroeconomic and international modules to address concerns like those raised in this comment about policy decisions that potentially affect energy demand and consumption. Each module incorporates the potential impact of government policies combined with the most likely trajectories for primary energy prices, technology adoption, and global economic growth. In order to produce a policy-neutral forecast, the AEO reference case used in NEMS incorporates only existing laws, rules, and regulations, taking into account the effective start and end date of each. The discussion of energy alternatives in this paper demonstrates the potential — independent of OCS leasing decisions — for reduction in oil and gas demand, both from increased efficiency and the transition to alternative fuels. To explore the impact of these factors, the EIA's AEO Outlook analyses also include a number of "side cases" that look at the impact of deviations from the baseline assumptions used in the reference case. The Energy Alternatives and Environment report has been revised to more clearly address side cases: policies and standards cases, technology cases, and greenhouse gas cases.

In general, the side cases illustrate the potential variability in future energy market conditions and examine many of the substitution opportunities already discussed in the No Action Alternative. The changes under these cases generally include reductions in overall energy consumption and may also accelerate the shift away from oil and gas; however, the alternative energy substitutes do not alter the fundamental dependence of the U.S. economy on oil and gas, or at least, reduce oil demand to the point that the United States would become a net exporter. Furthermore, the impact of any of these NEMS side cases would likely affect all alternatives, not just the no action alternatives. Therefore, the relative percentage changes of substitutions under the No Action Alternative are unlikely to change significantly under alternate NEMS cases. For this reason, BOEM does not conduct detailed MarketSim analyses for each side case and different set of policy assumptions. Finally, it is important to note that the Secretary's authority is generally confined to a decision on the oil and gas leasing program options, not the national energy policy decisions that are embodied in the NEMS side cases. As a result, information based on the policy-neutral forecast in the AEO reference case (reflecting only current laws, rules, and regulations) is the most useful for the Secretary in making his decision. BOEM acknowledges that there are other factors beyond the Secretary's authority that could lead to innovations in energy efficiency and renewable energy technologies, major changes in consumer attitudes towards "green" energy, and unforeseen changes in global energy markets.

In summary, the MarketSim analysis indicates that increases in imports and domestic onshore production as well as fuel switching would be necessary to meet continuing domestic demand for oil and gas resources. Although the model provides estimates specific to the anticipated production from each Planning Area, on average it indicates overall that most of the anticipated production would be replaced by increased oil imports, but with the remainder replaced by increased onshore gas production, gas imports, domestic coal production, electricity, onshore oil production, and other energy sources. As summarized in the PEIS in Section 4.6, the production reduction without new leasing would lead to slightly higher prices, which would lead to only a small change in the quantity of oil and gas demanded. Additional domestic production, increased imports, or fuel switching would be necessary to meet the continuing demand for oil and gas resources. Renewable energy contributions will account for less than around 2% of the substitution market, despite ongoing Administration initiatives to expand renewable energy sources on Federal lands and on the OCS.

7. Alternate/Renewable energy and energy efficiency need not replace all of the energy supplied by OCS oil and gas in order to be considered a viable alternative. Alternate/Renewable energy and energy efficiency would minimize significant impacts to the environment and create jobs, so an alternative that renewable energy can serve as a partial substitute for oil and gas leasing should be considered.

   Response: Section 2.9.4 presents the rationale why BOEM has eliminated from detailed analysis the alternative of partial substitution of renewable energy sources. As summarized in Section 4.5.7, the reduction in production provided no new OCS oil and gas leasing in the next five years would lead to slightly higher prices which in turn would lead to only a small reduction in oil and gas demand and substitution towards renewable energy sources (~4% in biofuels, solar, wind, hydropower, etc.). Additional domestic production, increased imports, or fuel switching would be absolutely necessary to meet the continuing demand for oil and gas resources as the United States will continue to be a net importer of oil. Although BOEM recognizes recent advances in renewable energy technology, renewable energy-friendly Federal and State energy policy changes (e.g., Department of Energy and tax subsidies, State renewable energy portfolio standards), and increases in U.S. market demand and supply, renewable energy, under the present set of policy assumptions, is not a major partial substitute over the window of consideration. Although CEQ's Forty Questions indicates that BOEM should consider alternatives outside of the Secretary's jurisdiction, in certain circumstances, the investments and policy changes required to achieve such a significant policy shift are not reasonable or economically practical within the 2012–2017 framework. This fact supports a less searching treatment of partial alternative energy as a reasonable alternative to some oil and gas OCS development.

   Consistent with judicial guidance on the 5-year Program, BOEM has incorporated by reference the Energy Alternatives and Environment report within the framework of the No Action Alternative to address the potential for substitution towards renewable energy sources. Within the constraints of the relevant authorities, the Secretary is already leading several initiatives to expand wind and solar energy development on Federal lands and on the OCS, such as Smart from the Start along the Mid-Atlantic coast. The Secretary has streamlined the regulatory burdens to facilitate renewable energy development and at the present time, there is no indication that, within market conditions, more can be done. If major policy changes were implemented over the 40–50 year life of the program, reduced consumption and/or increases in supply of renewable energy may affect the energy alternatives/substitutions. The Energy Alternatives and Energy report discloses that potential. However, as long as the United States is a net importer of oil and oil prices are determined on a world market, the alternative energy substitutes would likely affect all alternatives.

8. BOEM's rationale for not considering a 'Develop Alternate/Renewable Energy Sources' Alternative is flawed and the Final EIS should include an alternative to develop alternative energy and energy efficiency in lieu of OCS leasing.

   Response: Section 2.9.4 presents the rationale why BOEM has eliminated from detailed analysis the alternative of full or partial substitution of renewable energy sources. The role of renewable energy sources in meeting the energy demands of this country continues to grow. Such sources, however, could not replace the energy supplied by oil and gas from OCS sources in the near term. A more detailed discussion of alternative and other energy substitutes for oil and gas appears in Section 4.5.7, which considers the environmental effects of the No Action Alternative. BOEM has an offshore renewable energy program committed to orderly, safe, and environmentally responsible renewable energy development activities, such as the siting and construction of offshore wind farms on the OCS, as well as other forms of renewable energy, such as wave, current, and solar. For more information about this Program, we recommend that you visit the following bureau Web page: http://www.boem.gov/Renewable-Energy-Program/index.aspx.

   While BOEM's offshore renewable energy program seeks to expand and diversify the national energy portfolio, OCLSA mandates that the management of the OCS be conducted in a manner that considers economic, social, and environmental values of both the renewable and nonrenewable resources contained in the OCS. Notwithstanding the valuable contributions of renewable energy sources, OCSLA specifically mandates the development of an OCS oil and gas program every five years and, renewable energy development is neither a whole substitute nor a reasonable partial substitute for oil and gas development at this time. See also the response to Comment 7 in Alternatives.

9. The PEIS should thoroughly analyze an alternative to postpone the lease sales until the recommendations from the National Commission and the National Academy of Engineering are fully implemented.

   Response: As described in the PEIS, BOEM has considered but dismissed the alternative to postpone leases until the recommendations of the National Commission, the National Academy of Engineering, and other review bodies, including the Department's own Inspector General, are fully implemented. As described in Section 4.3.3, the Secretary of the Interior has pursued and continues to pursue an aggressive reform with respect to the regulatory oversight of OCS oil and gas. Many of these reforms address the underlying criticisms that resulted in recommendations for reform. The assumption that postponing leases will ultimately result in reduced activity levels on the OCS in the same timeframe is flawed, as was previously explained in context of the recommendation to delay lease sales for two years to allow the GOM ecosystem to recover from oil spill effects. In the PEIS, BOEM has further clarified its rationale for dismissal from further consideration in the PEIS of postponement of some or all sales. It also clarifies and explains that the Secretary maintains the discretion to consider the practical equivalent of the alternative suggestion at each lease sale and does so in the No Action Alternative considered at the lease sale stage. Moreover, consistent with BOEM's commitment to do so, Section 4.3 (Issues of Programmatic Concern) of the PEIS memorializes this alternative suggestion and will track its consideration through subsequent lease sales in the GOM, when it may be considered and analyzed if determined appropriate at the lease sale phase.

8.4.4.4 Issue 4 Environmental Issues and Concerns

8.4.4.4.1 Issue 4.1 General Concerns.

1. The Arctic is a fragile ecosystem that should receive special consideration; the PEIS should consider wide ecosystem impacts of a spill, and use an ecosystem approach when analyzing cumulative impacts. The PEIS should also consider climate change impacts at the ecosystem-level, and evaluate the cumulative effects of small oil spills on ecosystems.

   Response: BOEM recognizes that oil and gas development may affect natural, physical, and socioeconomic resources in the Arctic. Each resource section presented in Chapter 3 of the PEIS includes a subsection that specifically identifies the Arctic resources that may be affected by normal operations and/or accidental oil spills. Similarly, Chapter 4 of the PEIS identifies and discusses potential impacts on the Arctic environment and its resources. Specific mitigation measures for minimizing or avoiding impacts during normal operations, as well as spill response plans, will be developed at the lease sale stage and in subsequent development activities. Cumulative impacts on the Arctic environment and its resources are presented in Sections 4.6.2.3, 4.6.3.3, 4.6.4.3, and 4.6.5.3.

2. The PEIS should include discussions of how climate change, and especially changes in ocean acidification, sea ice loss, water temperatures, and freshwater inflows could affect primary and secondary productivity and nutrient cycling, and the range extension of sub-Arctic species and thus affect coastal and marine food webs and biotic communities in the Arctic.

   Response: The potential effects of climate change on coastal and marine environments and resources are discussed throughout the PEIS. Additional text discussing the potential effects of climate change (as associated with sea ice loss, increased ocean acidification, altered freshwater inflows, and increasing water temperatures) on primary and secondary productivity and food webs and associated effects on higher trophic levels, and range expansions of sub-Arctic species, has been added to several of the resource-specific discussions found in Chapter 3 of the PEIS.

3. The Draft PEIS fails to adequately analyze potential harm to the marine environment from noise impacts, including impacts to fisheries and marine mammals.

Response: The PEIS evaluates noise impacts on a variety of resources (see Chapter 4). Section 4.4.5 Potential Impacts on the Acoustic Environment examines the potential impacts of noise generated during routine oil and gas activities (such as vessel traffic, helicopter overflights, and seismic surveys) on ambient noise levels in the planning areas. BOEM does recognize the potential effects of operational noise (including that from seismic surveys), and noise-related impacts on marine mammals, marine and coastal birds, sea turtles, and invertebrates; these are addressed in the ecological resource-specific discussions of impacts found in Section 4.4.7 of Chapter 4. Those impact discussions have been revised to provide additional information regarding impacts. More detailed location- and resource-specific evaluations of noise impacts on resources will be conducted for lease sale activities and later NEPA documents. Compliance with ESA and MMPA will require consultations with NMFS and USFWS and will identify specific measures that will reduce the likelihood and magnitude of adverse impacts from routine operations to marine mammals (and other ESA-listed biota).

4. Biological hot spots and areas important for subsistence should be excluded from leasing plans. The USGS named a few of the known biological hot spots in its Arctic science review: Chukchi ice lead system, Barrow Canyon, Hannah Shoal, Point Barrow, Boulder Patch, and Camden Bay.

   Response: BOEM recognizes the presence and importance of biological hot spots in the Arctic. Camden Bay and the Boulder patch are specifically discussed in Section 3.7.2.3 of the PEIS, and the importance of ice leads is discussed in Section 3.8.1.3. Section 3.9 of the PEIS also identifies other areas of concern such as marine protected areas. Potential impacts on these various areas are discussed throughout Chapter 4 of the PEIS. The potential for impacting important biological areas will be addressed in more specific detail at the lease sale stage, as will the identification of mitigation measures to avoid or minimize impacting important areas.

5. Oil spills have impacts that can adversely affect biota and ecosystems and must be accounted for, including the effects of long-term exposure.

   Response: Chapter 4 of the PEIS discusses the impacts of oil spills, ranging in size from expected small accidental spills to unexpected catastrophic discharge events, on a resource-by-resource basis. The cumulative effects from long-term exposures are discussed in Section 4.6.4 Marine and Coastal Fauna.

6. Many sections of the Draft PEIS appear to utilize a single species approach when it comes to analyzing and describing impacts. Consider using an ecosystem approach for the cumulative impacts analysis. Suggest including a discussion on the food web and resulting ecosystem impacts.

   Response: The discussion of cumulative impacts to biota, as presented in the PEIS in Section 4.6.4, does not focus on individual species, but rather, discusses impacts on entire categories (e.g., marine mammals, coastal birds, etc.). When individual species are discussed, this is primarily in the context of providing examples of impacts. The text has been revised to present more of an ecosystem perspective, and text regarding the role of food webs in the movement of spill-related contaminants in affected ecosystems has been added to several of the fauna-specific impact sections in Chapter 4, as well as to the discussion of cumulative impacts on marine and coastal fauna in Section 4.6.4.

7. The Draft PEIS often broadly discusses biologic and physical aspects of Cook Inlet without regard for the specific area of the Inlet at issue, and there are important differences between these areas. The lower Inlet, in which the Federal lease sale may occur, is much different from the upper Inlet. Provide greater detail about the biological and physical aspects of Cook Inlet.

   Response: The affected environment discussion of the Cook Inlet Planning Area focuses on the area itself, which encompasses the lower half of the inlet. Section 4.2.3 also discusses the physical oceanography in the Cook Inlet. The level of detail provided in the PEIS is appropriate and does include resource status throughout the inlet. For example, the discussion regarding water quality (Section 3.4.2) identifies flushing times, riverine and marine inputs, and longitudinal gradients of suspended sediments within the inlet, and the discussion of marine and coastal birds identifies important avian areas throughout the inlet (see Figure 3.8.2-8 in Section 3.8.2.2). Many of the impact sections also discuss potential effects on resources in the upper portion of the inlet. Should a lease sale occur, greater detail regarding the inlet would be provided as part of the lease sale stage activities and NEPA analyses.

8. BOEM should incorporate information about the effects of the DWH event and conduct studies to examine the decomposition and weathering of spilled oil and on the effects of dispersants on water quality and ecological resources.

   Response: The programmatic-level NEPA analyses presented in the PEIS are appropriate for decision makers to make a general planning decision. The PEIS uses scientifically credible information and accepted scientific methods to make reasoned judgments and arrive at reasoned conclusions regarding the impacts and consequences of oil and gas development that could occur under the 2012-2017 Program. The PEIS discusses the effects of the DWH event on GOM resources throughout Chapter 3. Section 4.3.3 of the PEIS discusses the risk of spills (including large spills such as the DWH event), and includes a discussion of the breakdown and weathering of oil. In addition, the resource-specific impact discussions (beginning with Section 4.4.3) address the impacts of oil spills (including unexpected CDEs), as well as the impacts of cleanup activities, including the use of dispersants. These discussions have been updated to include more recent information. More detailed analyses would be conducted at later stages in the OCS leasing process. These analyses would incorporate the results of new studies that are currently underway regarding the effects of the DWH incident and the use of dispersants. There are currently numerous studies being conducted to support a Natural Resource Damage Assessment (NRDA) being prepared on the DWH spill. While much of the data and results of those investigations is currently unavailable, information from the NRDA studies will be included (as it becomes available) in lease sale and subsequent NEPA assessments. In addition, BOEM has a very robust research program through its Environmental Studies and Technology Assessment Research Programs, and the results of applicable studies coming from those programs would also be incorporated into later lease sale studies.

9. There is no proven technology to clean up an oil spill in Arctic conditions with cold temperatures, limited ability, broken sea ice, and high winds. Oil and gas development can impact bowhead, walrus, fish, and other subsistence resources. There is little baseline science that exists to measure the effects of the spill on the Arctic ecosystem.

   Response: BOEM has always recognized that a large spill could have significant environmental impacts, and also recognizes that spills occurring under winter Arctic conditions would be especially challenging to control and cleanup. In addition, the schedule for the proposed 2012-2017 Program provides that the first Arctic lease sale would not take place until 2015; leasing decisions made at that time would take into account any advances in spill response and cleanup technologies and comply with any new regulations and NTL's that may be issued by that time.

10. The Draft PEIS does not adequately account for the impacts of the Deepwater Horizon event or show the comprehensive impacts of the 5-year Program on GOM marine resources.

   Response: The purpose of the PEIS is to evaluate the potential effects of oil and gas development (from routine operations, expected accidental spills, and unexpected CDEs) on the natural, physical, and socioeconomic environment, and not to evaluate the DWH event. The PEIS does discuss the impacts of the DWH event on the current conditions of physical, natural, and socioeconomic resources of the GOM. These impacts are discussed on a resource-by-resource basis throughout Chapter 3. BOEM addresses the relevance of incomplete and unavailable information as it relates to impacts in Section 1.4.2. The PEIS has been revised to incorporate new information that has become available since the publication of the Draft PEIS. In addition, Section 4.3.3 of the PEIS discusses in depth the risk of CDEs. More detailed analyses will be conducted at the lease sale stage of the Program.

11. Chapter 6 of the Draft PEIS fails to discuss the effects of climate change, ocean acidification, and the impacts of oil spills on short-term use and long-term productivity; there is no analysis cited to support the suggestion that the pre-2010 impacts of oil and gas production in the GOM have not had an impact on biological productivity.

   Response: Chapter 6 has been revised to acknowledge the potential effects of climate change (including ocean acidification), and additional text has been added to Chapter 6 of the PEIS regarding the possible effects of oil spills (including CDE-level spills) on long-term productivity. Section 3.3 of the PEIS discusses the potential effects of climate change on baseline environmental conditions in the GOM and Alaska, including potential effects of sea level rise, ocean acidification, and other climate-related factors. While the DWH event clearly had short-term impacts on ecological resources in some portions of the GOM, it is too soon after the spill to draw any conclusions regarding the nature and magnitude of any long-term effects of the spill. As results of current, ongoing, and likely future studies evaluating long-term impacts of the spill become available, BOEM will incorporate those results in its future assessments and future decision making regarding oil and gas activities on the OCS.

8.4.4.4.2 Issue 4.2 Climate. A number of comments discussed concerns related to climate change, usually in regards to effects to specific resources. These comments are addressed in other issue comment categories and responses.

8.4.4.4.3 Issue 4.3 Water.

1. USEPA recommended the insertion of the following language in Section 4.4.3.1.

   "Permits issued under Section 402 of the Clean Water Act for offshore activities must comply with any applicable water quality standards and/or Federal water quality criteria as well as Section 403 of the Clean Water Act. Water Quality Standards consist of the water body's designated uses, water quality criteria to protect those uses and determine they are being attained, and anti-degradation policies to help protect high quality water bodies. Discharges from offshore activities near State water boundaries must comply with all applicable State Water Quality standards."

   In addition, USEPA recommended that BOEM consider incorporating the water quality effects information contained in the USEPA Region 10 Ocean Discharge Criteria Evaluations (ODCEs) previously developed for the 2006 Arctic Oil and Gas Exploration National Pollutant Discharge Elimination System (NPDES) General Permit (http://yosemite.epa.gov/rl0/water.nsf/npdes+permits/arctic-gp), as well as those that are currently being finalized for new Chukchi Sea and Beaufort Sea Exploration NPDES General Permits. USEPA Region 10 can provide copies of the latter documents when complete if they become available prior to the publication of the Final PEIS.

   Additional information should be provided about the expired USEPA Region 10 Arctic Oil and Gas Exploration NPDES General Permit and the two separate permits that will be issued for exploration for the Beaufort and Chukchi Seas that will replace the Arctic General Permit.

   Lastly, the entry for dredging and marine disposal in Table 4.6.2-1 (Section 4.6.2) should be clarified. USEPA is responsible for identifying recommended ocean disposal sites. USEPA and USACE are jointly responsible for management and monitoring of ocean disposal sites. USACE issues permits for ocean dumping of dredged material under the Marine Protection, Research, and Sanctuaries Act (MPRSA), subject to USEPA review and concurrence.

   Response: The suggested language on Sections 402 and 403 of the Clean Water Act has been added into Section 4.4.3.1 of the PEIS. The water quality effects information contained in the USEPA Region 10 NPDES permit for oil and gas exploration have been incorporated into Section 4.4.3.3 of the PEIS. Information about the USEPA Region 10 NPDES permit for has been added to Section 4.4.3.3 in the PEIS. Table 4.6.2-1 has been updated to clarify the entry for dredging and marine disposal.

2. What is the status of the DWH event? Is there oil still leaking through seeps?

   Response: The DWH event was capped on July 15, 2010. Text related to the DWH event has been updated throughout the PEIS to incorporate recent information (see Section 3.4.1.4). Naturally occurring oil seeps can be found on the sea floor of the Gulf of Mexico, and the contribution of such natural seeps to petroleum hydrocarbons in Gulf of Mexico waters is discussed in Section 3.4.1.2.2.

3. Section 4.4.3.2 of the PEIS should mention that on October 31, 2008 the United States Environmental Protection Agency (USEPA) formally approved the State of Alaska's National Pollutant Discharge Elimination System (NPDES) General Permit program application. Authority is being transferred in phases. Phase IV, which includes the discharges associated with the oil and gas industry, will be transferred to the State on October 31, 2012. The Alaska Department of Conservation (ADEC) will authorize discharges after that date.

   Response: Information on the NPDES authority transfer process has been updated in Section 4.4.3.2.

4. Section 4.4.3.2.1 of the Draft PEIS states: "The majority of wastes generated during construction and developmental drilling would consist of drill cuttings and spent muds (MMS 2002a). Drilling muds and cuttings generated when installing exploration and delineation wells would be discharged at the well site." Drilling muds are mentioned in many sections throughout the document. It would be helpful in all of these sections (not just in this one) if the reader was informed whether the muds associated with drilling in a particular geographic area were oil-based, synthetic-based, or water-based.

   Response: Additional information about drilling muds has been added to the water-quality text of the PEIS. Discussion of specific drilling muds used at a regional level is beyond the scope of the 5-year PEIS and would be presented in a lease sale or project-specific EIS.

5. Section 4.4.3.2.1 of the Draft PEIS states: "Fill deposited during artificial island construction also increases turbidity." NOAA does not have any disagreement with this statement. However, NOAA is not aware of artificial islands being used in Cook Inlet for drilling.

   Response: The reference to artificial islands in Cook Inlet has been omitted in the PEIS.

6. Section 4.4.3.3.2, Accidents: NOAA recommends clarifying the statement "A hydrocarbon plume in the water underneath the ice could persist with concentrations that are above ambient standards and background levels for a distance that would be five times greater than that in the open sea (MMS 2008b)." What is meant by "ambient standards"?

Response: Background conditions in the arctic are discussed in Section 3.4.3 of the PEIS. Text in Section 4.4.3.3 has been updated to reference the background conditions that are discussed in the Affected Environment section of the PEIS, Section 3.4.3.

7. Should the reference to "dispersant release" in Section 3.7.3.1.1 of the PEIS be changed to "dispersant application"?

   Response: The text in Section 3.7 has been revised as suggested.

8. Clarify the studies and information presented in the Draft PEIS about the fate of the oil that was released during the DWH event.

   Response: Further information and clarification about the fate of the oil that was released during the DWH event has been provided in Section 3.4, but many studies are ongoing, and may be for many years to come. Information from these and future studies will be evaluated and incorporated, when available, into future USEPA analyses conducted under the 2012-2017 OCS Leasing Program.

9. Section 3.4.1.4 of the Draft PEIS states, "The composition of the oil from the DWH event varies with the state of weathering of the oil; as the lighter-end components are removed from weathering process, only the heavier-end components remain (Core and Technical Working Groups 2010)." Should not this statement be revised to state that "only a portion of the heavier-end components remain" to clarify that heavier-end components are also partially weathered?

   Response: Section 3.4.1.4 has been revised to clarify the meaning of this statement, and additional references have been added.

10. Section 3.4.1.4 of the Draft PEIS states, "Some of the constituents released during the DWH event evaporated at the surface or rapidly dissolved into the GOM waters before the oil reached the surface." Should this statement include the fact that some constituents also underwent photo-oxidation at the surface?

    Response: The text in Section 3.4.1.4 has been revised to include photo-oxidation in the list of processes and to include additional references.

11. Section 3.4.1.4 of the Draft PEIS states, "Evidence from the DWH event indicates that methane gas released from the well was rapidly broken down by bacterial action with little oxygen drawdown (Camilli et al. 2010; Kessler et al. 2011." Should this statement refer to "natural gas" instead of "methane gas" because Kessler found that ethane and propane were also rapidly degraded, potentially even more quickly than methane?

    Response: The text in Section 3.4.1.4 has been revised to reflect that in addition to methane gas, ethane and propane gases were also present in the DWH event release, and were consumed by bacterial action.

12. Should the discussion of the fate of the oil released during the DWH event in Section 3.4.1.4 of the Draft PEIS be expanded to include a discussion of biodegradation of other oil components in the water column and along the shoreline, as discussed in work done by Operational Science Advisory Team of the Unified Area Command (OSAT) and studies by Gong and others presented at IOSC and SETAC?

    Response: The scope of this discussion is more appropriate for lease sale or project specific EISs. No changes were made to the PEIS as a result of this comment.

13. Section 3.4.1.4 of the Draft PEIS refers to the "four major constituents" of the chemical dispersant used during the DWH event. Should this phrase be changed to "four dispersant constituents" because the four items listed by BOEMRE are not the largest constituents of dispersants by volume?

    Response: The text in Section 3.4.1.4 has been revised as suggested.

14 Section 3.4.1.4.1 of the Draft PEIS discusses "a large amount of data" collected during the NRDA process regarding the scope of oil contamination. Should this discussion note that the last observation of surface oil by trained aerial observers occurred August 3, 2010, as discussed in OSAT-1?

    Response: This addition is not necessary for clarity. No changes were made to the PEIS as a result of this comment.

15. Section 3.4.1.4.1 of the PEIS states, "Within 3 km (2 mi) of the wellhead, however, concentrations of oil related chemicals in the deepwater sediments were still found to be elevated above benchmark concentrations for aquatic life (OSAT 2010)." Should this statement be qualified because not all samples in the region were above the benchmarks? Should this statement indicate that only "some samples" were above the benchmarks?

    Response: The text in Section 3.4.1.4.1 has been revised to indicate that only some samples were above the benchmarks.

16. Section 3.4.3 of the Draft PEIS states, "Hydrocarbon concentrations in sediments of the Beaufort Sea are relatively high compared with other undeveloped marine areas (Steinhauer and Boehm 1992)." Should this statement be revised to reflect the fact that the Steinhauer study uses the terms "elevated" (not "relatively high") and "non-polluted" (not "undeveloped")?

    Response: Page 249 of the Steinhauer and Boehm, 1992, report states that, "The relatively high concentrations of both saturated and aromatic hydrocarbons that constitute the sediment background in the Beaufort Sea may present difficulties in detecting low-level petrogenic inputs due to oil and gas-related activities." The PEIS text in Section 3.4.3 has been revised to reflect that Steinhauer and Boehm, 1992, presented the Beaufort Sea sediments as "non-polluted."

17. Section 3.4.3 of the Draft PEIS states, "Total hydrocarbon concentrations in sediments range from 2 to 85 milligrams per kilogram (mg/kg) (Steinhauer and Boehm 1992; Naidu et al. 2001; Brown 2003)." This statement is not included in any of the three references cited.

    Response: The text in Section 3.4.3 has been revised to reflect the hydrocarbon concentrations presented in the studies cited.

18. Section 3.4.3 of the Draft PEIS refers to "concentrations of hydrocarbons at a sampling site near West Dock in Prudhoe Bay…" Should this statement specify that these were "PAH concentrations of hydrocarbons…"?

    Response: The text in Section 3.4.3 has been changed to reflect that there were elevated concentrations of PAHs at the sampling site near West Dock in Prudhoe Bay.

19. Section 3.4.1.4 of the Draft PEIS states, "To evaluate the impacts of the DWH event on the environment, the USEPA has set benchmark concentrations of 41 compounds found in the oil from the DWH event for human health, aquatic health, and sediment (OSAT 2010). This statement could be clarified to better reflect USEPA's selection of the benchmarks. Should the phrase "USEPA has set" be changed to "USEPA selected" and should the phrase "compounds found in the oil form the DWH event" be changed to "compounds typically found in oil"? Additionally, should "41 compounds" be changed to "43 compounds" because benchmarks were also developed for nickel and vanadium?

    Response: Text was changed in Section 3.4.1.4 to reflect that the benchmarks were "USEPA selected." No change was made to the text with regard to the composition of the oil that was released during the DWH event. The text has been updated to reflect that the human health benchmarks included those for nickel and vanadium.

20. Sections 3.4.1.4.1, 3.4.1.4.2, and 3.4.1.4.3 of the Draft PEIS state that "oil leaks from boats" could have been alternate sources of oil detected after the DWH event. Should this text also note that natural seeps are a common source of oil in the GOM?

    Response: Reference to natural seeps has been added to the list of examples presented in Sections 3.4.1.4.2 and 3.4.1.4.3.

21. Section 3.4.1.4.3 of the Draft PEIS states that "seven sediment samples taken within 3 km (2 mi) of the wellhead exceeded the aquatic life sediment quality benchmark…" Should this statement indicate the total number of samples taken within the vicinity to clarify that not all samples exceeded benchmarks?

    Response: The text in Section 3.4.1.4.3 has been modified to include the total number of sediment samples (17).

22. Section 3.4.1.4.3 of the Draft PEIS states that Camilli et al. "conducted a subsurface hydrocarbon study two months after the DWH event…" Should this statement clarify that Camilli et al.'s sampling occurred while oil was still being released from the wellhead?

    Response: The statement in Section 3.4.1.4.3 has been clarified as requested.

23. Section 3.4.1.4.3 of the Draft PEIS states that Camilli et al. "found a continuous oil plume…" Should this statement be revised to refer to "dispersed oil" or "clouds of dispersed oil" to clarify that oil concentrations even in the so-called "plume" were in the low ppm to ppb range and that oil was not present in a continuous subsea "slick"? See Atlas & Hazen (2011).

    Response: The statement in Section 3.4.1.4.3has been clarified as requested.

24. In citing Camilli and Diercks, Section 3.4.1.4.3 of the Draft PEIS states that the "plume persisted for many months at this depth with no substantial biodegradation." The Camilli and Diercks studies cited here were based on conditions during the spill and are not representative of the current state of the GOM, or biodegradation once the release was stopped. Should this discussion also reference Reddy et al. (2011)? This study notes that petroleum hydrocarbons had a degradation half-life of approximately one month, while the gas and n-alkanes had a half-life on the order of two days, which suggests that biodegradation likely rapidly depleted the subsurface dispersed oil once the release was stopped.

    Response: Additional information and references have been included in the discussion of the DWH event that is presented in Section 3.4.1.4 of the PEIS. A reference to the study by Reddy et al. (2011) was added in Section 3.4.1.4, where the general fate of the released petroleum hydrocarbons is discussed. Additional discussion was added to Section 3.4.1.4.3 and clarification was provided that some of the studies cited, including the one by Camilli et al. (2010), were conducted while oil was still being released from the wellhead.

25. Section 3.4.1.4 of the Draft PEIS states that Camilli et al. (2010) "measured concentrations throughout the water column and found similarly high concentrations of aromatic hydrocarbons in the upper 100 m (328 ft)." Does this study in fact support this conclusion?

    Response: Yes, the study supports the conclusion stated in the PEIS. The attenuation at 10-m depth that Camilli et al. 2010 are referring to is hypothesized by the authors to be due to ventilation to the atmosphere that occurred near the surface. No change has been made to the PEIS as a result of this comment.

26. Should the discussion of Joye et al. (2011) in Section 3.4.1.4 of the Draft PEIS mention the sampling period (May/June 2010)?

    Response: The discussion in Section 3.4.1.4 has been updated to include sampling periods used by Joye et al. 2011.

27. Should the discussion of Joye et al. (2011) and Yvon-Lewis et al. (2011) in Section 3.4.1.4 of the Draft PEIS discusses Ryerson et al. (2011), which found "No CH4 enhancements correlated with the spill were detected on either of the two P-3 survey flights; rather CH_4 variability is attributed to larger-scale atmospheric transport and mixing of air masses affected by sinks and sources unrelated to the spill. …" Ryerson et al. (2011)?

    Response: Information from the study by Ryerson et al. 2011 has been included in the updated discussion of the DWH event presented in Section 3.4.1.4.

28. Section 3.4.1.4 of the Draft PEIS states, "The fate of 771,000 gallons of chemical dispersants injected at the DWH wellhead near the seafloor (1,500 m [4,921 ft]) was studied by Kujawinski et al. (2011)." Should this statement be revised to indicate that the quantity of chemical dispersants was approximate? Should it also be noted that Kujawinski et al.'s results were for DOSS (dioctyl sodium sulfosuccinate), only one of the dispersant ingredients? Should it be clarified that Kujawinski found DOSS concentrations to be extremely low, and below aquatic toxicity levels?

    Response: The text in Section 3.4.1.4 has been updated to clarify results of Kujawinski et al. (2011).

29. Section 3.7.2.1 of the Draft PEIS stated that impacts of a large spill "could be increased if they occurred in areas with degraded water quality, such as areas continuing to be affected by the DWH." Should this statement reference the extent of the "area" still affected, which is relatively limited?

    Response: BOEM has used the best available information at the time of publication of the FEIS to describe the area affected by the DWH event. NOAA, through the NRDA process, is still working to identify areas and resources affected by the DWH event. It should be noted that the area affected by the DWH event could expand or shrink over the years due to the influence of multiple factors.

30. Ocean discharge of a wide variety of waste streams also threatens to introduce toxins that can bioaccumulate in our food chain and disrupt the sensitive Arctic ecosystem.

    Response: Sections 4.4.7.1.3, 4.4.7.3.3, and 4.6.4.3.1 of the PEIS discuss bioaccumulation related to the OCS program in the Arctic.

31. The approach stated in Section 1.5.4 of the Draft PEIS for evaluating water quality impacts focuses on effects on biological resources: "Water quality issues relate primarily to marine water quality and how changes in water quality could affect biological resources". This statement should be expanded to clearly include human resources including public health, and traditional and customary uses.

Response: The PEIS discusses public health in Sections 3.15 and 4.4.14; water quality in Sections 3.4 and 4.4.3; and subsistence uses of resources in Sections 3.14, 3.15, 4.4.13, and 4.4.14.

32. Aquatic Life Benchmarks to estimate environmental toxicity do not reflect best available science. The Draft PEIS appears to rely heavily on the recommendations of the Aquatic Life Benchmarks developed during the BP/Deepwater Horizon incident in 2010. The PAH Benchmarks are useful because they are a measure of some of the most toxic compounds in crude oil, but they are not inclusive enough because they do not accurately measure the total toxicity of all substances in crude oil. Therefore, the toxicity of PAH Aquatic Life Benchmarks relied upon in this Draft PEIS are limited and not fully characterized. Nor does USEPA, the source of the Benchmarks, appear to currently have the resources to more fully evaluate toxicity of oil spills. The PEIS should recognize the limits of the Benchmarks and adjust assumptions to reflect those limits. Furthermore, recognizing limits in USEPA's ability to evaluate routes of exposure and mechanisms of toxicity of oil and oil-derived substances, BOEM should consider filling this gap through its environmental studies program.

    Response: The USEPA is the principal source for toxicity information. It should be noted that the USEPA states on its website (http://www.epa.gov/bpspill/health-benchmarks.html#gen2) that "benchmarks are meant to be used for screening purposes only; they are not regulatory standards, site-specific cleanup levels, or remediation goals." In Section 3.4.1.4 of the PEIS, the OSAT report is cited and the evaluation approach of the OSAT is discussed in the context of providing information about the DWH event and how that event has shaped the baseline condition of the water quality in the GOM. Much data was collected in the wake of the DWH event, and studies continue to be published discussing and evaluating that data. The OSAT study is only one of many studies cited in the PEIS to characterize the baseline condition of the water quality in the GOM, and the PEIS does not rely solely on this source in its analysis. Observed impacts on the ecological environment as a result of the DWH event are discussed in Sections 3.7 and 3.8. No changes were made to the PEIS as a result of this comment.

33. Section 4.4.11.2 of the Draft PEIS should restate the predicted amount of turbidity and drilling wastes so that there is a reference point to compare it with river discharge. In addition, it should specify the time frame in which the discharge will occur. Claiming that the turbidity and discharge by exploration and development is less than naturally occurring river discharge is misleading. River discharge carries nutrients to the ocean, and the turbidity occurs near shore extending only a few miles offshore. Furthermore, river discharge is a seasonal and predictable event to which organisms in the near shore community have adapted to. The drilling sites may occur far away from any river discharge. Increased turbidity and discharge resulting from exploration and development may impact the phytoplankton community by changing its species composition to organisms that are adapted to low light levels and have lower levels of primary production.

    Response: The text in Section 4.4.11.2 has been revised to address this comment.

34. Provide updated data concerning shoreline and nearshore impacts related to the Deepwater Horizon Event.

    Response: The text in Section 3.4.1.4 has been updated to reflect new information on shoreline and nearshore impacts of the DWH event available at the time of publication of the Final PEIS.

35. Should the Draft PEIS be revised to incorporate references to studies showing that natural seeps are common in the GOM, as well as the 2009 MMS study finding that background levels of PAHs in sediments on the Outer Continental Shelf can be as high as 1000 ppb?

    Response: The PEIS contains a discussion of natural seeps in the GOM (See Section 3.4 of the PEIS). A discussion of background levels of PAHs in sediments of the Outer Continental Shelf has been added to Section 3.4.

36. The Proposed Program notes that oil spills are unavoidable yet states that compliance with NPDES permits would reduce or prevent most impacts from normal operations. However, given the remoteness of the Arctic and the limited amount of development that currently exists, it is unclear whether sufficient government capacity is in place to ensure frequent monitoring and enforcement of NPDES permit terms. The Draft PEIS goes on to state that "in the presence of cold temperatures and ice, cleanup activities could be more difficult than in more temperate environments" (Section 4.4.3.4). Yet it goes on to conclude that a "large spill in coastal waters could result in longer term impacts on water quality, but cleanup efforts would reduce the likelihood of permanent impairment. A large spill in marine waters would be expected to have temporary impacts on water quality; however, cleanup efforts and evaporation, dilution, and dispersion would minimize the long-term impacts" (Section 4.4.3.4). This is an extraordinary and seemingly unsupportable conclusion, given the nation's past experience with oil spills, especially in colder waters; the anticipated difficulties of response and clean-up efforts in the Arctic; and the known lack of significant response infrastructure.

    Response: The USEPA is responsible for enforcement of NPDES permits. The information presented in Section 4.4.3.3 about oil spills in the Arctic has been updated.

37. The Draft PEIS estimates discharges of up to 12,000 barrels of drilling fluids and 12,000 tons of drill cuttings disposed in the Chukchi Sea (Section 4.3.3.3). Section 5.1 describes these discharges as having "unavoidable adverse environmental effects" and Section 4.4.3.4 states that "overall coastal and marine water quality impacts due to routine operations and operational discharges under the proposed action would be unavoidable." These intentional discharges, however, are clearly avoidable. We request the final EIS include a discussion of the feasibility of zero discharges during exploration activities. If zero discharges are required for production, they surely could be avoided during exploration.

    Response: The Alaska-Arctic scenario described in Section 4.4.1 includes a conservative estimate of the drilling fluids potentially discharged during exploration and development drilling in order to ensure that all potential impacting factors and water quality effects are disclosed. It should be noted that all potential discharges, either from exploration or development operations, will require USEPA NPDES permits. In the past, a limited number of widely scattered offshore exploration wells in Alaska have been allowed to discharge the drilling wastes onsite. USEPA Region 10 is in the process of reissuing the expired Arctic NPDES General Permit for exploration drilling as two general permits (Beaufort and Chukchi GP). Information about the USEPA Region 10 NPDES permit for has been added to Section 4.4.3.3 in the PEIS. The areas of coverage include potential discharges from existing lease locations and future leases that might be sold during the 2012-2017 OCS Oil and Gas Leasing Program. USEPA has signaled its intent to eliminate the authorization to discharge non-aqueous drilling fluids and associated drill cuttings, allowing only water-based drilling fluids and cuttings to be discharged, and even the latter would not be permitted to be discharged during active bowhead whaling activities in the Beaufort Sea, unless the USEPA authorizes the discharge after review of the operator's evaluation of the feasibility of drilling facility storage capacity and land-based disposal alternatives. The discharge standard may change during the 50-year activity profile associated with the program. Individual operations may provide for zero discharge as recently proposed by Shell for exploration drilling operations in Camden Bay at the Sivulliq and Torpedo prospects. Onshore exploration wells are typically required to haul all wastes back to an offsite disposal facility. For offshore production operations (many wells drilled from a platform), the PEIS assumes that drilling wastes will have to be hauled offsite for disposal. In comparison, in the GOM the USEPA allows onsite disposal.

38. The statements in Section 4.4.6.3.3 of the Draft PEIS regarding discharge of drill cutting practices should be verified against current BOEM requirements and industry practices currently being allowed. Re-injection of produced waters should not be assumed. The PEIS should describe the discharge of produced waters in more detail, including the potential volume, possible petroleum content, and potential impacts to the environment.

    Response: The Section 4.4.6.3 text states that "it is assumed that drilling muds and cuttings would be discharged in the Beaufort and Chukchi Sea Planning Areas for exploration wells only. Drilling wastes from development and production wells would be reinjected into the wells." This description is consistent with the scenario described in Table 4.4.1-4. For further information, see the response to Issue 4.3 Water, comment number 37.

8.4.4.4.4 Issue 4.4 Air.

1. The Draft PEIS should be revised to reflect the transfer in air permitting in the Arctic OCS from USEPA to BOEM.

    Response: Section 4.4.4.3 has been revised to indicate that jurisdiction for air permitting lies with BOEM and not USEPA, and a callout has been added to Appendix C, which discusses air-permitting authorities. The transfer of jurisdiction will not affect the conclusions regarding air quality presented in the Final PEIS.

2. Several comments noted the need to discuss icebreakers as important source of air emissions in the Arctic that is not present in the GOM.

   Response: The discussion in Section 3.5.2.3 of icebreaker emissions was expanded based on the information in the referenced website, as applicable.

3. Several comments noted that the air quality data presented in the Draft PEIS needs to be updated.

   Response: Air quality data were updated in Sections 3.5 and 4.4.4 with available recent data from the Alaska Department of Conservation.

4. USEPA recommends that the air quality analysis for future, project-specific EISs include the following, as appropriate, an evaluation of how the actions will comply with the new short-term 1-hr NO_2/SO_2 NAAQS and $PM_{2.5}$ standards, and an updated Class I increment analysis for the Breton National Wilderness area.

   Response: No text change required. In this PEIS, BOEM is only establishing a schedule of potential lease sales and framing the geographic scope for which OCS development can occur. If exploration and development occur following an actual lease sale, each ensuing project would undergo additional environmental review and analysis. These site-specific reviews would address impacts for all ambient standards in effect at that time and updated increment studies of affected Class I areas.

5. Section 3 — Affected Environment: Florida's State air quality standards and the nonattainment status of Hillsborough, Florida, which is a coastal GOM county, need to be updated.

   Response: Text was revised in Section 3 to update the Florida standards and nonattainment status of Hillsborough, Florida.

6. USEPA questions the validity of the analysis in Section 4.4.4 of the Draft PEIS. Based on USEPA's review of the analyses provided, it is not clear that these conclusions are supported with respect to the new short-term NO_2 and SO_2 standards and the $PM_{2.5}$ standards by ignoring the fact that SO_2 and NO_2 are precursors of $PM_{2.5}$, the time variation of NOx emissions, and USEPA source-specific modeling indicating that near-shore drilling activities may have significant NO_x impacts. The studies used in the PEIS do not address $PM_{2.5}$ impacts. USEPA is also concerned that future NEPA analyses required for the Lease Sales and Project Plan approvals may, as has occurred in the past, rely upon the more generalized analysis conducted in the PEIS, rather than provide the more detailed analysis that is needed to ensure protection of the NAAQS and coastal consistency.

   Likewise, the conclusion that the Program will be well within the PSD increments does not appear to be supported for Class I areas. Given the year of the study used in the PEIS, it does not incorporate recently permitted sources, nor include emissions from sources located within the lease blocks covered in this PEIS. The study also is reported to include only platforms and not exploratory operations. Hence, it is unclear whether it can be determined at this stage that impacts are "well within PSD increments" without more detailed analysis. USEPA recommends that the PEIS identify how the subsequent NEPA analyses for the Lease Sales for locations that may impact Breton will ensure protection of these sensitive Class I areas.

Response: No text change is required. There is often uncertainty with respect to the air impacts at the programmatic level of analysis. The PEIS used the information and studies available at the time it was written at that time, OCS activities had not been modeled to assess their potential impacts on the short-term NO_2 and SO_2 standards and the $PM_{2.5}$ standards. Since that time, additional Prevention of Significant Deterioration (PSD) modeling has been done, and the text in Section 4.4.4 was updated to include results of this modeling for the Frontier Discoverer and Noble Discoverer drillships. BOEM recognizes the need to address these issues and standards and the PEIS used available data to make reasonable estimates of the likely impacts. It was not felt that detailed assessments of impacts with respect these standards were essential to making a reasoned choice between alternatives at the programmatic level. BOEM plans to use the most detailed information available at each step in its NEPA analyses from the programmatic down to the individual lease sale level. At this programmatic stage, BOEM is only defining the geographic scope within which OCS development can occur. If exploration and development occur following an actual lease sale, each individual project would undergo additional air review and analysis focusing on the specific project area and addressing all applicable ambient standards.

7. In Section 3.5.2.2 of the Draft PEIS, the statement that ambient air concentrations in Alaska, outside of the metropolitan areas, are below the NAAQS is not correct. Elevated levels of PM_{10} and $PM_{2.5}$ have been measured at various locations throughout the State. Ambient air outside may not always be in compliance with the PM_{10} and $PM_{2.5}$ NAAQS. We recommend revising this statement to reflect actual conditions.

   Response: Text in Section 3.5.2.2 was updated based on the Alaska data referenced in the comment, as applicable.

8. The Draft PEIS discusses VOC (volatile organic compound) releases in Section 3.5.2.1 ("Evaporation from the oil spill itself would result in VOCs in the atmosphere."). This discussion should include a discussion of the dissolution of lighter and more volatile oil components.

   Response: There is no disagreement that atmospheric emissions could be affected by dissolution of certain fractions in the water. There is also no disagreement that VOCs would enter the atmosphere, regardless of the partitioning. Text was updated in Section 3.5.2.1 based on the reference to indicate, if supported by the reference, that lighter components dissolve preferentially in water.

9. The discussion in Section 3.5.2.1 of the Draft PEIS of SOA (secondary organic aerosols) should note that similar concentrations of SOA have been observed in urban data and note where that the measurements were not taken where the public has access.

Response: No text change was made. The concentration of SOAs in urban areas is not relevant. The text is limited to reported observations without attempting to account for them.

10. The Draft PEIS does not note that monitoring during the DWH response included more than BTEX (benzene, toluene, ethylbenzene and xylene) and the term “unmeasured” should be removed.

    Response: Text was added to Section 3.5.2.1 to note that additional compounds were measured. “Unmeasured” was not removed, as it accurately reflects the reference cited in the PEIS.

11. The discussion of in situ burning in Section 4.4.4.1.2 of the Draft PEIS should include a discussion of the Nova Scotia Offshore Burn Experiments.

    Response: The suggested reference for the Nova Scotia Burn Experiments was included and discussed in Section 4.4.4.1.

12. The discussion in Section 3.5.2.1 of the Draft PEIS of potential public health effects as a result of DWH event needs to account for evidence that the benzene measurements were unlikely to be attributable to evaporation from a surface slick, as measurement indicated that benzene was completely dissolved in the water column prior to surfacing. This discussion should note that short-term Louisiana benzene standard may have been exceeded as the result of numerous onshore sources. Should it also note that maximum onshore benzene concentrations measured by USEPA were higher than maximum offshore concentrations reported by BP, the National Institute for Occupational Safety and Health (NIOSH), and others, suggesting an onshore contribution?

    Response: The discussion in Section 3.5.2.1 was supplemented with information from Ryerson, T.B., et al., 2011 (Atmospheric Emissions from the Deepwater Horizon Spill Constrain Air-Water Partitioning, Hydrocarbon Fate, and Leak Rate, *Geophysical Research Letters* 38:L07803), noting that most benzene dissolved in the water column based on the referenced study. The statement about levels being above the standard was modified to indicate that the standard was met even though individual samples may have exceeded the standard level. Text was added to Section 3.5.2.1 to include the information regarding onshore sources presented in the comment.

13. In Section 3.5.2.1, the Draft PEIS appears to compare short-term monitoring results taken during the DWH event response to Louisiana’s annual ambient air quality standard for benzene.

    Response: The PEIS does not compare short term measurements to a long-term standard. It notes that even though some individual measurements exceed the long term value, the long term standard is still met (as invariably is the case for an average). However, the text in Section 3.5.2.1 was clarified to avoid confusion.

14. Section 4.4.4.1.1: The sentence about using low-sulfur fuel as a mitigation measure should be revised to indicate that low sulfur fuel and likely ultra-low sulfur fuel would only be available in the future.

    Response: The comment incorrectly states that low- and ultra-low-sulfur fuel would only be available in the future. Refineries began producing ultra-low-sulfur diesel (ULSD) in 2006, and the use of low-sulfur fuels is specified in the USEPA Clean Air Highway Diesel final rule (see http://www.epa.gov/oms/highway-diesel/regs/420f06064.htm). The PEIS text was updated in Section 4.4.4.1 to indicate that low-sulfur fuel is not a mitigating measure, but a requirement.

15. Section 4.4.4.4: The first sentence in this section should end with the additional phrase "in onshore areas".

    Response: The text in Section 4.4.4 was revised as suggested.

16. For a single operator with a single exploration plan, proposed activities can result in consumption of almost the entire National Ambient Air Quality Standards (NAAQS). Therefore, BOEM cannot conclude that additional leasing will not impact compliance air quality standards or human health in the Arctic.

    Response: No change was required. There is often uncertainty with respect to the air impacts at the programmatic level of analysis. Specific projects have not been proposed and the detailed data needed to accurately predict the potential impacts of OCS activities on NAAQS are unavailable. As discussed in Section 4.4.4, the PEIS assessed the potential impacts of OCS operations on the NAAQS using the information and studies available at the time it was written. At that time, it was felt that, in view of the unavailability of specific supporting data, detailed assessments of impacts with respect to these standards were not essential to making a reasoned choice between alternatives at the programmatic level. BOEM plans to use the most detailed information available at each step in its NEPA analyses from the programmatic level down to the individual lease sale level. At this programmatic stage, BOEM is only defining the geographic scope for which additional OCS leasing can occur. If exploration and development occur following an actual lease sale, each individual project would undergo additional air review and analysis based on detailed site-specific data. These reviews would include air quality modeling to address potential impacts of the specific proposal on all the NAAQS.

17. The discussion of ozone and ozone formation in Section 4.4.4.3 of the Draft PEIS is inaccurate and inadequate. The EIS concludes that "conditions in Alaska are seldom favorable for significant O_3 formation." This conclusion is contrary to air quality monitoring data collected by ConocoPhillips and Shell on the North Slope. Moreover, the Draft PEIS says nothing about USEPA's proposal to revise the standard. In light of the amount of background Ozone in the Arctic already, BOEM cannot ignore Ozone as a significant concern in the offering of additional leases in the Beaufort or Chukchi Seas.

Response: The text was updated where required in Section 4.4.4.3 using available data referred to in the comment. No changes were made based on what USEPA might do, what its opinion of USEPA's own standards is, or on proposed standards. An analysis based on proposed standards is inappropriate, as standards can change between proposal and promulgation.

18. BOEM cannot rely on the PSD increments to substitute for an analysis of air emissions impacts in the Arctic and the increments used are outdated. Section 4.4.4.3 of the Draft PEIS concludes that no modeling is required to analyze SO_2 and PM_{10} emissions relying upon data from a 1991 MMS document on NO_2 emissions. The Draft PEIS also concludes that if NO_2 emissions are so low (1.29 $\mu g/m^3$), no further analysis is necessary. However, this is factually incorrect. For example, Shell's air permits for the Discoverer showed modeling results far above the NO_2 concentration noted in the PEIS. Please ensure that you update the PEIS with current and real projections about the actual impacts that Arctic offshore operations will have on air quality.

    Response: The text was updated in Section 4.4.4.3 to include the PSD increments that were promulgated after the publication of the Draft PEIS and to clarify the use of PSD increments in the air impact analysis as discussed in the next paragraph.

    The analysis in the PEIS does not rely solely on PSD increments. It notes that, "The combined facility concentrations for Liberty plus background were well within NAAQS (between 2 and 30% of the standards)." Additionally, PSD increments are less than the corresponding NAAQS and, if a source meets an increment, that source alone will not cause a violation of the NAAQS. However a NAAQS analysis must also consider the contribution of other sources, often estimated by adding the source contribution to a background level as noted in the quote above. At the low impact levels provided in the references available for the PEIS, an analysis using PSD increments is reasonable. Even at the impact levels noted by the comment, which are about 10 times as large as those in the Draft PEIS, comparison with the PSD limits remains a valid indicator. The Discoverer permit was used as a source for $PM_{2.5}$ impact estimates and the text in Section 4.4.4.3 was revised accordingly.

    The $PM_{2.5}$ PSD increments were included in the discussion in Section 4.4.4.3, and in Section 3.5.2.

    BOEM plans to use the most detailed information available at each step in its NEPA analyses from the programmatic down to the individual lease sale level. At this programmatic stage, BOEM is only defining the geographic scope for which new OCS leasing can occur. If exploration and development occur as a result of an actual lease sale, each individual project would undergo additional air review and analysis based on detailed site-specific data. These reviews would include air quality modeling to address potential impacts of the specific proposal on all the NAAQS.

19. Section 4.4.4.2.2: The sections describing the air quality effects from oil spills, in situ burning and a catastrophic discharge event present different types of emissions for each region. Please identify if these emissions affect all areas or are specific to individual regions.

Section 4.4.4, Table 4.4.4-5: Because much of the activity in the Beaufort Sea and Chukchi Sea may be confined to ice-free portions of the year, it should be noted that the emissions will not be spread evenly over the year, but be condensed into approximately four months.

Response: The text was clarified in Section 4.4.4 to note whether there are expected differences in the emissions from in-situ burning in different regions. The discussions of CDE emissions in the two Alaska areas (Sections 4.4.4.2 and 4.4.4.3) refer to the GOM discussion and need no change. The discussions of spill emissions are essentially identical and need no change.

Text was added to Table 4.4.4-5 to note that emissions in Beaufort and Chukchi Seas will occur only during ice-free months.

20. In Section 4.4.4.1.2, the PEIS should specify where the measurements were taken and the relationship to the location of the public and workers; the discussion should also cite studies other than Schaum with significantly different measurements; the PEIS should clarify the term "small" by comparing it with standard reference values; and the use of Kuwaiti oil field fires should be supplemented with results from additional studies.

    Response: The reference is a source characterization and emission factor development study, not an exposure study. To avoid misinterpretation, text was added to Section 4.4.4.1 to note where the measurements were taken and that the general public does not normally have access to these locations.

    No change was required. The text fairly represents the results of the Schaum study and the reference to Schaum was not deleted. No additional studies were cited, as Schaum is an authoritative USEPA/NOAA study. The estimates from Schaum were included with the statement that the estimates "were below USEPA's level of concern" of 10^{-6}.

    Text was amended in Section 4.4.4.1 to note that there may be differences between burns in the desert and GOM environments. The PEIS text was expanded to include findings of other studies of health impacts of the Kuwaiti oil field fires.

21. The discussion of BTEX concentrations should be expanded to include comments beyond BTEX because significant sampling data is available to address the observed concentrations of other hydrocarbons.

    Response: No text change was required. The context of the paragraph is the concern over benzene levels, not the broader issue.

22. The rationale for not calculating the GHG (greenhouse gas) emissions resulting from the combustion of oil and gas produced under the Proposed 5-year Program is flawed. BOEM claims that the scope of the PEIS is too limited to account for such emissions, stating that "consumption of oil and gas is considered at a broader level when decisions are made regarding the role of oil and gas generally, including domestic production and imports, in the overall energy policy of the United States" (1-18). However, under the No Action Alternative, reduced demand would substitute for 6% of the lost OCS oil and gas (4-496,

Table 4.5.7-1). Clearly, then, the Proposed 5-year Program does have a direct bearing on the general decision of how much oil and gas the nation will consume, and where that oil and gas will come from. Although BOEM cannot predict where OCS oil and gas will be combusted, BOEM can predict and quantify in what sector OCS oil and gas will be combusted and the consequent GHG emissions. Data are available from the EIA and USEPA giving projected levels of consumption of oil and gas by sector to 2035 and GHG emissions factors for oil and gas. These data could be used to estimate GHG emissions from oil and gas produced under the 5-year Program.

Response: No text change was required. At this programmatic stage, BOEM is only defining the geographic scope for which new OCS leasing can occur. This PEIS is only examining the emissions caused by oil and gas operations on the Outer Continental Shelf (see Section 1.5.5.5). Regulation of the use of these products onshore is the responsibility of other government agencies and should be analyzed in their NEPA documents. Information on when and how the produced oil and gas will ultimately be consumed is speculative and would not inform a decision as to where OCS leasing should occur. Also, see the response to Comment 20, Section 8.4.4.1 Issue 1 as well as Section 1.5.5.5.

23. Please add greenhouse gases or CO_{2e} to the discussion of thresholds for BACT

    Response: The text was changed in Section 4.4.4 to acknowledge the 100,000/75,000 thresholds for CO_{2e}.

24. Section 4.4.4, Table 4.4.4-6: It would be useful to provide the total greenhouse gas emissions for the program in addition to the emissions by planning area.

    Response: The program totals (three planning areas) for all three planning areas were added to the tables for each planning area.

8.4.4.4.5 Issue 4.5 Acoustics.

1. Several comments noted that the discussion of sound impacts to marine mammals and birds in the GOM should receive a similar detailed level of treatment as the sound impact discussion for the Arctic region.

   Response: Text was updated in Sections 3.6 and 4.4.5 based on additional available studies that deal with the effects of noise on marine wildlife in the GOM. The discussions of sound impacts in each potential lease area reflect the availability of data, which varies between areas.

2. Several comments suggested using information from recent reports regarding background noise in the Arctic.

Response: Text was updated in Sections 3.6 and 4.4.5 to reflect the monitoring at Northstar Island and other relevant references as appropriate.

3. Several comments suggested that the Draft PEIS be updated to reflect the extensive references on marine mammals and listed species currently available.

   Response: No text change was required. The discussions of the acoustic environment presented in Sections 3.6 and 4.4.5 address only the potential changes to the acoustic baseline conditions that could result with oil and gas development under the 2012-2017 Program. Impacts of noise on marine mammals, birds, fish, and other biota are discussed separately in Section 4.4.7. At this programmatic stage, BOEM is only establishing a schedule of potential lease sales and framing the geographic scope within which additional OCS leasing can occur. The National Marine Fisheries Service (NMFS) and/or BOEM are currently preparing EISs and other environmental analyses that characterize sound sources used in oil/gas activities and potential impact of these sounds on marine mammals and other marine resources. It is at this activity-specific level that a more detailed analysis as requested in this comment should be conducted. For more information, please see http://www.nmfs.noaa.gov/pr/permits/eis/arctic.htm (Arctic), and http://www.nmfs.noaa.gov/pr/permits/incidental.htm (for the GOM).

4. Noise from oil and gas activities is an important concern because of the potential to disrupt the migration of species used for subsistence in the Northwest Arctic Borough. There is no detailed discussion of the cumulative effects of noise on animals from oil and gas activities combined with other activities such as increased shipping. In addition, the discussion of natural background noise in Section 3.6.3.1 does not recognize the lack of information about the level of background noise. The 2011 report of the U.S. Geological Survey (USGS) contains a good discussion on this topic.

   Response: The PEIS text was updated in Section 3.6.3.1 to reflect the information in the USGS report. In addition, NMFS is currently preparing an EIS addressing the effects of seismic surveys and exploratory drilling on marine mammals in the Arctic. BOEM and the North Slope Borough are cooperating agencies. BOEM anticipates that this document will contain the requested level of detail and discussion on noise effects and their impact to cumulative effects necessary for activity-level decisions (see http://www.nmfs.noaa.gov/pr/permits/eis/arctic.htm). Also see responses to related cumulative impact comments in Section 8.4.4.5 (Comments 3 and 5).

5. Section 4.4.7.1.3: This discussion contains several statements which appear to confuse frequency with sound pressure or intensity.

   Response: The text in Section 4.4.7.1 was clarified.

6. Section 2.10, Table 2.10-1, Impact-Producing Factors Associated with OCS Oil and Gas Development: Offshore construction noise should be included in the table under Noise.

Response: The table was updated as suggested.

7. Section 3.6.2.2: Regarding the statement about noise data for Cook Inlet oil platforms, Blackwell and Greene (2002) included inwater noise measurements; the highest level recorded was 119 dB re 1 µPa at a distance of 1.2 km.

   Response: The text in Section 3.6.2.2 was updated to incorporate the results of the referenced study as appropriate.

8. It is far more accurate to say that routine operations will affect the acoustic environment in the Beaufort Sea, (and in the Chuckchi Sea). Suggest changing the first sentence of Section 4.4.5.4.1 to "Routine operations will affect ambient noise conditions".

   Response: The text in Section 4.4.5.3 (previously Section 4.4.5.4.1) was revised as suggested.

9. Table 4.1.1-1, and Table 4.1.3-1: Offshore construction should be included as an impact producing factor.

   Response: The referenced tables in Section 4.1 were revised as suggested.

10. Section 4.4.5: Ambient noise levels should be stated, if known. If unknown, NOAA recommends that BOEM should conduct a study to quantify the amount of noise in the GOM.

    Response: No text change was required. BOEM has included a study profile in its new Study Development Plan to do this for the GOM. For a discussion of incomplete and unavailable information, see Section 1.4.2 and the response to Comment 10 in Section 8.4.4.2.

11. Tables 2.10-1 and 4.1.1-1 in Sections 2.10 and 4.1.1. BOEM should note that exploration drilling is accompanied by seismic noise.

    Response: The referenced tables in Sections 2.10 and 4.1.1 were revised as suggested.

12. In Section 3.6.1.4, BOEM has listed seismic technologies that, except for marine vibroseis, are outdated, are not in commercial use, and are not expected to be used during the life of this 5-year plan. Accordingly, IAGC believes that BOEM should remove these technologies from Subsection 3.6.1.4.4 and Table 3.6.1-1 or BOEM should include a comment that these technologies are not used.

    Response: BOEM concurs that the use of sleeve exploders and gas guns represents outdated seismic technology and references to their use were removed from Section 3.6.1.4.4 of the PEIS and the corresponding Table 3.6.1-1. BOEM does, however, believe that there may be potential (to what degree is yet unknown) for marine vibroseis to be used in some level of seismic surveying over the time period considered in this document. In order to cover that possibility, the references to marine vibroseis were retained in this section and the table. The use of smaller sleeve guns was added to the text and the table.

8.4.4.4.6 Issue 4.6 Coastal Habitats.

1. Decommissioned Pipelines: NOAA recommends that in Section 4.4.6.1.1 the PEIS address the potential loss of suitable sediment sources for renourishment/restoration activities that might result from pipeline construction or decommissioning.

   Response: BOEM agrees that loss of sediment sources should be included as a potential impact. BOEM has a significant sand resources policy that is memorialized in NTL No. 2009-G04 (Significant OCS Sediment Resources in the Gulf of Mexico) and is a standardized condition of all lease sales. Text has been added to Section 4.4.6.1 that discusses impacts of construction and decommissioning.

2. Section 3.5.2.1 of the Draft PEIS refers to various statistics regarding the fate of oil released during the Deepwater Horizon Event. Should this discussion note that the statistics given were accurate for the fall of 2010, and that residual oil amounts have decreased significantly as a result of biodegradation and continued weathering?

   Response: BOEM agrees that residual oil has decreased since 2010. A statement has been added and referenced in Section 3.5.2.1 regarding the dated nature of the statistics and the continued biodegradation and weathering.

3. Section 3.5.2.1 of the Draft PEIS states, "In summary, a third (33%) of the total leaked oil in the BP spill was captured or mitigated by the unified command recovery operations, including burning, skimming, direct recovery from the wellhead, and chemical dispersion." What source can be cited to support this number? Does this number reflect the amount of oil collected from the shoreline? If not, does it underestimate the effectiveness of the response?

   Response: BOEM agrees that a source should be cited and the sentence clarified. In Section 3.5.2.1, a citation has been added to the text and the discussion clarified regarding shoreline collection.

4. Section 3.5.2.1 of the Draft PEIS states, "Half of the total leaked oil (naturally and chemically dispersed and residual) is currently being degraded naturally." Why is dissolved oil not included in this estimate, as it is highly biodegradable? Much of dispersed, dissolved, and residual oil has been degraded since 2010. Should this statement also be modified to note that the oil "is continuing to be" degraded naturally?

   Response: BOEM agrees that dissolved oil and continual degradation should be discussed. The statement has been clarified in Section 3.5.2.1.

5. Section 3.7.3.1.1 of the Draft PEIS refers to a DWH oil "plume" that was "as thick as 200 m." Is use of the term "thick" misleading because it implies that the so-called "plume" was a solid mass? Additionally, rather than the term "plume," would it not be more accurate if this discussion referred to "dispersed oil" or "clouds of dispersed oil" to clarify that oil concentrations even in the so-called "plume" were in the low ppm range and that oil was not present in a continuous subsea "slick"? See Atlas & Hazen (2011).

   Response: BOEM agrees that the phrase should be clarified. The reference says the plume was "as high as 200 m, and in certain areas more than 2 km in width." Atlas and Hazen use the term cloud and plume. The text in Section 3.7.3.1.1 has been changed to "clouds of oil" to reflect the more recent reference. The hydrocarbon concentrations in the plume have also been added.

6. Section 3.7.3.1.1 of the Draft PEIS states, "The spill released both oil and methane gas into the water column. Some of it rose to the surface above the well." Should this statement be clarified to apply to the oil, not the methane? In the DWH event, effectively all the methane dissolved in the water column, with little or no methane reaching the atmosphere. Data collected by Yvon-Lewis et al. (2011) in June 2010, while the spill was still active, indicated the methane release was not significantly contributing to methane concentrations in the surface water or atmosphere. NOAA overflight measurements in June 2010 also found no methane at the surface (Ryerson et al. 2011).

   Response: BOEM agrees that the statement needs clarification. The text in Section 3.7.3.1.1 has been modified to clarify that methane was not released into the atmosphere. Additional references have also been cited.

7. Section 3.7.3.1.1 of the Draft PEIS states, "Surveys in late June 2010 indicated that there was a subsurface methane plume in 800 to 1,200 m (2,625 to 3,937 ft) of water that extended from the DWH." Should this statement clarify that the so-called "plume" was found in approximately 800 to 1,200 m of water?

   Response: BOEM disagrees. The comment is confusing — the PEIS already states that the plume is in 800–1200 m of water.

8. Section 3.7.3.1.1 of the Draft PEIS states, "However, by September 2010, the plume had not been found, despite extensive areal [*sic*] sampling coverage (Kessler et al. 2011)." Should this statement be clarified to reflect the fact that surveys conducted from August to October 2010 did not find methane concentrations elevated above background levels for the GOM? See Kessler et al. (2011).

   Response: BOEM agrees that the statement should be clarified. The text in Section 3.7.3.1.1 has been modified to clarify the sampling dates and add information on methane concentrations.

9. NOAA recommends adding “temperature” to the list of factors in the last sentence of paragraph 2 of Section 4.4.6.1.4 (impact conclusions).

   Response: BOEM agrees to the change. “Temperature” has been added to the list of factors in each of the CDE impact conclusions presented in Section 4.4.6.1.

10. Section 3.7.2.1.7 of the Draft PEIS states, “Some researchers have reported seeing dead and dying benthic animals as well as what appear to be thick deposits of oil or flocculants of oil and organic matter on the seafloor (BOEMRE 2010b).” Does the cited source support this proposition? Does this source state that further testing must be completed to determine if the substance observed was DWH oil?

    Response: BOEM agrees that the statement in Section 3.7.2.1.7 needs further explanation. The text has been modified to clarify the statement.

11. Section 3.7.4.1 of the Draft PEIS states, “Some researchers have reported seeing what appear to be thick deposits of oil or flocculants of oil and organic matter on the seafloor (BOEMRE 2010b).” The source cited uses the wording “brown substance” instead of “deposits of oil” and states that further tests will be done to identify the source of the brown substance. Should an updated source be used to explain the actual source of the substance? Alternatively, the statement could be revised to say “Some researchers have reported seeing what appears to be a brown substance on the sea floor, but have not yet confirmed the source of these deposits.”

    Response: BOEM agrees that the text should be revised. The text in Section 3.7.4.1 has been modified to remove the word oil.

12. Section 3.7.2.1.7 of the Draft PEIS states, “It is likely that the sediment hydrocarbon concentrations decreased significantly with distance from the well.” Rather than phrasing this conclusion in speculative terms, should not this statement discuss sediment data from OSAT?

    Response: BOEM agrees that sediment data should be used. The text has been modified in Section 3.7.2.1.7 to incorporate OSAT findings.

13. Section 3.7.2.1.7 of the Draft PEIS states, “In heavily oiled areas, the recovery time is unknown, but sediments in deeper waters may take longer to recover because of colder temperatures.” While microbial activity is generally greater in warmer waters, should this statement note that deep sea cold waters contain microbial populations evolved to consume oil at ambient, low temperatures? Hazen et al. (2010) have identified species responsible for rapid biodegradation observed after DWH. Laboratory studies by Ken Lee reported at the International Oil Spill Conference(IOSC) confirmed that biodegradation may be rapid and efficient at temperatures as low as 0.5°C.

Response: BOEM agrees that the text should be modified. Section 3.7.3.1.1 describes microbial degradation and states "These studies suggest the GOM has a tremendous natural capacity to assimilate accidental oil spills." The text has been modified in Section 3.7.2.1.7 to read: "However, studies of deepwater plumes following the DWH event suggest bacterial communities rapidly respond to the presence of oil and microbial reduction in oil concentrations occurred more rapidly than expected given the low temperatures and high pressure (Hazen et al. 2010). Whether the same rapid breakdown would occur along the seafloor is unknown."

14. Section 3.7.2.1.7 of the Draft PEIS states, "Overall, natural processes should break down the oil, and it is likely that no permanent changes in soft sediment habitat affected by the DWH event would occur." Should this statement be reworded to clarify that natural processes "will break down the oil"? Should this statement identify examples of natural process, such as biodegradation, dissipation, evaporation, etc.?

    Response: BOEM agrees that the sentence should be clarified. The text has been modified in Section 3.7.2.1.7 to read "Overall, natural physical and bioremedial processes will break down the oil…"

15. Section 4.4.6.1.1 of the Draft PEIS states, "In some locations, the potential exists for dredging to result in the resuspension and transport of oil spilled during the DWH event." Given the limited impact of the DWH event on sediments outside of the area immediately surrounding the wellhead (not a dredging area) and isolated areas with tar mats, would not such an event be a low probability event? Moreover, would it not be more accurate to say, "In some locations, the potential exists for dredging to result in the resuspension and transport of sediments that may contain residual oil from the DWH event…"?

    Response: BOEM agrees that the text should be clarified. The text in Section 4.4.6.1.1 has been revised to indicate low probability and the resuspension of sediments.

16. The Texas Parks and Wildlife Department (TPWD) agrees with the conclusions presented in Section 4.4.3.1.1 that construction of onshore support facilities (e.g., pipeline landfalls, pipe yards, processing facilities) could affect the quality of near shore and fresh waters in the GOM Planning areas. Impacted resources could also include jurisdictional and nonjurisdictional wetlands. Section 4.6.2 of the Draft PEIS does discuss Section 404 of the Clean Water Act as it pertains to cumulative impacts associated with dredging and marine disposal. However, it does not address potential impacts to wetlands (jurisdictional and non-jurisdictional) that may occur as result of infrastructure development associated with the oil and gas industry. TPWD recommends the PEIS include a discussion of Section 404 of the Clean Water Act (regulating the discharge of dredged and fill material into waters of the United States, including wetlands) as it may pertain to impacts to coastal resources associated with the proposed project. TPWD also recommends that Executive Order (EO) 11990 — Wetlands, be included in the PEIS. Activities associated with the proposed project should include measures per EO 11990 that would minimize the destruction, loss or degradation of wetlands regardless of jurisdictional determination.

Response: The text in Section 4.4.6.1.1, which discusses wetland impacts, has been revised to include a discussion of Clean Water Act (CWA) Section 404 and EO 11990 (the latter was also added to Appendix C).

8.4.4.4.7 Issue 4.7 Marine Habitats.

1. The following statement that appears in Section 4.4.6.3.2 of the Draft PEIS should be quantified: "Eventually, the oil would be broken down by natural processes, and pelagic habitat would recover." What is the expected time to recovery?

   Response: Recovery time is a function of the specific spill, environmental conditions, and resource of interest. Therefore, recovery time cannot be quantified in a general way. The text in Section 4.4.6.3 has been modified to remove 'eventually' and to instead state that "habitat recovery increases as oil breaks down."

2. The discussion presented in Section 4.4.6.4.1needs to consider meteorological and bacterial degradation at depth, not only at the water surface.

   Response: The Camilli et al. (2010) and Kessler et al. (2011) studies cited in the text are all investigations of microbial breakdown of oil in deepwater plumes. The text in Section 4.4.6.4.1 has been changed to "…quickly by bacteria both at the surface and at depth."

3. Section 4.6.3.2.2 states "Warmer temperatures may also increase phytoplankton productivity, potentially resulting in greater food inputs to benthic habitats and subsequent increases in the productivity of benthic biota." Warmer temperatures may increase productivity; however, in many cases the phytoplankton community shifts to dominance by small cell phytoplankton. Consequently, most of the production is consumed in the water column by microzooplankton, resulting in less input to food reaching the bottom. NOAA recommends quantifying the statement "Although pelagic habitat is likely to recover quickly following an oil spill…" What is meant by "quickly"?

   Response: Shifts from benthic to pelagic based food webs are discussed in the Arctic fish (Section 3.8.4.3) and benthic habitat (Section 3.7.2.3) sections. Additional text on the potential changes in primary and secondary productivity was added. The text was also modified to say, "Alternatively, the greater expected river discharge could increase stratification and reduce light available for primary productivity resulting in a reduction in algal inputs to the benthos." The impacts of climate change on phytoplankton are highly speculative because of the numerous controlling factors (Strom et al. 2010). Therefore, the text in Section 4.6.3.2.2 was modified to read "Climate change could increase or decrease phytoplankton productivity, potentially resulting in greater or lesser food inputs to benthic habitats and subsequent increases or decreases in the productivity of benthic biota." Also, the word "quickly" was removed.

4. The Marine and Coastal Habitats summary states that "Protective measures, currently required at the lease sale phase through lease stipulations, exist for seafloor habitats such as live bottom and pinnacle trend areas in the GOM." It is unclear what these protective measures are. These stipulation measures may be especially important in regions where seafloor habitat is not well studied such as in the Arctic. NOAA recommends that BOEM provide a citation to where these measures can be located.

   Response: Stipulations are lengthy and therefore inappropriate for the Summary of the PEIS. References to, and descriptions of, stipulations are provided in Section 4.4.6.2.1 and Appendix B Assumed Mitigation and Other Protective Measures. In the case of the Arctic, which is a frontier area, specific mitigation to protect habitat would be developed through the lease sale process.

5. The summary of Potential Impacts on Essential Fish Habitat presented in Table 2.10-2 for Alternative 1 – Proposed Action only mentions coral as a type of EFH (essential fish habitat). This summary should be similar to the Potential Impacts described for Coastal and Estuarine Habitats and Marine Pelagic Habitats in Table 2.10-2.

   Response: Text was added to Table 2.10-2 to include other EFH for which mitigation measures exist.

6. NOAA recommends that BOEM consider consulting pages 5-7 to 5-10 of the NOAA report "Impacts to Essential Fish Habitat from Non-fishing Activities in Alaska" to add to the discussion of impacts and mitigation options in Section 3.7.4.2 of the PEIS.

   Response: NOAA's mitigation recommendations from its report have been added to the impact discussions in Sections 4.4.6.4.2 and 4.4.6.4.3 of the PEIS.

7. Section 4.4.6.2.1 of the Draft PEIS states, "Modeling indicates that oil spilled at the surface could mix to a depth of 20 m (66 ft) at highly diluted concentrations (MMS 2008a)." Does this modeling include the surface application of dispersants, or are the results based on natural dispersion? This section also states, "However, if dispersants are used in the subsurface or if the released oil has a significant fraction of gas, a subsurface plume may form that would increase the potential for contact with a HDDC habitat." See also PEIS Section 4.4.6.3.1 ("A subsurface plume capable of traveling long distances could form if dispersants are used or if the well releases a mixture of oil and gas."). These statements imply that subsea dispersant use and a significant fraction of gas are the only means for a subsurface "plume" to occur, but any condition that produces very small dispersed oil droplets may result in such a plume.

   Response: 'Natural dispersion' was added to Section 4.4.6.3.1 and the commented sentence in Section 4.4.6.3.1 was modified to say "...or if the oil is released at high velocity."

8. What source was used to support the statement that natural gas would tend to rise in the water column and could degrade habitat quality in a large portion of the water column, and particularly the conclusion regarding the "degradation of habitat quality"?

   Response: Although not well studied, natural gas can be toxic to marine life, and therefore, its release into the water would represent a degradation of habitat quality within the area affected by the gas release. A large methane release in the Sea of Azov resulted in cell damage, biochemical alteration, impaired movement, blood disorders, and alteration of biochemical processes in fish collected around the platform and in fish held in water near the platform (Patin 1999). The blowout also reduced mollusk abundance in the benthos. The Patin 1999 reference was added to Section 4.4.6.3.1 of the PEIS.

9. Does the Camilli et al. (2010) study report that hydrocarbons were detected more than 35 km from the source, as suggested in Section 4.4.6.1 of the Draft PEIS?

   Response: Section 4.4.6.2.1 has been corrected to say 35 km, and not 56 km. This statement is correct elsewhere in the text.

10. There are many shallow and deepwater hard-bottom features that support an array of biological diversity. The commenter is supportive of BOEM's willingness to provide a buffer around biologically sensitive areas and recommends that BOEM should ensure that adequate information exists to confirm that biologically sensitive areas are not within the proposed area before permitting activities and that BOEM should consider oil and gas activities that have the potential to impact deepwater habitats outside the buffer zone.

    Response: NOAA is consulted before BOEM permits activities that could affect sensitive benthic habitat. BOEM has several lease stipulations protecting corals, deepwater corals, and live hard-bottom, as described in Section 4.4.6.2.1. The stipulations are NTL-2009-G39 and NTL-2009-G40. Descriptions of stipulations to protect sensitive coral habitats are provided in Section 4.4.6.2.1. Oil and gas activities do have a potential to affect these habitats located outside the buffer zone. Section 4.4.6.2.1 has a discussion of the potential impacts of drilling muds on corals located away from the drilling site.

11. A commenter requested more information be provided on oil spill impacts on EFH for Arctic cod (*Boreogadus saida*) because of the importance of this species to the Chukchi Sea and the Beaufort Sea Large Marine Ecosystems. They also request that it be stated that a CDE could have moderate effects on EFH.

    Response: The susceptibility of Arctic cod to spills is discussed in Section 4.4.7.3.3, and a discussion was added to Section 4.4.6.4.3. In addition, information regarding the spawning period of the Arctic cod was added to the Arctic Cod EFH description in Section 3.7.4.3. Species specific impacts will be considered in more detail in individual lease sale EISs.

12. The following statement was presented in Section 4.4.6.3.4 of the Draft PEIS: "Pelagic habitats would eventually recover their habitat value as hydrocarbons broke down and were

diluted." Statement needs to be quantified. How long would it take? Will the digestion be 100% effective? Suggest including findings of past and ongoing studies of natural degradation of hydrocarbons by indigenous bacteria (i.e., McFarlin, Leigh, 2011, indigenous microorganisms degrade dispersed oil in Arctic seawater).

Response: Discussions of additional studies were added to Section 4.4.6.3.3 to support the statement that the hydrocarbons would be broken down and indigenous oil-consuming bacteria are present. However, a specific time to recovery cannot be provided because each spill is different. All data from the Valdez spill suggests breakdown and dilution in the water column is rapid (Neff and Stubbenfield 1995; Boehm et al. 2007), while localized benthic contamination can persist for >10 years (Short et al. 2007; Taylor and Reimer 2008; Exxon Valdez Oil Spill Trustee Council 2010c).

13 Increased river discharge may intensify the strength of the Alaska Coastal Current making advection much more important than local production processes. Warming would prolong the period that phytoplankton is nitrate limited and production is dominated by small phytoplankton cells. This would lengthen the food chain with less production going into fish and other higher trophic levels.

Response: Any predicted changes in productivity resulting from climate change are highly speculative because of the numerous controlling factors (Strom et al. 2010). Text in Section 4.4.7.3 of the PEIS was modified to state that increases or decreases in primary productivity are possible, and additional discussion of potential changes in productivity was provided to this section.

14. Commenter requests two conference presentations be cited in Section 3.8.5.1 that describe benthic invertebrate communities near the Macondo well before and after the DWH event.

Response: Results of the OSAT sediment sampling data have been incorporated into Section 3.7.2. The results given in Putt et al. (2010) and Benfield et al. (2010) have been incorporated into the discussion of invertebrates (Section 3.8.5.1), although these are presentations, not peer-reviewed papers.

15. A commenter requested more information be added to Section 3.7.3.3.2 on the impacts of ocean acidification on the commercial shellfish (king and Tanner crab and snow crab) populations in the Cook Inlet Planning Area.

Response: This comment refers to the pelagic habitat section (Section 3.7.3), so benthic invertebrates were not discussed. The potential impact of climate change on snow crabs is discussed in the invertebrates climate change section (Section 3.8.5).

16. The commenter states that BOEM must analyze the effects of its leasing program in contributing to climate change, and analyze potential oil and gas activities in the context of climate change and provides several references that could provide information on this topic.

Response: The PEIS discusses the potential impacts of climate change on Arctic habitats and biota. Information from the cited reports was added to Section 3.3, as well as to Sections 3.7 and 3.8.

8.4.4.4.8 Issue 4.8 Mammals.

1. When describing potential oil spill clean-up impacts to endangered beach mice or the endangered Florida salt marsh vole in Section 4.4.7.1.1, it would be more appropriate to use more relevant citations rather than documents developed for Alaska.

   Response: The discussion in Section 4.4.7.1.1 of potential oil spill and oil spill clean-up impacts on beach mice and the Florida salt marsh vole has been modified to include more relevant and/or recent information on the GOM.

2. What is the cause of the recent ringed seal deaths in the Arctic Region? Can it be related to climate change?

   Response: A discussion of the Unusual Mortality Event (UME) that involves ringed seals and other pinniped species in the Arctic has been added to Section 3.8.1.3.1 and is also mentioned in Section 4.6.4.3.1. As of the drafting of this response, the NMFS has not yet determined the cause of this UME, but continues to post UME updates at http://www.alaskafisheries.noaa.gov/protectedresources/seals/ice/diseased/.

3. The endangered manatee should be included in the list of marine mammals identified as receiving detailed analyses in the PEIS since manatees are discussed in some detail further in the document.

   Response: The West Indian manatee has been added to the list of mammals in Section 1.5.4 that are receiving detailed analyses in the PEIS.

4. The cited reference, NMFS 2011f, is absent in the references section for Chapter 3. Please provide a detailed citation for that reference.

   Response: The citation for NMFS (2011f) found in Section 3.8.1.1 of the PEIS has been added to the Chapter 3 references (Section 3.17 of the PEIS).

5. The depicted range map for endangered beach mice (Figure 3.8.1-1) is inaccurate.

   Response: Figure 3.8.1-1 has been revised to include the historic range of the endangered beach mice subspecies, and the text of Section 3.8.1.1.2 has been updated to list the counties where each endangered beach mouse subspecies is known or believed to occur.

6. When referring to beluga whales in Cook Inlet, replace ‘stock’ with ‘distinct population segment.’

Response: As suggested, "stock" has been replaced with "distinct population segment" in Sections 3.8.1.2 and 4.4.7.1.2 where Cook Inlet beluga whales are discussed.

7. The UME that was declared in the northern GOM is still ongoing as the stranded bottlenose dolphins found with *Brucella* have been combined with the animals that stranded post-DWH.

   Response: The discussion in Section 3.8.1.1.1 of the UME in the northern GOM has been updated to include the information on the stranded bottlenose dolphins mentioned in the comment. The discussion also includes the web link to the NMFS website on this UME at http://www.nmfs.noaa.gov/pr/health/mmume/cetacean_gulfofmexico2010.htm.

8. When mentioning oil spills in the Cook Inlet Planning Area in Section 4.4.7.1.2, there is no mention of the Beluga whales although other whale species are mentioned.

   Response: The Section 4.4.7.1.2 discussion referred to in the comment has been amended to include mention of the beluga whale.

9 The PEIS should address the effects of climate change on sea ice and how this can impact marine mammals.

   Response: A discussion of climate change impacts on sea ice, as it may affect marine mammals, can be found in Sections 3.8.1.3.1 and 4.6.4.3.1.

10 An appropriate level of analysis on the effects of noise on bowhead whales in the Arctic Region was not included in the Draft PEIS.

   Response: The level of analysis presented is appropriate for a programmatic EIS. More thorough assessments of noise impacts on bowhead whales will be included in Arctic region-, lease-, or activity-specific NEPA documents prepared by BOEM during the 2012-2017 OCS Leasing Program. In addition, BOEM and the NMFS are preparing an EIS for geophysical (seismic) and exploratory drilling in the Arctic (http://www.nmfs.noaa.gov/pr/permits/eis/arctic.htm).

11. The Draft PEIS fails to include a discussion of bowhead whale use of the Beaufort and Chukchi Seas in regards to feeding habitat and migration routes.

    Response: Additional information on bowhead whale-feeding habitat and migration routes in the Beaufort and Chukchi Seas has been added to the PEIS. Region-, lease-, and activity-specific NEPA analyses will address potential impacts on bowhead whales in more detail. Lease-specific activities and permits will also be required to comply with the requirements of the Endangered Species Act and the Marine Mammal Protection Act.

12. The PEIS does not reflect the most current and accurate information on the movement patterns of bowhead whales.

Response: Sections 3.8.1.3.1 and 4.4.7.1.3 of the PEIS have been updated to include current information on the movement patterns of bowhead whales.

13. The PEIS needs to address the impacts of drilling muds on the walrus and its prey.

    Response: Information on potential impacts of drilling muds on Arctic resources are provided throughout Chapter 4. With regard to the walrus and its prey, please see Sections 4.4.6.2.3 (Arctic marine benthic habitats), 4.4.6.3.3 (Arctic marine pelagic habitats), 4.4.7.1.3 (Arctic marine mammals), and 4.4.7.5.3 (Arctic invertebrates and lower trophic levels).

14. The receding sea ice is impacting walrus.

    Response: BOEM recognizes the concern that climate change is having an adverse effect on sea ice, and that this may impact the Pacific walrus as well as several other marine mammals. Information about the Pacific walrus is provided in Subsection 3.8.1.3.1 of the PEIS; while information on climate change impacts on sea ice, as it affects marine mammals, can be found in Sections 3.8.1.3.1 and 4.6.4.3.1.

15. Manatees could be impacted by vessel strikes and oil spills.

    Response: Section 4.4.7.1.1 of the PEIS acknowledges the potential for vessels to strike manatees. While incidents cannot be discounted, the potential for an OCS vessel to hit a manatee is unlikely. Marine mammal observers and adherence to vessel speed requirements in shallow waters contribute to the protection of manatees from vessel strikes. The Draft Multisale EIS (available on BOEM's website: http://www.boem.gov/Environmental-Stewardship/Environmental-Assessment/NEPA/nepaprocess.aspx) provides an analysis of potential oil spill impacts on manatees. Site-specific mitigation measures, including those pertaining to oil spills, will be in lease-specific NEPA analyses.

16. The PEIS should include additional support (as cited in the comment) for the conclusion that seismic does not adversely affect marine mammals under current BOEM seismic survey requirements.

    Response: BOEM is aware of the information cited in the comment, but disagrees with the broad-scale recommendation that BOEM determine in this document that seismic does not "adversely affect marine mammals under current BOEM regulation." BOEM will undertake a more detailed discussion of seismic activities and impacts on marine mammals in lease sale and activity specific NEPA documents, especially the draft PEISs for geological and geophysical activities in the GOM, mid/south Atlantic, and Arctic (in preparation).

17. Marine mammals can also inhale oil when they surface to breathe which causes damage to mucous membranes and airways and can be fatal.

Response: Potential impacts on marine mammal mucous membranes and airway passages from an oil spill have been added to the accident discussions in Section 4.4.7.1.

18. Section 4.4.5.3.1of the Draft PEIS states: "However, most exploration activity takes place during the open-water season, minimizing the effects on polar bears (MMS 2008b)." NOAA notes that there are no polar bears in Cook Inlet.

    Response: The mention of polar bears in the Cook Inlet area has been deleted from Section 4.4.5.2 (previously Section 4.4.5.3.1).

19. Section 4.4.7, Table 4.4.7-1: NOAA recommends that the table be put into an MMPA context for marine mammals. Mortality and serious injury may also result from vessel collisions. Injury (Level A harassment) should be included in the decommissioning analysis as it was authorized in the Explosive Removal of Offshore Structures (EROS) rule. Dolphins have also been previously killed in EROS-related activities.

    Response: Table 4.4.7-1 has been amended, as suggested.

20. Section 4.4.7.1.1: Bryde's whales reliably occur in the DeSoto Canyon area.

    Response: Information on the Bryde's whale occurring in the DeSoto Canyon area has been added to Section 4.4.7.1.1.

21. Section 4.4.7.1.1: Sperm whales also commonly occur in the DeSoto Canyon area and west of the Florida Keys and Tortugas.

    Response: Information on sperm whales occurring in the DeSoto Canyon area and west of the Florida Keys and Tortugas has been added to Section 4.4.7.1.1.

22. Section 4.4.7.1.2, Alaska — Cook Inlet: The designated no-entry zone for Steller sea lion major haul outs and rookeries in and near the Cook Inlet OCS Planning Area is 3 nautical miles (5.5 kilometers) rather than 3,000 feet as indicated here (50CFR 223.202).

    Response: The distance of the designated no-entry zone near the Cook Inlet OCS Planning Area has been corrected in Section 4.4.7.1.2.

23. Section 4.4.7.1.2: The described prohibitions on helicopter approaches to humpback whales are not applicable to Alaskan waters, where no such prohibitions exist. NMFS has established regulations for vessels operating near humpback whales (66FR29502, May 31, 2001).

    Response: The sentence pertaining to restrictions on helicopter approaches to humpback whales in Hawaiian waters has been deleted.

24. Section 4.4.7.1.4, Conclusion: It is difficult to reconcile BOEM's conclusion that impacts to marine mammals in the Arctic could range from negligible to moderate against many of the statements and conclusions presented in this section. Examples of this include the following statements: "Any increased mortality in a pinniped population could impact the population as a whole, especially for sensitive or declining populations (e.g., Pacific walruses)"; and "a catastrophic discharge event contaminating ice leads or polynyas in the spring could have devastating effects, trapping bowhead whales."

    Response: The negligible-to-moderate impacts on marine mammals presented in Section 4.4.7.1 apply to routine operations. BOEM acknowledges that a catastrophic discharge event could potentially cause a major impact on marine mammals. All lease sales will require separate NEPA analyses on marine mammals and Endangered Species Act consultations.

25. Section 4.6.4.3.1, Marine Mammals. It would be helpful to have a quantitative estimate of cumulative effects on marine mammals. Tables earlier in the document indicate a range of possible number of drill sites, and likely locations of drilling. This kind of information could be combined with marine mammal density information and known "takes" of marine mammals to provide a quantitative estimate of the expected cumulative effects, at least for some species.

    Response: Quantitative estimates of cumulative impacts are not needed, or even reliable, at the programmatic level. Such assessments can be included in more region-, lease sale-, or activity-specific NEPA analyses.

26. There is often a 2–3-year lag between new research results and the inclusion in the marine mammal stock assessment reports. NOAA Fisheries (NMFS) recommends referring to more recent Alaska Marine Mammal Stock Assessments (Allen and Angliss 2011, and Allen and Angliss 2010) instead of the now-outdated Angliss and Allen 2009.

    Response: The marine mammal sections have been updated to incorporate information from NOAA's most recent Stock Assessment Reports.

27. In the Summary, Marine and Coastal Fauna: NOAA suggests deleting the example for "temporary abandonment of young".

    Response: The example dealing with temporary abandonment of young has been deleted from the Summary section of the PEIS location indicated in the comment.

28. In the Summary, the question is not whether vessel collisions may occur, but how frequently relative to a species' population size. Some populations (e.g., North Pacific right whales) are so imperiled that even infrequent collisions will have a population-level effect. NOAA recommends that BOEM modify the sentence (and any later parts of the document) to make it clear that what are important to analyze are the effects of collisions on the impacted population, not just the number of collisions.

Response: The Summary identifies the overall types of impacts possible. Text revisions have been made in Section 4.4.7.1 to indicate that the potential effect of vessel collisions on marine mammals depends on both the number of collisions and the population size of the species.

29. Section 3.7.2.3: Bowhead whales are also known to feed in this nearshore area and should be included in the list of species utilizing this habitat.

    Response: The bowhead whale has been added to the list of biota that feed in nearshore benthic areas in Section 3.7.2.3.

30. In Section 3.8.1, the original literature should be referenced whenever possible.

    Response: In the marine mammal sections of the PEIS, the original literature has been utilized whenever practicable and/or available. However, in a number of situations, NOAA's Stock Assessment Reports or other similar reports were referenced as they are more readily available to members of the public that may want to see a source document.

31. The Gervais' beaked whale (*Mesoplodon europaeus*) is also endemic to the deep waters across the tropical and temperate Atlantic Ocean.

    Response: The text has been modified to state that the Gervais' beaked whale is also endemic to deep waters across the tropical and temperate Atlantic Ocean.

32. Section 3.8.1, Table 3.8.1-1: The scientific name for sei whale is *Balaenoptera borealis,* not *Balaenoptera edeni*.

    Response: The scientific name for the sei whale has been corrected in the PEIS.

33. Section 3.8.1, Table 3.8.1-1: Spelling error. The scientific name for pygmy killer whale is *Feresa attenuate*, not *Feresa attentuata*.

    Response: The spelling of the scientific name for the pygmy killer whale has been corrected in Table 3.8.1-1.

34. Section 3.8.1.1.1: Gervais' beaked whale is not distributed worldwide, but is in deep waters across the tropical and temperate Atlantic Ocean, both north and south of the equator (Jefferson et al. 2008).

    Response: The distribution of the Gervais' beaked whale has been corrected, as indicated in the comment, in Section 3.8.1.1.1 of the PEIS.

35. Section 3.8.1.2.1: The NMFS Alaska Regional Office uses 340 as the population estimate, which is based on the 2010 aerial surveys.

Response: The population estimate for the population of Cook Inlet beluga whales in Section 3.8.1.2.1 has been updated using the 2011 aerial survey information.

36. Section 3.8.1.2.2, Terrestrial Mammals: BOEM should specify that the abundance estimates are based on old data, and provide the years of the surveys.

    Response: Statements have been added to Section 3.8.1.2.2 in the PEIS to mention the year of the surveys for which the older abundance estimates apply.

37. Summary, Marine Mammals: In other paragraphs, there have been statements about the magnitude of expected impacts, and this information should also be summarized here. For instance, "Disturbance from noise sources is the most likely impact and is expected to (insert expected magnitude of outcome here)." This same pattern should be followed for the expected effects of an oil spill (as is done for the expected impact of an oil spill on birds in the subsequent paragraph) and for related sections on the Chukchi Sea.

    Response: The marine mammal text in the Summary has been modified as suggested in the comment to make statements on expected impacts, to be consistent with those presented for other species groups such as birds.

38. Terrestrial Mammals. If the lease sale results in a discovery, there is likely to be additional development of onshore facilities, and subsequent impacts on terrestrial mammals. Although this document may not be required to consider possible long-term outcomes, it is suggested mentioning this possibility. The program document estimates net benefits from exploration and development beyond the lease sale period (e.g., page 100); it seems logical then that some assessment of impacts beyond the lease sale period should also be considered.

    Response: The impact analyses presented in Section 4.4.7.1 consider impacts over the life of the projects developed under the proposed action (40+ years). Region-, lease-, or activity-specific NEPA documents would address terrestrial mammals in more detail, including impacts from onshore facilities. The cumulative impact analyses in these documents would include an assessment of impacts on terrestrial mammals that would extend beyond the lease sale period.

39. The Draft PEIS discusses the consequences of a CDE in Section 4.4.7.1.1. The discussion assumes that several outcomes "would" happen as a result of a CDE. For example, the Draft PEIS states, "Additional effects on marine mammals would occur from water and air quality degradation associated with response and cleanup vessels…" PEIS in Section 4.4.7.1.1: Should these statements be revised to indicate that such consequences could happen, particularly given that the possible effects of PAHs (polyaromatic hydrocarbons) on marine mammals are not well understood? Should it also be noted that response measures to such an event will take into account the locations and potential impact on marine mammals and their habitat? On Scene Coordinator Report (Sept. 2011).

Response: The potential outcomes of a CDE on marine mammals in Section 4.4.7.1 have been changed from "would" to "may." A sentence has also been added that water and air quality degradation associated with response and cleanup vessels may also affect marine mammals. More detailed analyses of a CDE's impacts on marine mammals can be found in the Draft GOM Multisale EIS (available on BOEM's website: http://www.boem.gov/Environmental-Stewardship/Environmental-Assessment/NEPA/nepaprocess.aspx).

40. Section 3.8.1: Reference to Section 3.5.5 is incorrect. There is no Section 3.5.5. Further, Section 3.5 does not refer to subsistence resources or local knowledge (of marine mammals). Section 3.8.1.2.1: This paragraph has no mention of Humpback whales in Cook Inlet or near Kodiak Island. This paragraph would be more valuable with information specific to the Cook Inlet Planning Area and the stock(s) frequenting this area instead of a general summary of humpbacks in Alaska. Sentences regarding Chukchi Sea and Beaufort Sea humpbacks should be moved to 3.8.1.3.1 on the Arctic area.

    Response: Sections 3.8.1.2.1 and 3.8.1.3.1 of the PEIS have been amended as suggested in the comment.

41. Section 3.8.1.2.1: Are these stocks the one most likely to be present in Cook Inlet? If not, why are the population sizes only for these provided? Section 3.8.1.2.1: A reference and/or explanation regarding the effect of climate change on beluga whales is needed to support this statement. Section 3.8.1.2.2: American bison — the only wild population is located near Delta Junction, AK. This is not generally considered part of south central Alaska, but rather Interior Alaska and is over 200 miles from Upper Cook Inlet. Correct the sentence to reflect the proper geographic area. Section 3.8.1.2.2: Roosevelt Elk — This is an introduced species in Alaska, present on only two islands in south central Alaska and some islands in southeast Alaska. Recommend re-examining the species to be included in this list of select terrestrial mammals.

    Response: Sections 3.8.1.2.1 and 3.8.1.2.2 of the PEIS have been amended as suggested in the comment.

42. Section 3.8.1.2.2: Is the intent of providing population size for Kenai and Game Management Unit 16B to show the variation in population size in different areas or is it to try to represent the Planning Area population? If the former, a density estimate would be more informative. If the latter, these areas exclude bear population numbers for the southern half of the planning area. Section 3.8.1.2.2: Clarify the two population numbers. Is this a range? Are these estimates from two distinct years in the early 1990s? Section 3.8.1.2.2: Regarding the use of population estimates from Game Management Unit 16/16B. It should be noted that this unit includes the entire watershed for the upper western Cook Inlet, encompassing areas as distant as Denali National Park.

    Response: Section 3.8.1.2.2 of the PEIS has been amended as suggested in the comment.

43. Section 3.8.1.2.2: South Alaska has limited application. Is the intention to refer to south central and southeast Alaska? These areas are two very distinct and distant geographic areas that have been commonly recognized in public documents discussing both ecological and economic resources. It would be clearer to rephrase "throughout south central Alaska…" Further, are these food sources only in Southeast Alaska? Recommend removing information not applicable to the south central river otter population.

    Section 3.8.1.3.1: The text would be more clear and informative if it was more specific to the Arctic region and stocks that occur in this region. Much of this information is a repeat of information provided in the Section 3.8.1.2.1

    Section 3.8.1.3.1: The text expresses conflict concerning whether there are population estimates available or not. Is the concern that the NMFS estimate is not reliable or recent? Either remove statement that estimates are not available, or provide explanation on the discrepancy or doubt regarding NMFS estimate.

    Section 3.8.1.3.1: Recommend moving Pacific Walrus to this subsection since they are presently an ESA Candidate species, but within the lease period, they may be further listed as endangered or threatened. In 3.8.2 Candidate species are listed within the subsections on T&E Species.

    Section 3.8.1.3.1: Is there any information available on the decline of the Southern Beaufort Sea stock? When did the decline begin? Any causes attributed to the decline? As a species listed as threatened, with current litigation regarding its ESA Critical Habitat, it will be beneficial to provide additional information on this statement.

    Section 3.8.1.3.1: The killer whale text is a great example of a concise, region-specific description. Recommend using this as an example for revising paragraphs on Humpback whales and other species descriptions that include information on stocks elsewhere in Alaska or its range.

    Section 3.8.1.3.1: Move Pacific walrus paragraph to the subsection that discusses pinnipeds, as recommended in previous comment. Insert information on identification of species as a Candidate for listing by USFWS, including listing priority.

    Section 3.8.1.3.1: Include an explanation of possible cause to >36% population decline in 16 years between 1990 and 2006. This is particularly useful considering Candidate status of the Pacific walrus.

    Section 3.8.1.3.1: It may be beneficial to include information regarding the recent court decision on Center for Biological Diversity v. Lubchenco, 758 F. Supp. 2d 945 (N.D. Cal. 2010). The court found that Service did not violate the ESA in failing to list the ribbon seal as threatened or endangered. The court decision is stayed; however, pending Ninth Court mediation, with a report on mediation expected early 2012. Additionally, API (American Petroleum Institute) and AOGA (Alaska Oil and Gas Association) had filed comments with NMFS on March 25, 2011 that could be used in addressing the ribbon seal situation.

Section 3.8.1.3.2: Species list is randomly ordered, with species of same family not grouped together. We suggest listing the species taxonomically.

Response: Sections 3.8.1.2.2, 3.8.1.3.1, and 3.8.1.3.2 of the PEIS have been amended as suggested by commenters.

44. There is an incomplete sentence in Section 4.4.7.1.2 of the Draft PEIS.

    Response: The incomplete sentence in Section 4.4.7.1.2 has been amended.

45. Section 4.4.7.1.2: This information, and similar, regarding rookeries, haul-outs or other important use areas or population concentration areas would be beneficial in Section 3. This comment is intended globally for Section 3.8, but is particularly applicable to 3.8.1.

    Response: Information provided in Chapter 4 pertaining to haulouts, rookeries, and other important use areas or population concentration areas for several marine mammal species has been moved or duplicated in Chapter 3, Section 3.8.1.

46. "Accidents" Section 4.4.7.1.2: Consistent structure between the Planning Areas would assist the reader to review potential consequences. The description in the Arctic area is more specific with the discussion of the modes of exposure (inhalation, ingestion, and direct contact) compared to the more general statements of exposure in the Cook Inlet area. The Arctic section's format of "X action/behavior resulting in Y exposure with Z consequence" is straightforward and easy to access. Please review and update as appropriate.

    Response: The marine mammal accident assessment discussions have been modified to make them more consistent across the document (e.g., the Cook Inlet discussion has been changed to be similar to that provided for the Arctic region).

47. Section 4.4.7.1.2: Sentence is confusing and needs to be rewritten: "Since there are reports of oiled marine mammal's exposure."

    Response: The Section 4.4.7.1.2 sentence referred to in the comment has been amended.

48. Section 4.4.7.1.2: A discussion of the risk of oil spills to Beluga Whale is needed. The only mention of the species, whose Cook Inlet population is endangered, is the last sentence of the Catastrophic Discharge Event subsection.

    Response: A discussion of the risk of an oil spill on beluga whales has been added to Section 4.4.7.1.2.

49. Section 4.4.7.1.3: Resolve the conflict in the number of cetaceans present in different locations of this section.

Response: The conflict between the sentences in Section 4.4.7.1 (previously Section 4.4.7.1.4) mentioned in the comment has been resolved.

50. Section 4.4.7.1.4: Sentence regarding beluga whales is misleading. While belugas do primarily occur in the area north of the Planning Area, the ESA Critical Habitat includes, in addition to Upper Cook Inlet, the entire west coast of Cook Inlet south to Kamishak Bay and Kachemak Bay. Please review and update as appropriate.

    Response: The sentence regarding beluga whales in the Cook Inlet in Section 4.4.7.1.4 has been amended in response to the comment.

51. Section 4.4.7.1.4: The organizational variability between BOEM's approach for presenting marine mammal impacts vs. terrestrial mammal impacts is confusing. Why are all areas combined for marine mammals, but segregated for terrestrial mammals? With the high variability between GOM and Alaskan habitats and species under consideration, it does not make sense to assume all impacts for all areas would be the same. This is critical under the heading =Accidents' (page 4-293), but again, there is no differentiation between GOM and Alaska.

    Response: Section 4.4.7.1 has been revised to make the conclusions presented for marine mammals consistent with the format used for terrestrial mammals (i.e., improved differentiation in the impacts between the GOM region and the Alaska regions).

52. In the GOM, there are many areas in which information about sensitive resources and the impact of oil activities on them and their habitats are unknown. For instance, while noise impacts on cetaceans can be great, the impact of anthropogenic noise on endangered sperm whales in the GOM is unknown.

    Response: Where appropriate, the discussion in the PEIS of impacts on marine mammals in the GOM indicates where information may be incomplete. The potential impacts of anthropogenic noise on sperm whales and other marine mammals will be addressed in more detail in GOM-specific NEPA analyses, particularly in the *Programmatic EIS for the Geological and Geophysical Exploration of Mineral and Energy Resources in the GOM* currently being prepared by the NMFS and BOEM.

53. Section 4.4.13.3.1: The discussion of the impacts of noise from oil and gas operations (including seismic) only references traditional knowledge of the impacts of noise and none of the considerable body of western science that reaches similar conclusions. As an example, the attachment to these comments shows deflection areas for bowhead whales in the Beaufort Sea as documented by western science. BOEM needs to provide a Summary of both traditional knowledge and western science on the impacts of noise on bowhead whales and then analyze these impacts and discuss mitigation measures for them.

    Response: Impacts of noise on bowhead whales (and other marine mammals) based on "western science" are presented in Section 4.4.7.1.3 of the PEIS. A thorough assessment of noise impacts on bowhead whales will be included in Arctic region-, lease-, or activity-specific NEPA documents (i.e., the EIS currently in preparation by the NMFS and BOEM for geophysical (seismic) and exploratory drilling in the Arctic (http://www.nmfs.noaa.gov/pr/permits/eis/arctic.htm) and related authorizations under the Marine Mammal Protection Act and Endangered Species Act. For examples, see: (1) FWS — http://alaska.fws.gov/fisheries/mmm/Beaufort_Sea/76FR47010.pdf, http://alaska.fws.gov/fisheries/mmm/Chukchi_Sea/pdf/73FR33212.pdf and http://alaska.fws.gov/fisheries/mmm/itr.htm; (2) NMFS — http://www.nmfs.noaa.gov/pr/permits/incidental.htm; and (3) BOEM — http://www.alaska.boemre.gov/ref/Biological_opinions_evaluations.htm and http://www.alaska.boemre.gov/ref/eis_ea.htm.

54. ICAS (Inupiat Community of the Arctic Slope) joins in the comments of the AEWC (Alaska Eskimo Whaling Commission) in critiquing the consideration of impacts to bowhead whales, their habitat, and Inupiat subsistence practices in the Draft PEIS. The discussion of these topics is minimal and fails to analyze all the impacts to our communities from additional offshore oil and gas leasing.

    Response: The concerns raised in the comment will be addressed in detail in region-, lease-, or activity-specific NEPA documents.

55. Section 4.4.7.1.1: This "well documented aggregation" could also be because this was an area that experienced significant survey effort (see Jochens et al. 2008). Newer data indicates they are spread throughout the GOM. Additional study would be required to substantiate these statements, therefore we request that they be deleted.

    Response: Telemetry data from Jochens et al. (2008) suggests a core use area in the Mississippi Canyon, though tagged animals did use the entire northern GOM. The highest use area of the GOM was between the Mississippi Canyon and the DeSoto Canyons.

56. OCS oil and gas development in the Arctic should occur during the summer or after the whaling season to minimize disturbance from seismic surveys.

    Response: The potential effects of seismic surveys on marine mammals are reviewed in Section 4.4.7.1.3 of the PEIS. More detailed analysis of seismic surveys will be provided in lease- and activity-specific NEPA documents (i.e., the EIS currently in preparation by NMFS and BOEM for geophysical (seismic) and exploratory drilling in the Arctic (http://www.nmfs.noaa.gov/pr/permits/eis/arctic.htm)).

57. Section 4.6.4.3: Which whale species is the discussion referencing? Please review and update as appropriate.

    Section 4.6.4.3: Is this supposed to state "no known harvest"? Please review and update as appropriate.

Section 4.6.4.3: The annual subsistence harvest for Pacific Walrus seems very high. Garlich-Miller et al. (2006), states the following: "Since 1992, the harvest of Pacific walruses has been limited to the subsistence catch of coastal communities in Alaska and Chukotka. Harvest levels through the 1990s ranged from approximately 2,400 to 4,700 animals per year"). Please review and update as appropriate.

Response: Section 4.6.4.3 of the PEIS has been amended in response to the items mentioned in the comment.

58. In the past, our whaling captains have experienced firsthand how underwater noise associated with drilling, seismic studies, and icebreaking have interfered with the bowhead whale hunt at Cross Island. When whales are deflected from their normal migration route, our whaling captains are forced to travel great distances in dangerous conditions to obtain the food that feeds our people. Our traditional knowledge tells us that bowhead whales are very sensitive to underwater noise, and yet western science is still unable to tell us what the cumulative impacts are to the whales from multiple exposures to seismic, drilling, and icebreaking activities over a wide portion of the whale's range over a period of many years. We are also concerned about the potential impacts to other subsistence resources, including beluga whales, seals, fish, and caribou.

    Response: Section 4.4.7.1.3 of the PEIS discusses noise impacts on bowhead whales. Both Section 3.8.1.3.1 and 4.4.7.1.3 of the PEIS have been updated to include additional information on movement patterns of bowhead whales and the potential impact of noise on their movements. Section 4.4.7.1.3 also discusses potential impacts on belugas, seals, and caribou; while Section 4.4.7.3.3 discusses potential impacts on fish. Lease- and activity-specific NEPA documents will analyze potential impacts on these subsistence resources in more detail (i.e., the EIS currently in preparation by the NMFS and BOEM for geophysical (seismic) and exploratory drilling in the Arctic (http://www.nmfs.noaa.gov/pr/permits/eis/arctic.htm)).

59. The impacts of airgun surveys are felt on an extraordinarily wide geographic scale — especially on endangered baleen whales, whose vocalizations and acoustic sensitivities overlap with the enormous low- frequency energy that airguns put in the water (numerous citations provided).

    Response: The PEIS has been amended in Section 4.4.7.1.3 to include additional information (including that from several of the references listed in the comment) regarding noise impacts on marine mammals. Also, lease- and activity-specific NEPA, ESA, and MMPA documents will address noise impacts in more detail (i.e., the EISs currently in preparation for geophysical (seismic) surveying in the GOM, mid/south Atlantic and Arctic-see http://www.nmfs.noaa.gov/pr/pdfs/fr/fr69-67535.pdf, http://www.gomr.boemre.gov/homepg/offshore/atlocs/gandg.html, and http://www.nmfs.noaa.gov/pr/permits/eis/arctic.htm.

60. The amount of disruptive activity under consideration in the Draft PEIS is enormous. Potential impacts of seismic surveys should be discussed.

Response: Section 4.4.7.1.1 discusses the potential impacts of seismic surveys on marine mammals in the GOM. Lease- and activity-specific NEPA, ESA and MMPA documents will address noise impacts in more detail (i.e., the EIS currently in preparation for geophysical (seismic) surveying in the GOM (http://www.nmfs.noaa.gov/pr/pdfs/fr/fr69-67535.pdf). The cumulative impact sections of these documents will also address other sources of noise that marine mammals are exposed to in the GOM.

61. The Draft PEIS lacks any serious analysis of the potential impacts of program-related noise on marine wildlife, and offers in its place a number of specious claims in an apparent effort to diminish their serious effects. The Draft PEIS does not address the true elephants in the room: behavioral impacts, which have been demonstrated to occur at very large distances from seismic arrays, and masking effects, for which empirically-based, quantitative models are available. BOEM's dismissive treatment of acoustic impacts simply does not reflect the best available science. For all of the foregoing reasons, the PEIS must analyze and acknowledge that the activities under review – particularly the airgun surveys that presently represent the dominant means of offshore exploration – are likely to significantly impact marine mammals; affect vital rates in endangered species and populations, including the North Atlantic right whale.

    Response: Potential impacts of noise on marine mammals are provided in Sections 4.4.7.1.1 through 4.4.7.1.3. The PEIS has been amended to include additional information regarding noise impacts on marine mammals. Also, lease- and activity-specific NEPA, ESA, and MMPA documents will address noise impacts in more detail (i.e., the EISs currently in preparation for geophysical (seismic) surveying in the GOM, mid/south Atlantic and Arctic — see http://www.nmfs.noaa.gov/pr/pdfs/fr/fr69-67535.pdf, http://www.gomr.boemre.gov/homepg/offshore/atlocs/gandg.html, and http://www.nmfs.noaa.gov/pr/permits/eis/arctic.htm. The cumulative impact sections of these documents will also address other sources of noise to which marine mammals are exposed.

62. Section 4.4.7.1.1: This section summarizing the effects of seismic surveys on marine mammals should include effects to prey (e.g., fish and squid). Studies suggest that squid, the primary prey item of endangered sperm whales, may experience statocyst damage that may result in injury or death resulting from exposure to low frequency sound.

    Response: Potential impacts of seismic surveys on fish and invertebrates (which includes marine mammal prey) are provided in Sections 4.4.7.3 and 4.4.7.5, respectively.

63. Section 4.4.7.1.1: The seismic pulse is under 10 ms every 12 sec. or more, therefore the 10% duty cycle is much lower than cited, and thus any potential masking would be much smaller than suggested. This should be corrected.

    Response: Additional information on duty cycles of seismic pulses have been added to Section 4.4.7.1.1 of the PEIS to demonstrate that the duty cycle of seismic surveys can be much lower than 10%.

64. Section 4.4.7.1.3: Industry practices as mandated by the USFWS and NMFS include maintaining 1-mile exclusion zones around known polar bear dens, use of aerial Forward Looking InfraRed Radar (FLIR) surveys to identify polar bear dens, and Incidental Harassment Authorization and Polar Bear& Wildlife Interaction Plans which specify the means by which industry minimizes contact, conflict, or stress upon the Polar Bears. These industry and regulatory practices should be specified to demonstrate protection of the polar bears. This section should also note a prior USFWS finding that "documented impacts on polar bears by the oil and gas industry during the past 30 years are minimal" and "historically, oil and gas activities have resulted in little direct mortality to polar bears." Line 12: Statements similar to those presented in this paragraph on sensitive and listed species need to be provided more extensively throughout the document so that the reader understands the significance and regulatory authorization of the discussed impact, along with the mitigation measure(s) to be employed to reduce the impact to levels consistent with ESA directives.

    Response: The USFWS (2008b, 2011) has developed regulations that authorize the nonlethal, incidental take of small numbers of polar bears (and Pacific walruses) from oil and gas industry activities in the Chukchi Sea and Beaufort Sea areas, respectively. These documents include the requirement for maintaining 1-mile exclusion zones around known polar bear dens. A text addition has been made to Section 4.4.7.1.3 that refers to these documents. The FWS also has a website (http://alaska.fws.gov/fisheries/mmm/itr.htm) that addresses incidental take regulations on marine mammals under its jurisdiction (including polar bears, walruses, and sea otters). Section 4.4.7.1 defines level A and B harassment takes of marine mammals. As appropriate, statements similar to that presented in the paragraph referred to in the comment have been added to the PEIS.

65. "BOEM showed a slide earlier and it showed a red buffer zone of 25 miles up from Point Lay to Wainwright. It is really not enough. Walruses and other marine mammals are hauling out because there isn't any more ice nearby that they can rest on, where they can leave their juveniles and go forage for food. They find themselves making their way to land and spending one month, and it's working towards two months now, of every year looking for a place to rest. These animals, when they beach themselves, they're so tired they can't even get out of the surf. They're sick. We're finding sores all over these walruses, all over the seals, along with the belugas. Point Lay is a lagoon system that is about 100 miles long and is pretty unique. It's got more water fowl and sea mammals than anywhere else in the world. They spend their summers there. These areas are very sensitive, along with thousands of other sensitive areas along the Chukchi Sea and up towards Barrow and all the way to Kaktovik. All these shorelines are used. We were finding hundreds of dead walruses, mostly juveniles. These animals were getting sick, there were sores. Scores of them were dead. And I want to mention something about the belugas, too. Point Lay hunters have been harvesting belugas for as long as I've been there, and I have only been there since 1973. Point Lay's history goes way back, and belugas was one of the mainstays there. This year, the animals seem to be a different group. And that's kind of strange and unusual because the belugas that they were normally seeing were much larger. This is a group of — a pod of belugas that were mature but smaller. So we're not sure where this group actually came from."

Response: A discussion of the UME that involves predominately ringed seals, but also some walrus, in the Arctic has been added to Sections 3.8.1.3.1 and 4.6.4.3.1 of the PEIS. A discussion of climate change impacts on sea ice can also be found in those sections of the PEIS, as well other subsections throughout Sections 3.8.1.3 and 4.6.4.3. As of the drafting of this response, NMFS has not yet determined the cause of this UME but will continue to post updates at http://www.alaskafisheries.noaa.gov/protectedresources/seals/ice/diseased/. The Marine Mammal Stranding Network, as well as the North Slope Borough and others, are involved in the investigation of the UME. BOEM is aware that walrus are coming ashore in large numbers when the sea ice retreats northward of the continental shelf, leaving calves particularly vulnerable to deaths during disturbance events and energetically depleted from long swims between foraging areas and the shore. The U.S. Geological Survey (USGS) and USFWS have been studying this phenomenon since about 2007. Recent genetic samples taken from a pod of beluga in Kotzebue Sound seem to indicate that it is genetically distinct from the group that used to show up there. Both the Alaska Department of Fish and Game and the North Slope Borough take samples from the beluga hunts and have an ongoing research program that studies different beluga stocks. There are some changes in habitat use by at least some pods of beluga, though why and where they are going is not completely understood. It is possible that these changes may relate to climate change or changes in prey distribution. In past lease sales, BOEM has looked at both a 25-mile and 50-mile buffer along the coastline. While a 50-mile buffer offers more protection, a 25-mile buffer was selected for Lease Sale 193. There have been discussions about deferring important walrus foraging habitat, primarily the Hanna Shoal area. BOEM is aware of the changing distribution of some marine mammal species, which seems to be driven by factors related to loss of sea ice and climate change. This information will be considered along with other factors in determining the lease sale areas and possible deferrals in future sales in the Chukchi Sea.

66. Section 4.4.7.1.1: NMFS uses different thresholds for Level B harassment, depending on the sound source (impulse, continuous, sonar, etc.), not just 160 dB. For exploratory and production drilling in the Arctic, 120 dB is used as the threshold for Level B harassment as it is a continuous noise source.

    Response: Text has been added to Section 4.4.7.1.1 to include the NMFS thresholds.

8.4.4.4.9 Issue 4.9 Birds.

1. The PEIS should better address the attraction of migrating birds to offshore platform lighting.

   Response: Injury or mortality to birds from collisions with platforms is discussed in Section 4.6.4.1.2 of the PEIS. The text has been revised to include additional text regarding the attraction of birds to platform lighting.

2. The Draft PEIS should be revised to update distribution and habitat information (including figures) for the red knot, wood stork, Audubon’s crested caracara, piping plover, and the experimental eastern population of the whooping crane.

Response: Text and figures have been updated in Sections 3.8.2 and 4.4.7.2 to reflect current information and distribution of threatened, endangered, and candidate bird species, to update the numbers of bird species that could occur in each of the planning areas, and to clarify locations of important bird habitats that could be affected by oil and gas activities and accidental spills.

3. The Draft PEIS should be revised to provide information regarding the Migratory Bird Treaty Act, the ESA, and BOEM compliance with Executive Order 13186 Responsibilities of Federal Agencies to Protect Migratory Birds.

   Response: The Migratory Bird Treaty Act of 1918 (MBTA) is a strict liability law that contains no provision authorizing a permitting system for "incidental take" such as is contained in the Endangered Species Act. The Memorandum of Understanding (MOU) between the Minerals Management Service (MMS, now BOEM) and USFWS regarding implementation of Executive Order 13186, Responsibilities of Federal Agencies to Protect Migratory Birds, is carefully worded such that BOEM is not obligated to any specific action or actions, but is obligated "to the extent allowed by law, subject to the availability of appropriations and within budgetary limits, and in harmony with the Department's and the BOEM's missions and capabilities," to take bird conservation practices into consideration when taking any actions. BOEM includes an effects analysis to migratory birds, thereby taking bird conservation into consideration.

   Discussions of the Migratory Bird Treaty Act were added to Sections 3.8.2.1.1 and 4.4.7.2.1.

4. The accuracy of the presented DWH event bird impact data should be reviewed and updated if appropriate; additional information on affected species and oil toxicity may be warranted; the discussion of oil impacts on birds should be updated.

   Response: Table 3.8.2-6 was checked for accuracy and the provided source is correct. Water quality impacts resulting from the DWH event are discussed in Section 3.4.1.4 of the PEIS. "Seabirds" is a meaningful ornithological designation (as seen in Peterson field guides). Section 3.8.2.1.5 was updated to mention laughing gulls as the dominant bird species reported as affected by the DWH event. Section 3.8.2.1.5 was updated to include more specific information about the potential effects of crude oil and weathered oil on bird species.

5. Additional language should be added to expand on the attraction of birds to platform lighting. To mitigate collision impacts to birds, BOEM should require new lighting technologies (such as red lights) on offshore platforms.

   Response: BOEM recognizes recent advances in lighting technology as a potential bird collision mitigation strategy. Mitigation measures must comply with FAA and Coast Guard regulations (which currently do not allow for red lighting), and will be determined at the lease sale phase when more detailed analyses occur. Additional text has been added to Sections 3.8.2 and 4.4.7.2 regarding platform lighting and bird attraction. The identification of potential mitigation measures takes place at the lease sale EIS or EA level (see Table 1-1, Chapter 1). Please see Section 8.4.4.8, Issue 8, Mitigation, for additional responses concerning requests for specific mitigation measures.

6. The Draft PEIS discusses bird habitat disturbance by spill containment and cleanup activities in Section 4.4.7.2.1. Should this discussion take into account the involvement of wildlife experts in response activities for the purpose of minimizing response impacts to wildlife and habitat?

   Response: Section 4.4.7.2.1 was updated to explain that spill response plans will include consultations with wildlife experts to minimize potential impacts.

7. Table 4.4.7-2 indicates that potentially minor impacts on juvenile and adult birds may result from seismic noise. Seismic noise is not implicated in injury or mortality of these life stages of birds and the table should be corrected to indicate no or negligible effect anticipated.

   Response: Table 4.4.7-2 was updated to show no or negligible effects are anticipated for juvenile or adult birds from seismic noise.

8. The Draft PEIS incorrectly claims that missing information pertaining to the impacts of climate change on marine and coastal birds is not essential to a reasoned choice among alternatives. Better information on the effects of climate change on birds would allow for a more accurate understanding of the differential impacts of the alternatives, and thus allow for a more reasoned choice among alternatives.

   Response: BOEM disagrees. Programmatic-level analyses and decisions do not require the same detailed analyses that may be necessary at later stages of OCS leasing (see Section 1.4.2 for additional discussion of incomplete and unavailable information). Resolving the uncertainty regarding the effects of climate change on birds is not essential at this programmatic stage. BOEM acknowledges the potential effects of climate change on not only birds but all natural resources. The PEIS discusses the potential consequences of climate change on Arctic birds (Section 3.8.2.3.5). Additional text has been added to Section 3.8.2 of the PEIS to discuss climate change consequences for birds in the GOM and Cook Inlet planning areas. Also, see the response to Comment 9 in Section 8.4.4.2, Issue 2, NEPA Analysis.

9. The text should be modified to indicate that moderate impacts would be anticipated to marine and coastal birds in the case of a CDE.

   Response: Depending on the location, timing, and species and habitats affected, a CDE could have a moderate-to-major impact on marine and coastal birds. This impact range is identified for CDEs occurring in the GOM (Section 4.4.7.2.1), Cook Inlet (Section 4.4.7.2.2), and Arctic (Section 4.4.7.2.3) planning areas.

8.4.4.4.10 Issue 4.10 Reptiles.

1. The USFWS requests the inclusion of the Alabama red-belly turtle (*Pseudemys alabamensis*) and gopher tortoise (*Gopherus polyphemus*) in the Affected Environment and Impact Sections (Sections 3.8.3 and 4.4.7.4). Both of these species are reptiles listed under the Endangered Species Act.

   Response: Discussion of these species has been added to the Affected Environment Section (Section 3.8.3) and Impact Section (Section 4.4.7.4).

2. Table 4.1.3-1 in Section 4.1.3 should be revised to omit duplication of impacting factors and revise some of the impacts to sea turtle habitats and life stages.

   Response: This table in Section 4.1.3 has been revised to omit duplication and update impacting factors.

3. The stranding numbers of sea turtles during the Deepwater Horizon event have been revised. Revise sea turtle stranding numbers in the PEIS accordingly (Section 4.4.7.4.2).

   Response: Turtle stranding numbers have been revised in Section 4.4.7.4 to reflect the most up-to-date information at this time.

4. Additional discussion on the role of *Sargassum* to sea turtle life history is needed. The effects to *Sargassum* should be considered in the potential effects to sea turtle habitat resulting from a catastrophic discharge event. *Sargassum* is also a vitally important developmental habitat for sea turtles. *Sargassum* can be found throughout the GOM and can reproduces both sexual and through vegetative regeneration and can be affected in all planning areas. Although *Sargassum* may recover from such events in the long-term, the short-term effects to the ecosystem resulting from a catastrophic discharge event can be of high magnitude.

   Response: Additional discussion on the role of *Sargassum* in the sea turtle life history and impacts to *Sargassum* from OCS O&G activities has been added to Sections 3.7.3.1.2 and 3.8.3.

5. The habitat listed for Kemp's ridley sea turtles (Table 3.8.3-1 in Section 3.8.3) is missing the juvenile and oceanic habitat. Both oceanic and neritic habitats are important for different life history stages of Kemp's ridleys.

   Response: Text has been revised in Section 3.8.3 to discuss juvenile and adult habitats for Kemp's ridley sea turtles.

6. The Affected Environment section could benefit from a more rigorous description of both the neritic and oceanic developmental stages of sea turtles that could be affected by oil and gas activities. Sea turtle life history patterns and the developmental habitat shifts have been

categorized as Type 1, Type 2, and Type 3, depending on the species. Oceanic stage Kemp's ridleys, as well as neritic stage animals, were directly impacted during the Deepwater Horizon Oil spill and could be impacted by other OCS activities in the GOM.

Response: Reptile section (Section 3.8.3) has been updated to include additional discussion of habitat preferences of all turtle life stages.

7. Request discussion of other reptile species listed as sensitive species or species of concern by the USFWS or the States in the GOM Planning regions. Non-federally listed reptile species were not discussed in the Draft PEIS.

   Response: Only reptile species that are federally listed as threatened or endangered under the Endangered Species Act are discussed in this PEIS. The discussion of other sensitive or rare reptile species is more appropriate at the more detailed lease sale or activity-specific stages.

8. Figure 3.8.3-1 in Section 3.8.3 does not accurately represent the occurrence of sea turtles or the nesting of sea turtles along the Texas coast. The inclusion of this figure may lead one to draw inaccurate conclusions regarding the potential impact of oil and gas development in the Western GOM Planning Area.

   Recommendation: Either omit this figure from the PEIS or revise it to more accurately reflect the occurrence of sea turtles and nesting sea turtles in the GOM and particularly along the Texas coast.

   Response: Additional data sources will be reviewed and the figure will include the best available data. However, new information that could be used to revise the figure is not essential in order to make a reasoned choice among alternatives.

9. The Draft PEIS states, "Following the DWH event, a total of 1,146 sea turtles were recovered from the GOM that had come in contact with or were in the vicinity of spilled oil" (Section 3.8.3.1). Does this statement account for the fact that some of these turtles were collected well after the DWH well had been capped? As a result, it is unlikely that those turtles were ever in the vicinity of the spilled oil. Additionally, some were collected in Florida, which also reduces the likelihood that they were in the vicinity of oil. Is there any data indicating that sea turtle nests were in fact oiled, or is this speculation?

   Response: Text has been revised in Section 3.8.3.1 to clarify the interpretation of the data regarding turtle and nest fouling following the DWH event.

10. The BOEM is legally obligated to prevent the deaths of protected species under the Migratory Bird Treaty Act and the Endangered Species Act. Similar concerns could be expressed about the Draft PEIS treatment of issues relating to endangered and threatened marine turtles.

Response: The PEIS identifies sea turtles as being listed as threatened or endangered under the ESA. Any discussion on impacts to these species will be conducted at the lease sale or activity-specific level in compliance with ESA and MBTA requirements. The PEIS describes the ESA and MBTA requirements in Sections C.1.8 and C.1.10, respectively, in Appendix C.

11. BOEM has admitted that the "range of toxicity, the degree of sensitivity to oil hydrocarbons, and the effects of cleanup activities on sea turtles are unknown . . ." (Supplemental EIS for Lease Sale 218 at 4-139). Id. at 4-160.

    Response: It is unclear whether the comment refers to this 5-year OCS PEIS or to the GOM Lease Sale 218 EIS. Regardless, more detailed analysis on these issues will occur at the lease sale or activity-specific level following the PEIS.

8.4.4.4.11 Issue 4.11 Invertebrates.

1. Section 3.8.5.3, Alaska — Arctic — More detailed information on crab stocks in this region can be found in Rand and Logerwell (2011) and in the Arctic FMP. See Rand, K. M., and E. A. Logerwell 2011. The first demersal trawl survey of benthic fish and invertebrates in the Beaufort Sea since the late 1970s. *Polar Biol.* 34:475–488.

    Response: Additional information on the snow crab was added to Section 3.8.5.3.

2. The commenter states that in Sections 3.7.2.1.7 and 3.7.4.1 of the Draft PEIS, the statements regarding the brown substance coating deepwater corals are incorrect because the source does not attribute the "brown substance" to the DWH event and states that laboratory analysis is still needed to determine the source.

    Response: The statement modified to say brown substance. Text modified in Sections 3.7.2.1.7 and 3.7.4.1 to state "covered in brown flocculent (http://www.boemre.gov/ooc/press/2010/press1104a.htm), and recent analyses (White et al. in press) provide evidence that the flocculent contained oil from the DWH event located approximately 11 km (7 mi) to the northeast."

3. Section 4.4.6.2.1 of the Draft PEIS states, "There is evidence that oil released from the DWH event was mixed with dispersant … and may have killed deepwater corals…" Should this statement be clarified to note that testing is still underway to determine if the substance was DWH oil or dispersants? Can the results be provided? In addition, should this passage note that while the effects of dispersant on deepwater corals are poorly understood, dispersant chemicals contain constituents that are considered to have low levels of toxicity when compared to toxic constituents of spilled oil (Wells 1989)?

    Response: The text in Section 4.4.6.2.1 has been modified to say "There is evidence that oil released from the DWH event was mixed with dispersant (Kujawinski et al. 2011), and there is some evidence that oil from the DWH event killed habitat-forming deepwater corals (http://www.boemre.gov/ooc/press/2010/press1104a.htm; White et al., in press; Section 3.7.2.1.7)." The effect of chemically dispersed oil on corals is equivocal, with some studies finding large effects of oil and dispersant mixtures on corals and others finding only minor effects (Dodge et al. 1984; Wyers et al. 1986; Epstein 12 et al. 2000; Haapkvla et al. 2007; Shafir et al. 2007).

4. Sections 4.6.4.1.5 and 4.6.4.3.4 of the Draft PEIS discuss the magnitude and severity of potential effects to invertebrate resources from oil spills. Should these discussions note that the distribution and densities of invertebrate communities in waters potentially affected by the Deepwater Horizon event are under investigation? See NOAA, NRDA Workplans and Data, available at http://www.gulfspillrestoration.noaa.gov/oil-spill/gulf-spill-data/ (linking over a dozen studies of oysters, benthic invertebrates, nekton, and zooplankton). In addition, LDWF has conducted, and continues to conduct, sampling and analysis of crab, shrimp, and oysters.

   Response: Ongoing studies were noted in Section 4.6.4.1.5, the section that discusses invertebrates in the GOM. However, very little data from these studies has been synthesized and peer reviewed. Therefore, it is too soon to do a comprehensive evaluation of the impacts of the DWH event. However, as more information becomes available, BOEM will include the results in subsequent environmental analyses. The purpose of this PEIS is to identify and document the potential impacts of the proposed action and alternatives to the proposed action. To support planning decisions for establishing a 5-year schedule for lease sales, detailed analyses of highly variable, region-specific and/or well-specific risk is neither feasible nor appropriate. See Section 1.4.2 for a discussion of incomplete and unavailable information.

5. The commenter states that Section 3.8.5.1 of the Draft PEIS should note that the yearly hypoxic zone occurs on the Louisiana and Texas continental shelf, away from the deepwater zone where the DWH event occurred.

   Response: This was a general statement about bacteria contributing to the GOM hypoxic zone and was not in reference to the DWH event. It was noted in the text in Section 3.8.5.1 that the hypoxic zone is on the continental shelf not in deepwater. Hypoxia in the GOM is discussed in detail in the water quality section (Section 3.4.1).

6. Sections 3.8.5.1 and 4.4.6.3.1 of the Draft PEIS state that studies following the DWH event demonstrated that the amount of methantropic and oil-eating bacteria increased greatly after the DWH event (Camilli et al. 2010; Kessler et al. 2011). Should these statements also cite Hazen et al. (2010)?

   Response: Reference added as requested to Sections 3.8.5.1 and 4.4.6.3.1.

7. Tables 4.4.7-8 and 4.4.7-9 in Section 4.4.7: The table shows the impact level from noise from seismic surveys potentially affecting invertebrates as blue = minor. Yet the language in

Sections 4.4.7.5.1 and 4.4.7.5.3 suggest that the effects would be "negligible." This table should be changed to reflect an impact level from seismic noise to white = negligible.

In addition, in Table 4.4.7-10, the colors are not consistent with Footnote A. If this table is incorrect, and seismic noise was intended to be classified as a higher impact level, please immediately advise the writer as to the correct classification. In such a circumstance, we reserve and request the right to comment on the corrected table.

Response: The PEIS defines negligible as "no measurable impacts" and minor as "most impacts on the affected resource could be avoided with proper mitigation." If impacts occur, the affected resource will recover completely without mitigation once the impacting stressor is eliminated." Noise can affect invertebrates and, therefore, the definition of Minor better fits with the impacts on invertebrates as described in the literature. Negligible has been changed to minor in the text in Sections 4.4.7.5.1 and 4.4.7.5.3 to match the tables.

8. Commenter requests that a discussion of the impacts of oil spills on pelagic marine invertebrates be added to Section 4.4.7.5.3 and Section 4.4.6.3.3 and notes that if dense aggregations of spawning zooplankton contact oil, reproduction and recruitment may be halted for a year or more depending on how long it would take to clean up the oil spill.

   Response: Invertebrates (including zooplankton) are discussed throughout Section 4.4.7.5. In order to avoid text duplication, Section 4.4.7.5.3 directs the reader to Section 4.4.7.5.2 for a complete discussion of the effects of exploration and site development activities on invertebrates. The existing text has been expanded to discuss impacts on zooplankton from oil spills.

8.4.4.4.12 Issue 4.12 Threatened and Endangered Species.

1. There should be full ESA Section 7 consultation, including the preparation of a Biological Assessment and Biological Opinion. BOEM must avoid conflating the ESA take prohibition with critical habitat designation.

   Response: The Program broadly defines the portion of each planning area that is proposed for subsequent leasing consideration, and decision options for the leasing program are preserved for the Secretary at the time the decision is made for each sale. It is at the lease sale stage or activity-specific stage (i.e., regional seismic EISs) that BOEM begins Section 7 consultations (see Section 1.5.5.4 of the PEIS). BOEM agrees that critical habitat and species listings are separate under the ESA and that designation of critical habitat does not directly prohibit take of the species. BOEM fully complies with all requirements of the ESA, and impacts to ESA-listed species and designated habitats are discussed in various section of Chapter 4 of the PEIS. Also see responses to ESA-related comments presented in Issue 9 of this section of the PEIS.

2. The impact levels used in the Draft PEIS are directed at populations not individuals. However, per ESA, BOEM should direct that evaluation of impacts to individuals that are

much more critical and justified for listed threatened and endangered species. Text should be provided to clarify this issue and subsequent evaluations should consider the uniqueness and vulnerability of listed species when assessing and/or designating a particular impact level.

Response: The impact level definitions provided in Section 4.1.4.1 have been revised to indicate that for evaluations of ESA-listed species, the impact levels consider impacts on individuals as well as populations. In addition, the PEIS has been revised to provide a more uniform and consistent discussion of impacts on ESA-listed species at both the individual and population level. As discussed in Section 1.5.5.4 of the PEIS, ESA Section 7 consultations (whether informal or formal) are premature at the 5-year programmatic stage, and ESA Section 7 consultations would begin at the lease sale stage. It is at this stage that more species-specific impact evaluations would occur, including identification for adversely affecting individuals. BOEM recognizes the uniqueness and vulnerability of listed species. The PEIS identifies these species in Section 3.8, and discusses possible impacts in Section 4.4.7, of the PEIS.

3. The sections on ESA (and other) birds associated with Cook Inlet and Arctic areas are treated much more extensively than any other discussions on ESA species. Revise the document to provide a consistent treatment of the important sensitive biological receptors within each proposed lease area.

   Response: Section 3.8 of the PEIS has been revised to present a more equal treatment of impacts on ESA species and other non-listed species.

8.4.4.4.13 Issue 4.13 Land Use and Infrastructure.

1. The commenter suggested a modification to the text to indicate that the Trans-Alaska Pipeline System (TAPS) could not transport gas. Gas from the Beaufort and Chukchi, therefore, would not be transported via the TAPS, but instead would be transported via a new gas line to the lower 48 States or a port in south central Alaska or directly from future North Slope infrastructure.

   Response: A typographical error was made in the PEIS that indicated that TAPS would transport both oil and gas in Sections 2.1 and 4.4.1.3. The text was amended to show that TAPS will only transport oil. The text revision in these two sections did not result in changes to potential impacts discussed as part of individual resource sections and conclusions.

2. The commenter was concerned about the future viability and operations of the TAPS (including the economic implications for the owners) being connected to the actions described in the Draft PEIS. The comment text indicated that while substantial interest in resources along the North Slope is present, as evidenced by recent lease sales of State lands, the actions undertaken as part of this PEIS are not essential to the future of TAPS.

   Response: While BOEM recognizes the economic and infrastructural importance of TAPS, the concerns for maintenance, improvements, and future viability for this pipeline are out of scope for the evaluation conducted as part of this PEIS, and for BOEM and its compliance with OCSLA. It should be noted that a new 40-year right-of-way was approved in 2003 for TAPS, which was followed shortly afterward by an upgrade of the system's pump stations. Additional activities have been conducted with the goal of extending the economic life of TAPS, while maintaining operational efficiencies and safety. See the response to Comment 7 in Section 8.4.4.2.

3. This commenter described a concern for potential impacts on onshore and offshore resources associated with the use of helicopters, planes, and other vessel traffic.

   Response: The expected levels of helicopter and vessel traffic that could occur under the proposed action are presented in Table 4.4.1-1 for the GOM planning areas, Table 4.4.1-3 for the Cook Inlet planning area, and Table 4.4.1-4 for the Beaufort and Chukchi Seas planning areas. The potential impacts resulting from use of various transport modes (e.g., helicopters and airplanes) are analyzed on a resource-by-resource basis in Chapter 4.

4. The commenter suggested that oil and gas exploration companies should locate support facilities and infrastructure onshore in order to create a tax base and training opportunities for locals, while at the same time reducing the cost of health care, schools, transportation, utilities, and housing in the Northwest Arctic Borough.

   Response: Support facilities and onshore infrastructure for Chukchi oil and gas activity are unlikely to be located within the borders of the Northwest Arctic Borough. However, workers in the Northwest Arctic Borough could be involved in work generated by OCS activities. The Northwest Arctic Borough might consider partnering with the oil and gas industry, the North Slope Borough, and/or other entities for work training programs, which would be applicable to work on the OCS.

   Job training and other reductions in cost (e.g., health care, schools, and utilities) as described in this comment are not, per se, a part of BOEM's responsibilities.

5. The commenter suggested that the TAPS is only used for crude oil, rather than gas as described in the PEIS. The commenter further suggested that the use of a natural gas pipeline to the mid-continent and the tanker concepts are not viable for transporting resources from the Chukchi and Beaufort Seas. The commenter, therefore, suggested two scenarios, one in which resources remain stranded, and another in which the natural gas is exported outside the country.

   Response: The Draft PEIS incorrectly stated that the TAPS would be used to transport both oil and natural gas from the Arctic to Valdez. This error has been corrected in Sections 2.1 and 4.4.1.3 of the PEIS. As discussed in Section 4.4.1.3, a natural gas pipeline from near Prudhoe Bay is assumed to be in place and operational by 2020. The construction of a pipeline for natural gas transport to the lower 48 States has been under serious consideration by industry since 2011, and more recently, industry and the State of Alaska are examining the potential for a pipeline to the southern Alaska coast to support liquefied natural gas (LNG) export outside of the country. Examination of LNG export is outside the scope of the

PEIS. Authorization to export LNG is provided by the U.S. Department of Energy, Office of Oil and Gas Global Security. See the response to Comment 21 regarding LNG export in Section 8.4.4.2.

6. The commenter suggested that the text showing Kivalina as the third largest port in the State of Alaska should be changed to Ketchikan, since Kivalina only has a barge landing.

   Response: The listing of ports was provided by port tonnage based on figures from the United States Army Corp of Engineers (USACE) for the year 2009 (http://www.ndc.iwr.usace.army.mil//wcsc/portname09.htm). According to this data source (which lists the top 100 ports, by tonnage), Valdez was listed as the 18th-largest port in the United States; Nikiski (formerly Nikishka) was listed as 76th; Kivalina was listed as 89th; and Anchorage was listed as 96th. Ketchikan is not included in this listing by the USACE.

   Kivalina is a port for a large mine at Red Dog. The actual port is located outside the immediate community.

   The text in Section 3.11.2 was amended to clarify this information and therefore lists the port as Kivalina (Red Dog).

7. The commenter was unaware of any applications for a gas line that would connect the Beaufort and Chukchi Seas to the lower 48 States.

   Response: Applications for the development of natural gas pipelines are being processed. The BLM, for instance, is processing right-of-way (ROW) applications for the Denali-Alaska Gas Pipeline, the Alaska Pipeline Project, and the Alaska Gasoline Development Corporation Stand Alone Pipeline.

   Among these projects, the initial open season for the Alaska Pipeline Project was conducted from May to July 2010. Project proponents intend to file to the Federal Energy Regulatory Commission (FERC) in October 2012.

8. The commenter stated that the Arctic has very limited coastal infrastructure outside of the Prudhoe/Kuparuk development. The commenter suggested that the opportunity should be used to carefully plan where needed coastal development should be located, including infrastructure to support coastal communities, exploration, production, transportation, safety, and pollution response.

   Response: Existing infrastructure in the Arctic is described in Section 3.11.3. Additional information is also provided in the exploration and development scenario, which is presented in Section 4.4.1.3. While the scenario indicates what types of infrastructure would be needed as part of the overall program, the location, construction, and operation would be determined by an individual applicant and in consideration of other permitting/regulatory requirements. To plan for coastal development at this level (as described in this comment) is outside the scope of this PEIS as well as outside the authority of BOEM.

9. The commenter suggested that the Draft PEIS lacked a discussion of the use of jack-up rigs or platforms in the Chukchi Sea, drill ships, specific drilling techniques (e.g., the extended reach and directional drilling), and gravel islands, thereby ignoring current oil and gas technologies and strategies for protecting critical marine resources and potentially conflicting uses.

   Response: The PEIS includes a discussion of the types of drilling approaches and technologies that would be used in the Arctic, including the Chukchi Sea. Section 4.4.1.3 of the PEIS discusses the uses of gravel islands, mobile platforms, and drill ships under various depth and weather conditions.

10. The commenter requested that the PEIS clarify why the Beaufort Sea required a pipeline, and how oil and gas would be transported from the Chukchi Sea, referencing the text in Section 4.4.7.2.3, the construction of onshore pipelines section.

    Response: The exploration and development scenario for the Arctic is described in further detail in Section 4.4.1.3. The section referenced in the comment summary above is a summary statement that references the exploration and development scenario. As stated in Section 4.4.1.3, oil produced in the Beaufort Sea Planning Area would be delivered via trenched subsea pipeline to existing onshore facilities. In the Chukchi Sea Planning Area, production operations would use gravity-base structures with trenched subsea pipelines to transport oil to landfalls. In both areas, onshore pipelines would convey the oil and gas from the landfall facilities to production facilities at Prudhoe Bay.

8.4.4.4.14 Issue 4.14 Fish and Fisheries.

1. Commenter requests the PEIS note that the U.S. Fish and Wildlife Service issued a substantial 90-day finding (50 CFR Part 17: 60431-60444) on September 29, 2011, for the American eel and is currently conducting a status review of the species to determine if it warrants protection under the Endangered Species Act of 1973.

   Response: The text has been updated in Section 3.8.4.1.12 to reflect new information about the status of the American eel.

2. Commenter states that lakes used for ice roads contain fish and that small fish are pumped out of these lakes when the ice roads are being made and the fish are visible along the road. These impacts should be addressed.

   Response: A discussion of impacts to fish from ice roads has been added to Sections 4.4.7.3.3 (Fish) and 4.4.6.4.3 (EFH).

3. Commenters state that they were horrified by the BP oil disaster and that impacts to oysters and menhaden are unknown because the studies are ongoing. They have also heard stories that oil is coming up from around the Macondo well and that Corexit is still being sprayed. Commenter also noted that more fish have sores on their bodies that never used to be there.

Response: The spill at the Macondo well was capped on July 15, 2010, and Corexit is no longer being sprayed. BOEM concurs that some effects from the oil spill may take years to determine. BOEM also concurs that all effects are not know at this time, and we will continue to follow research on this issue. However, it can be difficult from anecdotal information to determine causality.

4. The commenter states that airgun surveys have important consequences for the health of fisheries and provides several citations to support the claim.

   Response: Section 4.4.7.3 acknowledges that fish hearing is potentially damaged by air guns and the literature cited in the comment has been discussed in the text when applicable to fish. Potential impacts on commercial fisheries were noted in the commercial fisheries section.

5. Section 4.4.7.3, Fish: BOEM acknowledges that trace metal and hydrocarbon constituents in drilling fluids can be toxic to fish at all life stages if they are exposed to high enough concentrations. NOAA recommends that BOEM either include a reference, or a brief description of what constituents might be present in these fluids.

   Response: Section 4.4.3.1 (Potential Impacts on Water Quality-GOM) describes the various categories of drilling fluids and their primary constituents. A reference to this section and the papers it cites has been added to Section 4.4.7.3.

6. Sections 4.4.11.1.2 and 4.4.11.2.1, Commercial Fisheries: NOAA has previously commented that negative values in tables describing the estimates of increased costs to fishing vessels need explanation. Based on how positive values are treated in the text, a negative value implies operational costs will decrease as a result of the placement of new oil/gas structures. These negative values require explanation; absent explanation, the underlying model becomes suspect, raising questions on the estimated increased costs as well. Further, it is unclear how the results in Section 4.4.7.5.2 are derived. For example, the PEIS states that for the Western Planning Area 0-60m depth, the cost impact for one structure is estimated to be $41.24 (Table 4.4.11.1-1). If 44–80 platforms are to be built, the respective range of cost is $1,815 ($41.24 × 44) − $3,299 ($41.24 × 80) and not the $1,993−$3,819 reported. Similar math "disconnects" result from examining the estimates for the Central Planning Area.

   Response: The commenter is correct is assuming that negative values in Tables 4.4.11.1 and 4.4.11.2 indicate that costs would decrease as a result of the placement of offshore oil and gas structures. Specifically, in Table 4.4.11.1, coefficients for platforms in the 0–60 m (0–197 ft) depth range are negative in the Central and Eastern Planning Area, which implies that additional platforms in this depth range will dampen the negative impacts of platforms in other depth ranges in the Planning Area. The text in Section 4.4.11 of the PEIS has been changed to clarify the nature of impacts, and provide more information on the calculation procedures.

7. Section 4.6.3.2.3, Essential Fish Habitat: "Egg and larval stages would be at greater risk of exposure to oil spills because spawning aggregations of many groundfish species (e.g., walleye pollock) produce pelagic eggs that could come into contact with surface oil slicks. Herring are also potentially susceptible to oil spills because they spawn in nearshore waters for protracted periods of time." In Shelikof Strait pollock eggs are spawned at depth 250-300m and rise to the surface. Larvae are found 30–40m depth. Pollock eggs are found at the surface in the eastern Bering Sea so there could be other areas in the Gulf of Alaska where the eggs would be right at the surface. Note that Sablefish larvae are neustonic. They would be at risk in an oil spill that left Cook Inlet proper and contaminated the Gulf. Please check the AFSC (Alaska Fisheries Science Center) Icthyoplankton Information System http://access.afsc.noaa.gov/ichthyo/index.cfm for a complete listing of the habitats for the target species.

   Response: Additional information on pollock was added to Section 4.6.3.2.3. Detailed fisheries impact analysis would occur at the individual lease sale.

8. In the assessment of potential impacts on fish resources and EFH, the conclusion was that no permanent impacts on fish populations are expected although some fish populations may be measurably depressed for several years in the event of a spill. This conclusion fails to recognize the relative importance of a single year class to overall population health, such as is found with some gadid and herring species.

   Response: The size of a particular year class is affected by a variety of physical, chemical, and biological factors. Most impacts are unlikely to affect a whole year class unless the species is concentrated in one location. The text in Sections 3.7.4 and 4.4.6.4 was modified to add information on gadids and herring as appropriate to addressing permanent impacts on fish populations.

9. Commenter requests that the effects of platform removals be added to the summary section on fish and EFH impacts.

   Response: Added effects of platform removals to Section 4.4.6.4 on fish and EFH impacts.

10. The NMFS is in the process of rulemaking, which will remove the species identified below (Section 3.7.4.1) from their respective fishery management units in the GOM. Although final action has not occurred at this time, BOEM should verify their status prior to publishing the Final PEIS. (Contact: David Dale, Southeast Region Essential Fish Habitat Coordinator david.dale@noaa.gov). Reef Fish: dog snapper, mahogany snapper, schoolmaster, misty grouper, red hind, rock hind, blackline tilefish, anchor tilefish, sand perch, and dwarf sand perch. Coastal Migratory Pelagics: bluefish, cero, dolphin, and little tunny.

    Response: David Dale has been contacted, and the text in Section 3.7.4.1 was revised to reflect species updates provided by Mr. Dale.

11. Section 3.7.4.2: This section has an incomplete reference pointing only to NMFS (2005).

Response: It is uncertain as to what the commenter means by saying the reference is incomplete. However, the referenced link www.fakr.noaa.gov/npfmc/fmp/fmp.htm is no longer functional and has been replaced with www.fakr.noaa.gov/npfmc/index.html.

12. Section 3.8.4.2.3, Demersal Fishes: "Groundfish typically use Cook Inlet as a seasonal feeding area, while spawning occurs offshore, often on the continental shelf edge of the GOA." This is accurate for most but not all groundfish. Pollock, for example, use Shelikof Strait and the Shumagin Islands as their primary spawning areas, which are located above the continental shelf. NOAA recommends BOEM revise this text.

    Response: Areas used by Pollock have been clarified in Section 3.8.4.2.3.

13. Section 3.8.5.2, Alaska — Cook Inlet. Climate-change effects on commercially important crustacean species such as king and Tanner crab should be specifically mentioned here.

    Response: Text on ocean acidification and commercial crabs has been added to Section 3.8.5.2.

14. Section 3.8.5.3, Alaska — Arctic: More detailed information on crab stocks in this region can be found in Rand and Logerwell (2011) and in the Arctic FMP. See Rand, K. M., and E. A. Logerwell (2011). The first demersal trawl survey of benthic fish and invertebrates in the Beaufort Sea since the late 1970s. *Polar Biol.* 34:475–488.]

    Response: Snow crab information from Rand and Logerwell (2011) has been added to Section 3.8.5.3.

15. Commenter states that the DWH event resulted in potential long-term impacts to fish and impacts to commercial fisheries and cites literature support. Such revenue losses and long-term effects of spill- induced fishery closures on fishing communities must be recognized in Chapter 6 of the PEIS.

    Response: It is premature to say what the long-term effects of the DWH event may or may not be on fisheries in the GOM. Throughout the implementation of the 2012-2017 Program, BOEM will continue to review and incorporate research findings into our understanding of effects and our OCS oil and gas activities. The Whitehead study referenced in the comment was added to Section 3.8.4.1. The impacts of the DWH event on commercial fisheries are addressed in Section 3.12.1.1. Text has been added to Chapter 6 that discusses the effects of an unexpected CDE on long-term productivity.

16. The commenter wants more acknowledgement that the DWH event could produce long-term impacts to fish and provides citations for additional information.

    Response: The text in Section 4.4.7.3 states "...although there remains the potential for long-term population impacts from sublethal and chronic exposure." Discussion of impacts on the bluefin tuna was expanded in this section. Population dynamics are difficult to predict.

Productivity can be density-dependent. It is hard to determine the limiting factors for populations. Sublethal effects are possible, although they may be less pronounced in far-ranging species since they may not be exposed to geographically concentrated contamination. BOEM would concur that the true impact will take years to determine.

17. The commenter does not like the data cited in the text as sourced from a Mississippi State University website, feeling that the information is too limited, and provides his own analysis of fisheries impacts.

    Response: BOEM agrees that the information provided on the cited website is very limited in scope, and the text in Section 3.8.4.1 has been revised to remove the citation and associated reference. Information provided by the commenter was not peer-reviewed in nature, consisting of newspaper articles, and thus was not used to revise the PEIS. The PEIS does not claim there were no impacts on shrimp populations or shrimp fisheries from the DWH event. It is too early to assess the impacts of the DWH event on fish populations and fisheries catch and it will take time and rigorous scientific inquiry to determine the extent and severity of impacts from the DWH event.

18. Section 3.7.4.1 of the Draft PEIS states, "Oil released as a result of the DWH event affected more than 1,046 km (650 mi) of the GOM coastal EFH," citing OSAT-2 (2011) and National Commission (2011). Do these authorities refer to "EFH," or instead to "Gulf Coast habitats"? The commenter also states the PEIS should include the results from Atlantic Bluefin Tuna Status Review Team, 2011. Status Review Report of Atlantic Bluefin tuna (*Thunnus thynnus*), Report to National Marine Fisheries Service, and that there are many studies of the DWH event on marine life.

    Response: Gulf Coast habitats are considered EFH for reef and other species under the Gulf of Mexico Fishery Management Plan (Section 3.7.4.1). The Status Review 2011 report results were incorporated into the PEIS, and other text was modified to indicate there are many ongoing studies of the DWH event but little of the data is synthesized, peer-reviewed, and available.

19. Commenter asks whether the "long-term, population-level impacts" described in the Draft PEIS are adequately supported or, instead, largely conjectural? At a minimum, should not these statements be qualified by referring to current research suggesting that, while certain fish species may have experienced biological impacts in the short-term as a result of the DWH event, there is little evidence of a significant decrease in fish populations after the DWH event? See Fodrie et al. (2011); Atlantic Bluefin Tuna Status Review (2011).

    Response: This statement was not referring to the effects of the DWH event, but rather, the potential effects of catastrophic spills in general. The effects of the *Exxon Valdez* spill may have had population effects (see the *Exxon Valdez* Oil Spill Trustee Council site http://www.evostc.state.ak.us/), although it can be difficult to differentiate what was spill-caused and what was due to other factors.

20. Section 3.7.4.1 of the Draft PEIS states, "Although much of the oil remaining after cleanup is highly weathered, several constituents have the potential to cause toxicological effects (OSAT-2 2011)." Should this statement clarify that oil weathering depleted a large portion of the more toxic PAHs in oil? Should this statement reference Boehm SETAC (Society for Environmental Toxicology and Chemistry) and IOSC (International Oil Spill Conference) presentations on high rates of biodegradation for DWH oil?

    Response: The text has been clarified in Section 3.7.4.1 as suggested, but also includes a discussion of the OSAT-2 finding that the residual oil evaluated contained high-molecular-weight hydrocarbons, including the more toxic PAHs that are resistant to weathering and microbial biodegradation.

21. Section 3.7.4.1 of the Draft PEIS states, "The methane plume appeared to be relatively short-lived (Kessler et al. 2011), but dispersant was still detectable at low, nontoxic levels up to 300 km (186 mi) away from the wellhead 64 days after the dispersant release ended (Kujawinski et al. 2011).". The cited Kessler article reviews methane concentrations in August and September 2010, one to two months after the wellhead was closed. The timeframe of the Kessler article is similar to the 64-day timeframe of the dispersant study. Should the quoted PEIS statement be rewritten to note that methane was effectively consumed within one to two months, and that dispersant concentrations, while still detectable, were very low (at the ng/L level) — well below toxic concentrations - in the same time period?

    Response: Text in Section 3.7.4.1 modified to: "The methane plume appeared to be relatively short-lived with most of the methane being consumed by bacteria within 120 days from the onset of release (Kessler et al. 2011). Dispersant was detectable at low, nontoxic levels up to 300 km (186 mi) away from the wellhead 64 days after the dispersant release ended (Kujawinski et al. 2011). Sediment and water quality contaminant data from OSAT also added.

22. Section 3.12.2.2: The 1987 sourced information appears dated. Suggest including a statement that no more recent data are available in place of the implicit statement. Suggest investigating the availability of more recent information on recreational fishing than 1987 studies.

    Section 3.12.2.3: There is quantitative data presented for most types of the fishing or statements to indicate the lack of such data. Provide similar statements for the subsistence fishing as other fisheries if available.

    Response: The text in the PEIS has been changed in Sections 3.12.2.2 and 3.12.2.3 to reflect the data noted in the comment.

23. Section 4.4.7.3.1, Protected Species: Gulf Sturgeon: Although accidents are addressed to some degree for this species, why have impacts from a CDE not been discussed more extensively, or at least within the "Accidents" section? Data obtained during the DWH event

studies (i.e., OSAT 1) would aid in understanding the vulnerability and/or potential effects (or not) from such a unique event.

Response: Section 4.4.7.3.1 has been modified. Although there are many ongoing studies, there is very little actual data and even less consensus on the effects of the DWH event on future fish populations. The Fodrie paper is one of the few peer-reviewed papers currently available and it is cited in the PEIS as is the population model for bluefin tuna. The OSAT studies were of sediment and water column PAH concentrations and are discussed in the habitat discussions presented in this PEIS (see Section 4.4.6). Also, the DWH event should not be taken as being necessarily similar to future spills, although the PEIS includes an analysis of the potential effects to fish and fish habitats in an unexpected CDE were to occur in the GOM.

24. Section 4.4.11.1.1: This section is extremely limited considering the biological, economical and sociological attributes associated with commercial and recreational fishing in the GOM.

Response: The biological, economic, and sociological aspects of commercial fishing in the GOM are covered in detail in Sections 3.12 and 3.14 of the PEIS. The intention of Section 4.4.11.1 is to provide a description of expected cost impacts on commercial fisheries, and the various regulatory limits on activity. Additional information was added as appropriate. Detailed evaluation of fisheries will be considered in specific lease sales.

25. The Draft PEIS fails to appropriately consider information from the Deepwater Horizon event in analyzing the environmental impacts of future spills. Chapter 6 asserts that there has been "no discernible decrease in [biological] productivity in U.S. offshore areas where oil and gas have been produced for many years." Yet, early data from the Deepwater Horizon event strongly suggests that this is not the case. At the height of the Deepwater Horizon event, 36% of Federal waters in the GOM were closed to commercial and recreational fishing, suggesting there were, in fact, significant biological impacts. We understand that the timeframe for completing the PEIS makes it impossible to incorporate all the lessons learned from the Gulf spill. However, this does not absolve BOEM from considering existing information and analyzing the potential for environmental impact, especially given the numerous assurances of Federal leaders and agencies that the same mistakes will not be made twice.

Response: Reasons for fishery closure are not tightly linked to biological productivity. The closures were to protect human health and the perception of the quality of the seafood not from spill areas. This way the public is reassured that fish being sold could not be from spill-affected areas. Studies of the DWH event are ongoing and conclusions cannot be drawn at this time concerning effects on overall productivity.

26. Commenter requests clarification and consistency on impact tables in Section 4.4.7.

Response: Definitions of the impact levels used in the PEIS are provided in Section 4.1.4. Minor is defined as: "If impacts occur, the affected resource will recover completely without mitigation once the impacting stressor is eliminated." There is literature describing how noise can affect fish, and therefore, the definition of "minor" better fits with the impacts on fish as described in the literature. Text has been modified in Section 4.4.7 to match the table when they are not consistent.

27. Section 4.4.7.3: The sentence "However, fish larvae may suffer greater mortality because of their small size and relative lack of mobility" is speculation, and should be referenced or removed.

    Response: A reference has been added in Section 4.4.7.3 to support the original statement.

28. Summary, Fish Resources and Essential Fish Habitat: This language incorrectly singles out seismic potential impact for displacement of fish in the vicinity of the activity. The implication made that seismic surveys such as those that will be conducted under the Program will injure or kill fish in the vicinity of the seismic survey activity is not correct, and is not supported by the scientific literature. Therefore, these references/statements should be corrected or removed.

    Response: The text in the Fish Resources and Essential Fish Habitat section of the Summary was modified to include other noise sources. There is some uncertainty as to the impact magnitude of seismic surveys on fish, but impacts are possible. Complete discussion of noise effects on fish can be found in Section 4.4.7.3.1 (Fish Resources-GOM), which can include mortality.

29. Section 4.4.7.3.3: It should be stated that moderate impacts are expected in the case of a CDE.

    Response: The text in Section 4.4.7.3.3 was modified as requested.

30. Section 4.4.7.3.1, Protected Species: Gulf Sturgeon, Accidents: The essential features of Gulf sturgeon critical habitat could be affected by accidental discharges of oil and other chemicals. NOAA recommends that the essential features of critical habitat be discussed for their potential to be adversely affected.

    Response: The potential for impacts on Gulf sturgeon critical habitat are noted in the existing text in Section 4.4.7.3.1. The potential impacts of oil spills on coastal habitats that comprise the critical habitat of the Gulf sturgeon are described in Section 4.4.6.1, and a reference to this section has been added to Section 4.4.7.3.1, where the Gulf sturgeon is discussed. More detailed treatment of Gulf sturgeon Critical Habitat would be provided in future specific lease sale EISs.

31. Section 3.8.4.1.4: The units that may be affected by the lease plan should be listed and described. Maps should also be provided. The essential features of Gulf Sturgeon critical habitat that are provided in the final rule should be described as well. Southeast U.S. critical habitat metadata can be found on NMFS GIS page at http://www.nmfs.noaa.gov/gis/

data/critical.htm#se. An image of all the critical habitats units is available at http://www.nmfs.noaa.gov/pr/pdfs/criticalhabitat/gulfsturgeon.pdf.

Response: An expanded listing of Gulf sturgeon critical habitat and supporting citations have been added to Section 3.8.4.1.4. The coastal habitats used by Gulf sturgeon are described in Section 3.8.4.1.4 and a figure depicting critical habitat has been added to this section.

32. Section 3.12.2.3, Alaska — Arctic. NOAA recommends that the paragraph on subsistence fisheries be expanded considerably. There is abundant literature documenting the locations, levels, and importance of subsistence fishing to Arctic communities.

    Response: Section 3.12.2.3 discusses only recreational fisheries, so subsistence fishing is not discussed. The paragraph was removed because it is not appropriate for the section. Subsistence fishing is discussed in detail in Section 3.14.3.2

33. Section 4.4.7.3: The text in this section is erroneous and misleading, as the circumstances created by the study (i.e., repeated, close exposure to an airgun over an extended period of time) would almost certainly not take place in association with actual seismic surveys conducted under the Program. The sentence should be removed or corrected.

    Response: Section 4.4.7.3 states that the study refers to continuous long-term exposure. Later in the paragraph, the text states that “For adult fishes, continuous exposures are unlikely under natural circumstances as fish could move from the area.” The text in Section 4.4.7.3 was modified to make this clearer.

34. Section 2.10, Table 2.10-2, Essential Fish Habitat: The summary of Potential Impacts on Essential Fish Habitat for Alternative 1 – Proposed Action only mentions coral as a type of EFH. This summary should be similar to the Potential Impacts described for Coastal and Estuarine Habitats (Section 4.4.6.1) and Marine Pelagic Habitats (Section 4.4.6.3).

    Response: The text in Section 2.10 was modified to include other EFH and relevant mitigation measures.

8.4.4.4.15 Issue 4.15 Oceanography.

1. Commenters requested a more detailed description of ice conditions and dynamics in Cook Inlet be provided in the PEIS, as ice and scour are important impact-producing factors, and sea ice conditions differ between the upper and lower portions of Cook Inlet.

    Response: Section 4.2.2 of the PEIS was revised to describe differences in sea ice conditions in the lower and upper reaches of Cook Inlet.

2. The State of Alaska requested that BOEM contrast in Chapter 2 the Alaska OCS planning areas to deepwater environments in the GOM, differentiating physiography and physical oceanography.

   Response: The principal purpose of Chapter 2 is to present the alternatives considered and analyzed in the PEIS, rather than differentiating between planning areas evaluated under the Program alternatives. Section 2.9 describes the alternatives that were considered but eliminated from further consideration. Section 4.2 provides a detailed description regarding the physiography and physical oceanography of the Arctic and Cook Inlet in comparison to the GOM.

8.4.4.4.16 Issue 4.16 Areas of Special Concern.

1. Several sections of the Draft PEIS discuss "areas of special concern." These discussions focus on designated areas such as marine protected areas. Since there are few marine protected areas designated for the Alaska Arctic, we (the Northwest Arctic Borough) recommend these sections be expanded to include important ecological areas. The 2010 Arctic Marine Synthesis Atlas of the Chukchi and Beaufort Seas provides a good source for areas of ecological importance.

   Response: The different types of Areas of Concern (AOCs) are given at the beginning of Section 3.9. Ecologically important areas of the Arctic are described in the PEIS in detail under separate resource categories presented in Sections 3.7 and 3.8. More detailed habitat descriptions are most appropriate for a specific lease sale EIS.

2. Discussion should be included as to whether or not consideration was given to the exclusion of areas designated as national marine sanctuaries and monuments, essential fish habitat, or habitat areas of particular concern from leasing. Additionally, some consideration should be given at the program planning stage to alternatives other than sales of all unleased acreage. In particular, recognition of sensitive and protected marine habitats (e.g., Hanna Shoal) should be considered at this stage, rather than waiting until the lease sale stage.

   Response: Exclusion areas are generally determined at the lease sale stage. Section 2.9.5 of the PEIS addresses alternatives recommending the addition of new areal and temporal exclusion areas, as well as the rationale for generally deferring the designation of exclusion areas to the lease sale phase. In addition, a new section (Section 4.3.2) discussing programmatic deferrals and mitigation can be found in Section 4.3, Issues of Programmatic Concern. Also, see responses to Comments 2 and 3 in Section 8.4.4.1, NEPA Process and Public Involvement, for further discussion of exclusion areas and alternatives.

3. The Natural Diversity Database maintained by Texas Parks and Wildlife Department (TPWD) indicates that more than 200 rookeries and migratory bird fallout sites, more than 50 rare or special terrestrial communities, 40 rare plant populations, and over 170 records of State and/or federally listed endangered, threatened, or rare vertebrates have been documented within 10 miles of the Texas coastline.

Response: The different types of AOCs are given at the beginning of Section 3.9. The important ecological areas of the Arctic do not have the legal definitions typical of AOCs. However, the ecologically important areas of the Texas coastline are described in the PEIS in detail under separate resource categories. These include Section 3.8.2.1, Marine and Coastal Birds, and Section 3.7.1.1, GOM Coastal and Estuarine Habitats. Endangered species are discussed under individual sections on birds, reptiles, and fish. Specific mention of the importance of the large coastline of Texas for biota has been added to the text in these sections. More detailed habitat descriptions would be provided in lease sale-specific EISs.

4. The Draft PEIS states, "These habitats were also affected by prevention and cleanup efforts (NOAA 2010)." PEIS at Section 3.7.4.1. To which NOAA source does this statement cite?

   Response: The text in Section 3.7.4.1 has been revised to cite OSAT-2 (2011) rather than NOAA 2010.

8.4.4.4.17 Issue 4.17 Archeological and Historical Resources.

1. The proposed 5-year leasing program includes two sales in 2014 and 2016 in the Eastern GOM Planning Area. We do have concerns about potential adverse impacts to cultural resources. Requirements for cultural resource surveys in areas that have potential to encounter historic sites and properties should be implemented. Adequate buffer areas for site protection of significant resources and the avoidance of adverse impacts should be required. Both coastal and submerged sites and properties must be considered prior to any undertaking.

   Response: The required Section 106 consultations set forth in the National Historic Preservation Act (NHPA) and its implementing regulations will be carried out during the lease sales proposed under the oil and gas program and during subsequent undertakings that require approval subsequent to lease issuance. As required in the *Identification of Historic Properties* part (36 CFR 800.4), BOEM will determine the scope of identification efforts, review existing information, and seek information on existing and potential historic properties from consulting parties and the public. BOEM may require cultural resource surveys as part of its reasonable and good faith effort in carrying out appropriate identification efforts based on current research, the magnitude and nature of the undertaking, and the nature and extent of potential effects on historic properties. Any adverse effects on cultural resources may require mitigation.

2. There is a concentration of the wrecks of historically important whaling ships off of Cape Lisburne.

   Response: Section 3.16.3.2 acknowledges that numerous shipwrecks are found in the Cape Lisburne area. In the event that exploration or development operations are proposed for that area, BOEM is required to comply with the Section 106 process of the NHPA. As required in the *Identification of Historic Properties* part (36 CFR 800.4), BOEM will determine the scope of identification efforts, review existing information, and seek information on existing and potential historic properties from consulting parties and the public. BOEM may require cultural resource surveys as part of its reasonable and good faith effort in carrying out appropriate identification efforts based on current research, the magnitude and nature of the undertaking, and the nature and extent of potential effects on historic properties. Any adverse effects on cultural resources may require mitigation.

8.4.4.4.18 Issue 4.18 Human Health Assessment.

1. Commenters from both the GOM and the Arctic expressed concern regarding a variety of health issues such as the incidence of diabetes, heart disease, cancer, and respiratory ailments, and concern that these health issues could be caused or exacerbated by oil and gas development activities and oil spills. Commenters from the Arctic cited that their concerns were based on traditional knowledge and personal observations.

   Response: BOEM recognizes the concern for human health and the potential impacts of oil and gas development on human health. BOEM has identified human health impacts as an issue of programmatic concern and expanded the discussion presented in the PEIS (see Section 4.3.4). Health effects will be further considered at the later stages of the oil and gas development process (e.g., with NEPA documents prepared during the lease sale stage).

2. Commenters requested that human health assessments be conducted as soon as possible, including before a decision is made on the 2012-2017 OCS O&G program; commenters also question BOEM’s decision for deferring the conduct of health assessments to later stages of oil and gas development (lease sale or later).

   Response: This PEIS is a broad-level document discussing impacts over entire planning regions, which address a different spatial scale than would the examination of health issues of specific human populations at specific locations. The conduct of human health assessments to evaluate potential impacts to populations at specific locations is more appropriate at the lease sale or plan stage, when there will be a better understanding of where development may actually occur and who may be affected.

3. There is concern of mercury poisoning that is occurring throughout the Arctic (including Canada) needs to be addressed. The commenter also expressed concern regarding flaring.

   Response: The PEIS evaluates potential impacts at a broad, planning area scale. The analysis of cumulative impacts presented in Sections 4.6.1.2.2, 4.6.1.2.3, and 4.6.1.2.4 of the PEIS discuss the cumulative impacts of persistent contaminants, including mercury. The evaluation of mercury releases and flaring will be further addressed at the lease sale level, where the evaluations can focus on specific locations and populations.

4. BOEM should review the Operational Science Advisory Team report (OSAT-2) on the fate and effects of remnant oil and revise the Draft PEIS to better address the potential for human contact with tar balls, oil weathering and human contact, reoiling potential, and the fate of oil-related volatile organic compounds.

Response: The OSAT-2 report was reviewed and is cited in Section 4.3.4.4 of the PEIS. This section has been revised in the PEIS to better discuss human contact with tar balls, human contact with oil and oil weathering products, reoiling potential, and the fate and transport of VOCs.

5. Was the Goldstein et al. 2011 study on the mental and physical health effects of the DWH event, cited in Section 4.3.4.4 of the Draft PEIS, done using an appropriate baseline? Should this statement be revised or deleted because it pertains to surveys of first responders to Hurricane Katrina?

   Response: The Goldstein et al. 2011 report is a summary article that reports the finding of multiple other peer-reviewed publications that specifically investigated the impacts of oil spills on mental and physical health. Some studies did note that some of the mental health effects observed following the DWH event may have been compounded, as some of the spill responders were also Hurricane Katrina responders who suffered some of the same mental health effects. Section 4.3.4.4 has been revised to include the findings of a recent study (Osofsky et al. 2011) that specifically examined mental health impacts following the DWH event and considered effects from Hurricane Katarina.

6. Section 4.4.4.1 of the Draft PEIS states, "The effects of a catastrophic discharge event on public health and the environment can be classified as short-term and long-term effects. The short-term effects include watery and irritated eyes, skin itching and redness, coughing, and shortness of breath or wheezing." Should this statement be revised to state that short-term effects may include the aforementioned issues?

   Response: BOEM agrees that the aforementioned effects 'may' occur, and the referenced text in Section 4.4.4.1 has been revised to state that the short-term effects 'may' include the aforementioned effects.

7. Section 4.3.2.4.1 of the Draft PEIS states, "After an accidental release of oil into the environment, the more volatile, water-soluble, and degradable compounds will be weathered and degraded, leaving behind the heavier, less degradable elements." Should this statement be clarified to reflect the fact that hydrocarbons with higher molecular weights will ultimately undergo weathering, but at slower rates? Additionally, the heavier, less-degradable elements have lower toxicity.

   Response: BOEM agrees with the comment, and the text in Section 4.3.4.4.1 (previously Section 4.3.2.4.1) has been revised as suggested.

8.4.4.4.19 Issue 4.19 Socioeconomics.

1. Concerns about oil and gas development, and especially oil spills, will affect tourism and the restaurant, fishing, and service industries in the GOM.

Response: BOEM acknowledges that socioeconomic impacts are possible, especially in the event of large oil spills. The role of the food service, fishing, and tourism sectors in the economic baseline of the GOM, and the potential impacts of OCS oil and gas activities (and spills) on these sectors are discussed in Sections 3.10, 4.4.9, 4.4.11, and 4.4.12 of the PEIS.

2. The resources of the OCS are a vital source of jobs, revenue, energy, reliability, security, and economic growth, the importance of which is reported in an independent study in the GOM.

   Response: The PEIS has been revised in Section 3.10 to include information referenced in the comment.

   The economic impact of the oil and gas industry on employment in the GOM is presented in Section 3.10.5 of the PEIS. Although no projections of direct oil and gas employment are provided, current baseline conditions and projections to 2030 provided for population, employment, and earnings for the region, assuming current levels of leasing activity. These projections include long-term projections of oil and gas industry activity, spending, and employment, and implicitly assume levels of activity in the industry based on existing lease sales before the DWH event and the drilling moratorium.

   Although BOEM agrees that the oil and gas sector has significant impacts on the remainder of the United States, both in terms of capital and labor expenditures, the PEIS assessed the impact of existing oil and gas activity and of proposed OCS activity in the counties adjacent to the GOM, rather than the entire United States, as this would be the region most affected by the proposed OCS activity.

3. Section 4.4.9.3 demonstrates that most of the estimated employment benefits from oil and gas activities in the Arctic will go to Alaska's largest population centers. While the North Slope Borough may tax infrastructure within its boundaries associated with offshore development, the Northwest Arctic Borough would receive increased risks to its socioeconomic structure without commensurate economic impacts/benefits. Recommend the PEIS include a discussion of how revenue sharing could increase local economic benefits, and how environmental justice issues are involved with the leasing of the area, particularly with low-income minority communities being placed at risk.

   Response: Under current fiscal circumstances, the Northwest Arctic Borough would not receive direct revenue from OCS activities in the Chukchi Sea. The Borough is currently receiving fiscal support from the State of Alaska as a result of the shipment of oil and gas through TAPS and associated infrastructure and from Alaska Native Corporation investments in oil companies. Individuals resident in the Borough also receive benefits from the Alaska Permanent Fund Dividend. Per Section 18 requirements of the OCSLA, the "Equitable sharing of Developmental Benefits and Environmental Risks" section (in Part IV.C) of the Proposed Final Program (PFP) discusses equitable sharing of development benefits and risks. The PFP describes the three current programs that contribute revenue to coastal producing states, including Section 8(g), Revenue Sharing, which provides coastal producing states with 27% of revenues from all leases within 4.8 km (3 mi) of a state's submerged lands boundary. While impact assistance and other such programs provide a share of Federal revenues to

States and political subdivisions adjacent to or near OCS development to help to mitigate environmental risk, the Secretary cannot expand, extend, or otherwise revise the provisions to further the equitable sharing of the developmental benefits and environmental risks. Although different revenue schemes could change the flow of economic benefits to different States, or indirectly to certain coastal communities, it is speculative at this phase what those impacts could be, given different, potentially wide-ranging revenue-sharing scenarios. Analysis of the impacts of OCS activities on sociocultural resources in the Northwest Arctic Borough is also presented in Section 4.4.13.3 of the PEIS.

Projected economic benefits of OCS activities in the Arctic region, including labor income and employment estimates, are described in Section 4.4.9.3 of the PEIS. Detailed analysis of economic flows to a specific local community is not ripe at the 5-year decision point, as the programmatic analysis is too broad to distinguish local economic impacts. It should be noted that direct benefits from OCS activity may come in the form of property taxes on onshore operations or other sources. A more detailed analysis of the potential fiscal impacts of OCS development in the Chukchi Sea would be undertaken at the lease sale level.

Potential environmental justice impacts of OCS activities in the Northwest Arctic Borough are included as part of the analysis of impacts in the Arctic region. These impacts are described in Section 4.4.14.3 of the PEIS.

4. NOAA has previously commented that public perception of contaminated seafood and market/price/economic impacts may be great, as was seen with Deepwater Horizon. NOAA recommends that the PEIS discuss public perception of contaminated seafood as a potential impact.

   Response: The impacts of the DWH event on commercial and recreational fishing are discussed in Sections 3.12.1.1 and 3.12.2.1 of the PEIS, and additional text has been added to Section 3.12 regarding public perception of contaminated seafood. The PEIS states that although the impact of the event on fish landings has not been determined, Federal waters were closed to fishing for two months after the event, to address the perception of contamination.

   The potential impacts of perceived contamination of commercial and recreational fish as a result of OCS accidents are discussed in Sections 4.4.11.1, 4.4.11.2, and 4.4.11.3 of the PEIS. Given the region-specific nature of fisheries, additional information on the impact of adverse perceptions on demand for fish in OCS areas would be analyzed at the lease sale level.

5. BOEM needs to better evaluate and present potential economic costs and benefits of the alternatives under its consideration, taking particular care to ensure that information about the potential economic impacts of various alternatives is accurate. It also must ensure that this information is fully and fairly depicted in the PEIS. Importantly, BOEM must revisit its analysis of the no action alternative in order to more fully depict the potential benefits of no action, ensure that costs are depicted appropriately for the Arctic region, appropriately incorporate conservation and efficiency, and include a discussion of option value. Once it

corrects those failings, BOEM must use this information in the PEIS to more accurately reflect the costs and benefits of alternatives relevant to the Arctic Ocean.

Response: An analysis of the economic impacts of each alternative, including the No Action Alternative, is included in the PEIS (Section 4.5.7). A cost-benefit analysis was prepared in support of the Program, and this analysis is discussed in Section 2.12 of the PEIS. Impacts of the proposed action on population, employment, and earnings, are presented in Section 4.4.9, on commercial and recreation fisheries in Section 4.4.11, and on recreation and tourism in Section 4.4.12. The impacts of the No Action Alternative, which includes population, employment, and earnings projections to 2030, assuming that currently leased OCS activities continue, are presented in Section 4.5.7, which has been revised to provide additional analyses. Energy substitutes that could be used in association with the No Action Alternative are described in this section. Presentation of more specific information, including a discussion of option value, is more appropriately included in the assessment of the impacts of individual lease sales.

6. The Deepwater Horizon event threatens the long-term productivity of over 100 species of fish, crustaceans, mollusks, and invertebrates that are commercially fished in the GOM. Commercial fisheries represents a revenue stream that drives part of the GOM economy. However, as demonstrated above, oil and gas drilling (and especially spills) threatens the long-term integrity of GOM species. This tradeoff needs to be acknowledged in Chapter 6 of the PEIS.

   Response: The discussion in Section 4.4.11.1 on the importance of commercial fisheries to the economy of the GOM has been revised to include more recent information. Chapter 6 has been revised to include a discussion of the potential effects of oil spills on the long-term productivity of the GOM.

7. The Draft PEIS makes several statements regarding the effects of the DWH event on the surrounding coastal housing markets. Many of the cited sources are inappropriate, and the statements ignore the general nation-wide collapse of the housing industry. The comment provides several citations and requests that the PEIS be revised to more accurately portray the housing market of the GOM.

   Response: Text in the PEIS has been revised in Section 3.10.7 to clarify the status of the GOM housing market and include data referenced in the comment.

8. Section 3.10.2.2: The percentage of individuals living in poverty in the North Slope Borough and the Northwest Arctic Borough were both compared to the community of Barrow; however, the comparison is for a community within the borough. Barrow is located within the North Slope Borough and not within the Northwest Arctic Borough.

   Response: The text and table in Section 3.10.2.2 have been revised to reflect the comment.

9. Section 3.13.3.2: There is only one casino in Alaska operated by Metlakatla Tsimshian Tribe, which is an Indian-owned establishment on their land. There are gaming (pull-tab and bingo) establishments operated for the benefit of non-profit organizations.

   Response: The text in Section 3.13.3.2 has been revised to reflect the comment.

10. Section 4.4.11.1.1 is extremely limited considering the biological, economic, and sociological attributes associated with commercial and recreational fishing in the GOM.

    Response: The biological, economic, and sociological aspects of commercial fishing in the GOM are covered in detail in Sections 3.8.4.1, 3.12.2.1, and 3.14.1 of the PEIS. The intention of Section 4.4.11.1 is to provide a description of expected cost impacts on commercial fisheries and the various regulatory limits on activity.

11. Section 5.3 has no discussion on 'Economic Activity' included in this subsection. Consider adding the section from either the Supplemental EISs for the GOM Central or Western Planning Areas (OCS EIS/EA BOEMRE 2011-027 or -034 respectively).

    Response: Text in Section 5.3 of the PEIS has been revised to include a discussion of economic activity.

12. The Draft PEIS states that the impacts to local economies and employment would be minimal with the expansion of leases. It was also noted that current employment related to oil and gas in the Gulf States is roughly 62,000 people, with most of those jobs located in Texas and Louisiana. In comparison, the recreation and tourism industries employ roughly 1,000,000 people across the Gulf Coast. While we understand the oil and gas leasing program's importance in ensuring adequate energy resources for the nation, it is important to recognize the oil and gas industry's potential to impact the health of other industries, as was clearly displayed by the 2010 Deepwater Horizon Event.

    Response: A description of the role of the recreation sector, including beach recreation, casino gambling, and recreation and tourism employment, as well as a description of the benefits of oil and gas development and also the economic impacts of historic oil spills, are included in Section 3.13. The economic impacts of the DWH event, including those on recreation and tourism, are described in Section 3.10.7; while the economic impacts of OCS activity (including impacts of expected and unexpected accidental oil spills) on recreation and tourism are discussed in Section 4.4.12 of the PEIS.

13. We are concerned that the analysis presented in the Draft PEIS does not appear to be considering the socioeconomic impacts of the Proposed 5-year Program on people living in all 50 States of this country. We strongly recommend that the final program and environmental impact statement fully consider the socioeconomic impacts on all the American people that would come from both producing energy from the offshore, and of not producing energy from many areas of the offshore. The resources of the OCS are owned by

all Americans, and the hardship created by withholding our energy resources from people in middle America should be considered in the decision-making process.

Response: Although BOEM agrees that the oil and gas sector affects the remainder of the United States, both in terms of capital and labor expenditures, the PEIS principally assessed the socioeconomic impact of existing oil and gas activity, and of proposed OCS activity, in the counties adjacent to the GOM, and in Alaska as a whole, as these would be the regions most affected by the proposed OCS activity. Impacts to specific states or communities in the remainder of the United States would be comparatively small and are not therefore specifically addressed in the analysis. However, the aggregate, national net benefits and costs of the Program are summarized in Chapter 2 of the PEIS and presented in detail in the Proposed Final Program.

14. The Draft PEIS erroneously concludes that in areas where tourism and recreation provide significant employment, accidental oil spills, including catastrophic discharge events, would result in only “short-term loss of employment, income and property values.” The Draft PEIS even goes so far as to imply that oil spills could benefit the economy in some affected coastal regions because “expenditures associated with spill clean-up activities would create short-term employment.” The conclusion that a catastrophic oil spill would only result in short-term economic impacts is totally unfounded and is contradicted elsewhere in the Draft PEIS where the Department acknowledges that the Deepwater Horizon event had “significant economic impacts throughout the (GOM) region, affecting population, employment, and regional earnings and incomes.

    Response: Although it is often not possible to quantify all the impacts that may occur as a result of an oil spill, the analysis in the PEIS does not intend to suggest that there would be no adverse impacts resulting from an accidental spill. There could be some longer-term economic impacts because of real or perceived changes in the quality of resources or recreational values, especially with an unexpected CDE. It is clear that there would be employment and income impacts from a spill with the loss of tourism and recreation spending, and the temporary loss of revenues from the sale of commercial fish catches. These losses have been documented in the PEIS where data are available. For small and large anticipated accidental spills, employment and income losses in these two sectors would be offset, at least to a certain extent, by spill cleanup expenditures and the resulting employment and income, offsetting adjustments that are likely to occur over a number of years. For an unexpected CDE, impacts could be much more long-term, depending on the location, size, and duration of the CDE and the effectiveness of spill control and cleanup activities.

8.4.4.4.20 Issue 4.20 Environmental Justice.

1. Indigenous peoples and tribal communities in the Arctic are disproportionately impacted by industrial activities in the Gulf of Alaska, Bering Sea, Chukchi Sea, and Beaufort Sea. Please refer to the recent MMS study entitled Three Decades of Research and Socioeconomic Impacts Related to Offshore Petroleum Development in Coastal Alaska

Response: Text in the PEIS has been revised to include the document referenced in the comment.

2. The co-existence of native subsistence hunting and fishing and modern commercial and industrial development in Alaska should be more fully explored in the context of the future lease sales. These uses of the OCS can co-exist with the proper stipulations and mitigations in place. The PEIS should include a discussion of the Inupiat customs and culture along with a description of the North Slope Borough and its villages and towns. The PEIS should also discuss some of the proposed oil and gas development activities in this region and the mitigation measures (e.g., the marine mammal monitoring program and the oil spill response plans) that have been developed to avoid or minimize potential adverse effects.

   Response: The impact of individual lease sales and Alaska Native hunting and fishing for subsistence purposes would be assessed in the relevant lease sale EIS. Sections 3.14 and 4.4.13 of the PEIS provides a discussion of the programmatic impact of oil and gas development on subsistence activities in Alaska. The PEIS also includes discussion of the sociocultural aspects of the North Slope, including descriptions of the villages and towns in Sections 3.14 and 4.4.13 of the PEIS. Demographic information on these communities, where data are available, is provided in Section 3.10.2 of the PEIS. Mitigation measures developed to protect species important to Alaska Native communities are presented in Appendix B of the PEIS.

3. An environmental justice analysis should be conducted that identifies whether and to what extent the Inupiat people are being asked to bear a disproportionate share of the environmental burdens created by the Nation’s 2012-17 offshore program.

   Response: Section 3.15 provides a description of the distribution of low-income and minority populations in the areas adjacent to the planning areas considered for leasing under the 2012-2017 Program, and Section 4.4.14.3 presents an assessment of the environmental justice impacts of OCS activities, that could occur on the North Slope under the 2012-2017 Program. BOEM uses the most up-to-date information that can be gathered from public participation, studies, and census bureau data.

4. While local communities in Northwest Alaska receive few benefits from OCS activities, they bear all direct risks from offshore oil and gas activities including threats to the environment, social structure, and Inupiat culture. Recommend the PEIS include a discussion of how revenue sharing could increase local economic benefits, and how environmental justice issues are involved with the leasing of the area, particularly with low-income minority communities being placed at risk.

   Response: Potential environmental justice impacts of OCS activities in the Chukchi Sea on the Northwest Arctic Borough are included as part of the analysis of impacts in the Arctic region, which also includes the North Slope Borough. These impacts are described in Section 4.4.14.3 of the PEIS. Analysis of the impacts of OCS activities on sociocultural resources in the Northwest Arctic Borough is also presented in Section 4.4.13.3 of the PEIS.

Projected benefits of OCS activities in the Arctic region are described in Section 4.4.9.3 of the PEIS. A more detailed analysis of the potential fiscal impacts of OCS development in the Chukchi Sea on the Northwest Arctic Borough would be undertaken at the lease sale level.

8.4.4.4.21 Issue 4.21 Invasive Species.

1. In the past, the threat of invasive species introductions has not been considered significant as it compares to the threat in other areas, because there has not been a large amount offshore drilling in the Alaska OCS. However, the potential for introduction may increase in the future with increased oil and gas development activities.

   Response: The text in Section 4.3.5, Invasive Species, has been revised to indicate that while introduction of invasive species through oil and gas activities was historically not considered significant because of the very low level of offshore drilling in Alaskan waters, the potential for introduction may increase with increased drilling, together with potential climate-related changes in environmental baseline conditions.

8.4.4.4.22 Issue 4.22 Sociocultural and Subsistence Issues.

1. Subsistence harvesting is essential to Arctic Alaska Native communities both as an important source of food and as a central defining aspect of their culture. Marine and coastal environments provide a significant part of their diet, which is both important to Native health and not easy to replace from outside sources. The exchange of resources harvested from the wild is important to the maintenance of social ties both within and between communities. Participation in learning subsistence harvesting skills is an essential part of passing Alaska Native culture on to the next generation. Arctic Alaska Native culture depends upon the maintenance of healthy ecosystems.

   Response: BOEM is aware of the central importance of subsistence harvesting, in particular the bowhead whale hunt, to Arctic Alaska Native communities with regard to food security, human health, traditional socio-cultural values, and cultural continuity. BOEM strives to manage oil and gas development on the OCS in a manner that minimizes or eliminates threats to subsistence harvesting. The importance of subsistence harvesting to native cultures is discussed in Sections 3.14.3 and 4.4.13.3.

2. Several Alaska Native commenters expressed concerns over the effects of an oil spill on subsistence marine resources. They feared that spilled oil could taint or eliminate species important to their survival. They expressed doubts that a spill could be contained in Arctic waters, that there was not sufficient local infrastructure or labor force for a quick, efficient response and that clean-up procedures in icy conditions are unproven.

   Response: BOEM understands these concerns regarding the possible effects of an oil spill in the Arctic and has updated Section 4.3.3, Risk of a Low-probability Catastrophic Discharge Event, with new information that pertains to oil spill response and containment in the Arctic.

BOEM has also added additional text in Section 4.3.2, Programmatic Deferrals and Mitigations, which discusses stakeholder requests to delay Arctic leasing until adequate oil spill response and containment is proven in the context of how these concerns will be further evaluated during the program. The effects of an oil spill on marine mammals are discussed in Section 4.4.7.1 of the PEIS

3. Several Alaska Native commenters related experiences in the past where off shore oil and gas exploration and development had had negative effects on subsistence resources.

   Response: The BOEM and BSEE take seriously Alaska Native concerns regarding subsistence resources and seek to take into account what has been learned about the effects of oil and gas development from past experience, including the experience of Alaska Natives, in developing and enforcing stipulations at future lease sale stages.

4. Several Alaska Native commenters have advocated additional spatial and\or temporal deferrals that would lessen adverse effects on marine mammal migration and behavior at critical times and in critical places such as whale migration routes at certain times of the year.

   Response: There has been an extensive dialog between the North Slope Borough and BOEM regarding prospective deferrals. BOEM seeks to work with stakeholders in formulating mitigation, particularly to protect bowhead whales and other marine mammals and minimize conflicts with subsistence practices. Section 4.3.2 of the PEIS discusses programmatic deferrals and mitigation, and describes a process that BOEM is putting in place to identify, evaluate, and prepare for implementation, and mitigation strategies (which may include deferrals) that may be applied at appropriate program decision points. This process includes stakeholder input into the development of mitigation strategies. BOEM has informed the North Slope Borough that consideration of deferrals will be carried forward into the lease sale stage.

5. Several commenters related their perception of climate change and its effects on the Arctic environment. These included warmer temperatures and diminished ice pack. They expressed concern over the loss of ready access to sea mammal haulouts because of retreating and thinning ice. They were also concerned that more ice free days would encourage an increase in shipping traffic, which in turn would interfere with whale migration patterns.

   Response: Section 3.14.3 has been revised to include more information on climate change and its possible effects on subsistence harvesting

6. Several commenters expressed the need for greater communication both with Federal Government agencies and oil and gas companies. They felt that Federal agencies were not listening to their concerns and requested more consultation. They requested increased avenues of communication among local populations. Alaska Natives requested additional training on how they could have more input into decisions related to oil and gas

development. They also felt that oil and gas company personnel would benefit from a better understanding of local culture.

Response: BOEM is committed to meaningful communication and consultation with the Alaska Native communities that rely on subsistence harvesting from Arctic waters. Consultations with Alaska Native tribal governments took place during the scoping process and in association with public meetings on the draft. Alaska Natives expressed their concerns in public meetings during the scoping period and submitted letters commenting on the draft. These comments have been taken into account in the PEIS. Under DOI Order No. 3117 issued in December 2011, meaningful consultation with Alaska Native villages is planned for early in the planning process for lease sale NEPA evaluations.

7. Several commenters raised the issue of the impacts of industrial noise, especially of the noise from seismic exploration, on the migration habits of whales and other marine mammals. Noise-induced deflection of whales from their normal migration routes increases the difficulty and danger of the whale hunt and can lead to a reduced or eliminated whale harvest with serious repercussions in subsistence-based communities.

   Response: BOEM has analyzed the potential effects of noise on marine mammals as discussed in Section 4.4.7.1 of the PEIS. The analysis of potential effects of noise in the PEIS has been expanded to take into account more recent studies of the effects of noise on marine mammals. BOEM will consider including stipulations meant to minimize or eliminate the deflection of marine mammals from their normal migration routes due to industrial noise at the lease sale phase.

8. Several commenters have indicated that BOEM should take traditional environmental knowledge acquired over many generations of experience with the local ecology into account in its long-term planning and leasing program.

   Response: BOEM has great respect for the accumulated knowledge of Alaska Native whalers and elders. BOEM strives to keep channels of communication with local native communities open and has striven to incorporate traditional knowledge throughout the PEIS.

9. An oil spill in the Arctic would have devastating and long-lasting effects. The GOM is still feeling the effects of the DWH event and traditional foods are still tainted.

   Response: The long-lasting effects of the DWH event have been investigated and the text of Section 4.4.13 of the PEIS updated as appropriate. The potential effects of accidental spills as well as of unexpected CDE-level spills are discussed on a resource-by-resource basis throughout Section 4.4 of the PEIS. These analyses acknowledge that an unexpected CDE spill in the Arctic would have major impacts on physical, biological, and sociocultural resources and systems in the Arctic.

10. The oil industry cannot prove that Alaska Native communities would not be disproportionately affected; that coastal communities would not be affected by pollution in waterways that they rely on for subsistence

    Response: The PEIS acknowledges in Section 4.4.14 that a large oil spill, especially a CDE that comes in contact with subsistence resources, could have disproportionately high impacts on the Alaska Native population, particularly if the subsistence resources were diminished or tainted as a result of the spill. In the event of a CDE, long-term impacts on subsistence resources would be expected, and these may lead to longer and greater environmental justice impacts. Similarly, the PEIS evaluates other potential impacts from routine operations, such as vessel and drilling discharges, on Alaska Native communities.

11. The results of whaling patterns and other hunting patterns should be made available and taken into account.

    Response: Studies of Alaska Native whale hunting patterns were taken into account in the description of the environment in Section 3.14.3.2.

12. A program sharing revenues from the royalties of off-shore oil and gas production would be of great benefit to local communities and would help fund research on the effects of oil and gas production on Arctic ecosystems.

    Response: Revenue sharing would require a change in the law and is beyond the scope of this PEIS. Also see the response to Comment 3 in Section 8.4.4.4.19, Issue 4.19, Socioeconomics, for additional discussion of revenue sharing.

13. Subsistence whaling is a difficult and dangerous activity. It is riskier if the bowhead whale are deflected from their normal migration pattern farther from land, both because of dangerous currents and the longer distance required to tow the whale to the butchering site. Camden Bay is utilized by whales as a calving area. If Shell develops a facility near Camden Bay, whalers fear the bowhead whales will be deflected from their usual migratory route, making the whale hunt riskier, more difficult, and likely less successful.

    Response: BOEM is aware of the difficulties and dangers associated with pursuing deflected whales. They are discussed in Section 4.4.13.3. Additional information on bowhead whale feeding habitat and migration routes in the Beaufort and Chukchi Seas has been added to Section 3.8.1.3 of the PEIS. Lease sale stage NEPA analysis will address potential impacts on bowhead whales in more detail. Lease-specific activities will also be required to comply with the requirements of the ESA and the MMPA, and will take traditional knowledge of Iñupiat whalers into account. For a discussion of possible deferrals that would restrict oil and gas activities at times and in places that could affect migrating whales, see the response to Comment 4 earlier in this section.

14. Captaining a whaling crew is an expensive proposition because of the equipment and number of people involved. Conflict avoidance agreements and enforcement of regulations and

stipulations are vital to the success of a whaling crew in that they reduce deflection of migrating whales. Since local communities have to deal with the impact of oil and gas development, it is only fair that they share in the revenues from that development.

Response: BOEM is aware of the socioeconomic challenges that whaling captains face. Working out conflict avoidance agreements between local subsistence-based communities and oil and gas developers is one of the lease stipulations intended to mitigate the effects of oil and gas development on subsistence whalers (see Appendix B.2.1.6). Sharing of the revenues from oil and gas development would require both a policy change and a change in the law. This is beyond the scope of this PEIS. For additional discussion regarding revenue sharing, see the response to Comment 3 in Section 8.4.4.4.19.

15. The commenter is a subsistence whaling captain who has experienced negative consequences from oil and gas development in the past, including a change in the taste of whale meat. Less regulated past development had great negative consequences including deflecting game, pollution form drill cuttings. There is less ice now than in days past.

    Response: BOEM acknowledges the effects of oil and gas development on the physical, biological, and human environments. The potential effects oil and gas development under the 2012-2017 leasing program are discussed on a resource-by-resource basis throughout Section 4.4 of the PEIS. A discussion of traditional knowledge of ice loss may be found in Section 3.14.3.2 of the PEIS. Also see responses to Comments 3 and 5 in Section 8.4.4.4.22.

16. Changes are appearing in the Arctic environment. Diseased ringed seals have recently been found that also have sores. Research is required to determine whether sores and disease among the seals is a result of oil and gas development activities for from some other source. There has also been a marked reduction in the amount of ice on the Arctic Sea.

    Response: A discussion of the UME that involves ringed seals and other pinniped species in the Arctic has been added to Section 3.8.1.3.1 and is also mentioned in Section 4.6.4.3. A discussion of climate change impacts on sea ice can also be found in those sections of the PEIS.

17. The Alaska Eskimo Whaling Commission seeks to protect whales and has learned to mitigate past impacts by working directly with industry, not always with government help.

    Response: BOEM seeks to work with stakeholders, including the Alaska Eskimo Whaling Commission, in formulating mitigation measures that minimize or eliminate adverse effects on Arctic whales.

18. The commenter feels a long-standing tie to the land and has seen the development of oil and gas in his lifetime. He is now barred from areas near Prudhoe Bay where he formerly ran a dog sled, fished, and hunted caribou. He would like to see his culture continue on to future generations of Alaska Natives.

Response: This perspective on changes at Prudhoe Bay has been used to enhance the discussion in Section 3.14.3.

19. Anaktuvak, while not on the coast, is tied to coastal communities through trade, barter, and good will, and receives marine mammals as subsistence foods. It supports the concerns of coastal communities.

    Response: Text explaining that Anaktuvak Pass is connected to the coastal economy by trade relationships, and is thus partially reliant on the harvest of wild marine resources, has been included in Section 3.14.3.2 of the PEIS.

20. The commenter is undecided as to whether he supports oil and gas development on the outer continental shelf. He is concerned for preserving his subsistence life style and would like to know what local economic benefits development could have.

    Response: While BOEM cannot control where workers will come from or where money earned will be spent, with proper job training there should be employment opportunities for the local population. See also the response to Comment 1 earlier in this section.

21. The commenter refers to past adverse effects of seismic surveys on seal and tomcod populations. The food chain was impacted and although studies were done on the dying seals, no information was provided to local communities.

    Response: Sections 4.4.7.1 and 4.4.7.3 discuss impacts of noise on mammals and fish, respectively. A discussion of the UME that involves ringed seals and other pinniped species in the Arctic has been added to Section 3.8.1.3.1 and is also mentioned in Section 4.6.4.3.

22. The Northwest Arctic Borough has passed a resolution establishing a policy for responsible resource development that protects important subsistence resources, Inupiaq culture, and health. Oil and gas companies do not have local traditional knowledge and will need local help to manage production in a responsible manner.

    Response: See the response to Comment 1 provided earlier in this Section. BOEM acknowledges Northwest Arctic Borough's desire to see responsible resource development off the coast of the Northwest Arctic Borough, and is committed to responsible development in any leasing program. It is the intent of BOEM and BSEE, through careful management of OCS activities, that minimal to no impacts on the marine subsistence harvest, Inupiaq culture, and health would occur. The management tools available to accomplish this would be mitigation measures, spatial and temporal deferrals, rigorous inspections, and implementation of rules and regulations. BOEM and BSEE also would seek to work with the Boroughs, tribes, and other relevant stakeholders to maximize the use of traditional knowledge to assist in the management and stewardship of OCS activities and resources.

23. The North Slope Borough and Northwest Arctic Borough are committed to being proactive and insisting that any development on the OCS be done in a responsible manner consistent

with Alaska Native values. They insist on proper planning, gathering and funding baseline data, sharing of data gaps and raw data so that industry can develop appropriate measures to mitigate impacts to subsistence resources and hunting, and the health of local communities.

Response: BOEM acknowledges Alaska Natives desire for responsible development and is committed to meaningful communication with all stakeholders including Alaska Native villages and organizations. BOEM funds a range of multidisciplinary studies relevant to the impacts of oil and gas development on Arctic Alaska. The results of these studies are made public; however, to ensure accuracy, raw data gathered cannot be released until vetted and peer-reviewed. Similarly, raw data from oil companies is often proprietary and can only be released with their permission. BOEM uses the results of these studies for baseline description of the environment and assessment of potential impacts for NEPA documents. It is the intent of BOEM and BSEE, through careful management of OCS activities, that minimal to no impacts on the marine subsistence harvest would occur. The means available to accomplish this could include mitigation measures, rigorous inspections, and implementation of rules and regulations. Mitigation measures are developed through the lease sale and plan processes.

24. Alaska Native communities of the Northwest Arctic Borough are directly affected by the success or failure of subsistence harvest of marine mammals in the Arctic because they are connected through a region wide bartering web. The Arctic marine harvest is an important part of the regional subsistence base through barter and exchange.

    Response: Section 3.14.3 has been revised to indicate that exchange and kinship ties bind coastal and inland Alaska Native communities and that inland communities are tied to the marine subsistence harvest even when they are not direct participants.

25. No one has demonstrated that an oil spill in the Arctic could be cleaned up effectively. A spill would be disastrous for subsistence harvesters. In addition, recent warming trends have resulted in a lessening of polar ice. More leasing will result in more shipping, including an increased presence of ice-breakers. This could make traveling on ice by subsistence hunters more hazardous.

    Response: Climate change and its effect on baseline environmental conditions are discussed in Section 3.3, and the condition of sea ice is discussed in Section 4.2.2 of the PEIS. Impacts from increased Arctic shipping are discussed in Section 4.6.5.3.5 and in other discussions of cumulative effects. The PEIS has been revised to strengthen the discussion of the impacts of increased ocean-going vessel traffic. Also see the responses to Comments 2 and 5 earlier in this section.

26. Industrial byproducts of oil and gas development will taint subsistence food supply. A very large oil spill would result in the contamination of marine food sources and would increase subsistence harvesting on land resulting in pressure on caribou, moose, and bird populations.

Response: Text discussing the potential shift of subsistence harvesting to inland resources in the event that marine resources were inaccessible or tainted has been added to Section 4.4.13.3. Also see responses to Comments 1 and 2 earlier in this section.

27. Gaps in our knowledge of the effects from a very large oil spill include studies of the cultural consequences of such a spill, consequences of the diversion of subsistence harvesting to inland sources, and the effects of chronic petroleum waste introduced into marine mammal diets.

    Response: The sociocultural effects of a very large oil spill, such as those from the *Exxon Valdez* incident, have been studied including effects on subsistence harvesters. These are discussed in Section 4.4.13.2. Text discussing the shift of subsistence hunting to inland resources as the result of an oil spill has been added to that section. Section 4.4.7.1 includes discussion of potential oil spill impacts on marine mammals and terrestrial mammals. Section 4.4.7.2 addresses impacts on marine and coastal birds.

28. The people of the Northwest Arctic Borough rely on the subsistence harvest, which plays a central role in Inupiaq culture. The Draft PEIS pays more attention to the North Slope Borough than the Northwest Arctic Borough. Northwest Arctic Borough communities would also be affected by oil and gas activities. All vessel traffic to the north coast would pass through Northwest Arctic Borough waters, and an oil spill could migrate into those waters as well. The Draft PEIS incorrectly asserts that Northwest Arctic Borough communities would be less directly affected than North Slope communities. More discussion of the impacts of routine operations on Northwest Arctic Borough communities are needed and must include a discussion of inland communities, all of which are included in coastal zone studies, that interact with coastal communities. Impacts on anadromous fish and other species that migrate long distances should be included. Effects of a CDE should not be considered temporary.

    Response: The discussions of subsistence patterns in the Northwest Arctic Borough in Sections 3.14.3.1 and 3.14.3.2 have been expanded to include inland communities with ties to the coast. The discussion of impacts from events in the Arctic planning areas in Section 4.4.13.3 has been expanded to include the Northwest Arctic Borough. Impacts of routine operations on sociocultural systems and subsistence in the Arctic are discussed in Section 4.4.13.3, which addresses impacts on communities both within the Northwest Arctic Borough and the North Slope Borough. BOEM understands your concerns regarding the possible effects of an oil spill in the Arctic. The impacts of oil spills in the Arctic are addressed on a resource-by-resource basis (including marine and terrestrial mammals, birds, and fish) throughout Section 4.4 of the PEIS. In addition, the discussion in Section 4.3.3 of a CDE has been updated with new information that pertains to oil spill response and containment in the Arctic.

29. The discussion of subsistence whaling should be expanded to include additional areas important to whaling crews such as areas to the east of fall hunting grounds where industrial activities could deflect whales around hunting grounds, and pursuit areas.

Response: Section 3.14.3.2 has been updated to include an expanded discussion of other key areas important to subsistence whalers as indicated in the comment.

30. The PEIS should include a discussion of Inupiat culture and North Slope Borough communities and monitoring and mitigation plans that have been made to avoid or minimize potential adverse effects of oil spills.

    Response: The discussion of North Slope communities and subsistence in Sections 3.14.3.1 and 3.14.3.2 have been expanded as appropriate for a PEIS. More detailed discussions of North Slope communities will be included in region- and lease-specific NEPA documents. BOEM has updated Section 4.3.3 with new information that pertains to oil spill response and containment in the Arctic. Also see the comments and responses related to Arctic oil spills presented in Section 8.4.4.6.3. BOEM has also added a new Section 4.3.2, Programmatic Deferrals and Mitigations, to the PEIS that discusses the process that BOEM will follow to identify mitigation measures in later stages of the Program.

31. Revise Summary, Social, Cultural, and Economic Resources section text, to "(including whales and other marine mammals, fish and birds)."

    Response: The suggested text has been added to the Summary.

32. Text should be added to the discussion of GOM subsistence harvesters to include mention of their psychosocial welfare now and following major disturbances to existing conditions. The commenter also identifies inaccuracies in the discussion of the Alaska Native Claims Settlement Act.

    Response: The suggested changes to the discussion of subsistence and renewable resource harvesting along the Gulf Coast have been made in Section 3.13.1.2. The discussion of land claim disputes between Alaska Native communities and the State of Alaska in Section 3.14.3.1 has been revised to state more accurately the roles played by the Alaska Statehood Act and the Alaska Native Claims Settlement Act (ANCSA) in resolving those disputes.

33. The characterization of Northwest Arctic Borough as small and relatively poor is not supported by the text. The Draft PEIS erroneously equates NANA with the Northwest Alaska Native Association. Currently NANA is not an acronym.

    Response: The indicated text corrections have been made in Section 3.14.3.1. The characterization of Northwest Arctic Borough communities as relatively poor has been removed.

34. U.S. law requires that the OCS be managed in a manner that considers economic, social, and environmental values of its renewable and nonrenewable resources, and the potential impact of oil and gas exploration on other resource values of the OCS and the marine, coastal, and

human environment. How will BOEM ensure that no unmitigatable adverse impacts to subsistence harvest will occur under the 5-year plan?

Response: It is the goal of BOEM and BSEE, through careful management of OCS activities, to minimize or prevent adverse impacts on the Arctic subsistence base. The means available to accomplish this could include mitigation measures, spatial and temporal deferrals, rigorous inspections, and implementation of rules and regulations. Specific mitigation measures, lease stipulations, and protections are developed at the lease sale and later stages. This PEIS considers economic, social, and environmental values.

35. BOEM does not have a science-based plan for meeting its obligations under the MMPA. Alaska Natives depend upon a healthy bowhead whale stock. If multiple oil and gas operations are implemented in the Arctic, and whale stocks are adversely impacted, the International Whaling Commission (IWC) could halt or curtail subsistence whaling to the detriment of local communities dependent on subsistence whaling.

    Response: BOEM does not have control over IWC decisions. BOEM coordinates with NOAA to ensure compliance with the MMPA. It is the intent of BOEM and BSEE, through careful management of OCS activities, to avoid or minimize to the extent possible impacts from OCS-related oil and gas development on the bowhead whale or other marine mammals. The means available to accomplish this could include mitigation measures, spatial and temporal deferrals, rigorous inspections, and implementation of rules and regulations. See Section 4.3.2 for a discussion of BOEM's approach for mitigation planning under the Program. Also see the response to Comment 1 earlier in this section.

36. Impact levels as defined in Section 4.1.4 do not address impacts on subsistence resources. Major impact levels do not comport with the MMPA if they threaten the viability of bowhead whales and other marine mammals that Alaska Natives depend on.

    Response: The impact levels presented in Section 4.1.4.2 apply to socio-cultural impacts, including subsistence harvesting. Text has been added to make this clearer. Adverse impacts on subsistence from routine oil and gas operations can be mitigated through consultation and scheduling (windows avoiding migrations). Major accidental spills that adversely affect marine mammals would be in violation of the MMPA and result in enforcement actions by NOAA. Section 3.8.1 discusses the MMPA and its requirements, as well as its relationship with Alaskan subsistence users. Additional discussion of the MMPA and the harassment or taking of marine mammals is provided in Section 4.4.7.1.

37. The PEIS includes some inaccurate statements regarding the Alaska Native subsistence whale hunt. It does not include subsistence whaling communities Kivalina, Wales, Savoonga, Gambell, and Little Diomede in its analyses and includes misstatements about the whale hunt from Barrow and Wainwright.

    Response: Corrections have been made to the discussion of whaling schedules in Section 3.14.3.2. The more distant whaling communities mentioned in the comment lie outside the planning areas that are the subject of this PEIS. While the whales and other marine resources upon which these communities depend for subsistence could be affected by oil and gas development in the Chukchi and Beaufort Seas, there will be no leases in the waters adjacent to these communities. Sections 3.14.3.2 and 4.4.13.3 have been revised to include these communities and to address the potential effects on them from oil and gas development in Chukchi and Beaufort Planning Areas.

38. BOEM needs to have accurate information about impacts to subsistence activities in Alaska to support decision making and to comply with its obligations under the MMPA.

    Response: In the PEIS, BOEM strives on the basis of scientific studies and literature, traditional knowledge, and public engagement to present accurate and current information on subsistence activities in the areas of the Arctic that could be affected by the 5-year plan.

39. The discussion of the impacts of noise from oil and gas operations on subsistence species only references traditional knowledge. Western science has reached similar conclusions and should be referenced.

    Response: Discussions of the impacts of noise on marine mammals (including subsistence species) are presented in Sections 4.4.7.1.1, 4.4.7.1.2, and 4.4.7.1.3 of the PEIS. Similar discussions on the effects of noise on birds and fish are presented in Sections 4.4.7.2 and 4.4.7.3, respectively.

40. BOEM needs to revamp the PEIS to adequately address impacts to subsistence communities in northern Alaska in compliance with the MMPA.

    Response: Section 4.4.13.3 has been revised to more adequately address potential impacts to subsistence communities in northern Alaska. BOEM has no direct responsibilities under the MMPA, and no authority to enforce the MMPA, but it does require oil and gas companies to comply with the MMPA and therefore, industry must obtain permits from NOAA for the incidental harassment of marine mammals before operating in the Arctic OCS. Under MMPA Section 101 (16 USC 1371 Sec. 101 (l)) such permits are issued only when the activity "…will not have an unmitigatable adverse impact on the availability of such species or stock for taking for subsistence uses." This permit then ensures that there will be no unmitigatable adverse impacts on the availability of a stock or species taken for subsistence uses.

41. The commenter disagrees with the statement made in Section 4.4.14.3.1 that altering the local availability of subsistence resources would be a short-term and local impact. The lack of subsistence resources would be significant. Since local communities exchange food and resources with other communities, it would not be local.

    Response: BOEM recognizes the importance of subsistence resources to Alaska Native communities and is aware of the exchange connections between villages. Discussions of subsistence harvesting and bartering are found in Section 4.4.13.3. BOEM seeks to work with stakeholders in formulating mitigation measures that would reduce or eliminate local impacts. There has been an extensive dialog regarding prospective temporal and spatial deferrals. BOEM has informed stakeholders that mitigation (which may include deferrals) will be carried forward into the lease sale NEPA documents. Section 4.3.2 of the PEIS discusses programmatic deferrals and mitigation, and describes a process that BOEM will put in place to identify, evaluate, and prepare for implementation, and mitigation strategies (which may include deferrals) that may be applied at appropriate program decision points. This process includes stakeholder input into the development of mitigation strategies.

42. There is a tension between unavoidable adverse impacts to the subsistence harvest under the 5-year plan listed in Chapter 5 of the Draft PEIS, and the prohibition against "unmitigatable adverse impacts" to subsistence hunts in the MMPA, which BOEM must resolve.

    Response: BOEM has no responsibilities under the MMPA, and no authority to enforce the MMPA, but it does require oil and gas companies to comply with the MMPA, and therefore, industry must obtain permits from NOAA for the incidental harassment of marine mammals before operating in the Arctic OCS. Under MMPA Section 101 (16 USC 1371 Section 101 (l)) such permits are issued only when the activity "will not have an unmitigatable adverse impact on the availability of such species or stock for taking for subsistence uses." This permit then ensures that there will be no unmitigatable adverse impacts on the availability of a stock or species taken for subsistence uses. There is a difference between "unavoidable" and "unmitigatable." An "unavoidable" impact may be susceptible to mitigation, resulting in a reduced level of effect, unavoidable though it may be. In contrast, no action could be implemented to reduce the level of effect from an "unmitigatable" impact.

43. The Inupiat Community of the Arctic urges BOEM not to offer additional leases in the Beaufort and Chukchi Seas during the next 5 years, because of potential damage to the environment and their subsistence culture which is sensitive to environmental damage. Loss of subsistence resources would result in damage to their physical, mental, and spiritual health.

    Response: The PEIS considers the potential for environmental damage, the potential for the discovery of oil and gas, and the potential for adverse impact on the coastal zone for a variety of alternative courses of action. Under Alternatives 5, 6, and 8 there would be no leasing in one or both of the Arctic planning areas. The PEIS seeks to clearly articulate the consequences of these alternatives as an aid to the decision-maker as he or she decides whether or not to move forward with the proposed action. Also see the response to Comment 1 in this section.

44. The Federal Government has not effectively analyzed the cumulative effects of oil and gas operations on multiple lease tracts. Alaska Natives who depend upon marine resources bear the brunt of potential risk from these activities. The Draft PEIS is greatly lacking in

information and analysis on subsistence activities necessary to understand what areas should be preserved.

Response: BOEM seeks to include current, complete, and accurate data appropriate for an EIS at the programmatic level. Subsistence activities in Alaska are discussed in Sections 3.14.2.2 and 3.14.3.2, while impacts on subsistence are discussed in Sections 4.4.13.2 and 4.4.13.3. The cumulative impacts of OCS oil and gas development on Alaskan subsistence activities are discussed in Sections 4.6.5.2.5 and 4.6.5.3.5. More detailed information on subsistence activities will be included in region- and lease sale NEPA documents. BOEM seeks to fill data gaps in part through consultation with local communities and through the scoping process.

45. The Draft PEIS lacks a sufficiently detailed discussion of subsistence whaling, and potential impacts of oil and gas development on the OCS on subsistence-based communities.

    Response: Section 1.4.2 discusses incomplete and unavailable information, and discusses the analytical requirements for programmatic analyses and decisions. The PEIS presents discussions of subsistence (see response to previous comment), which are appropriate for a programmatic EIS. More detailed information and analyses on subsistence activities will be included in region- and lease sale NEPA documents and later phases of the Program. BOEM seeks to fill data gaps in part through consultation with local communities and through the scoping process.

46. Inaccurate statements regarding the bowhead subsistence whale hunt must be corrected.

    Response: Information regarding the bowhead whale hunt in Section 3.14.3.2 has been corrected and brought up to date.

47. Traditional knowledge can help to fill in some of the gaps in our understanding of Arctic ecosystems as well as guide future efforts to collect necessary information. In order to incorporate traditional knowledge we need funding. Create indigenous science positions within BOEM, have those positions advertised and based in Alaska. A real collaborative approach to research and data sharing will result.

    Response: BOEM agrees that traditional knowledge can help to fill in some of the gaps in our understanding of Arctic ecosystems, and BOEM has partnered with members of Native communities to incorporate traditional knowledge in past environmental studies. These studies are in various stages of completion, and the information is continually utilized to support environmental analyses related to BOEM permitted activities in the Arctic. BOEM welcomes opportunities for future collaboration.

48. The leasing plan and subsequent exploration and development activities should comply with Executive Order 13175 and the Presidential memorandum regarding consultation with tribal governments. Commenters are concerned that BOEM intends to engage in “after the fact” government-to-government consultations, instead of consultations that may actually have an

impact on the design or conclusions in the plan. Merely holding hearings in a Native community does not constitute adequate government-to-government consultation. Commenters were pleased that the North Slope Borough was designated a cooperating agency in the preparation of the PEIS. However, they expressed that this participation alone will not satisfy BOEM's responsibility to engage local communities, especially tribal governments. It was recommended that BOEM have government-to-government meetings with the local tribes before public hearings. The tribal council members protect the native way of life. The tribes need partnership so that they can run smoothly and make clear decisions. They do not seem to have any real control over their destiny and the industry continues to move forward despite their concerns.

Response: In conjunction with the scoping meetings for this PEIS, BOEM scheduled multiple separate government-to-government consultation meetings with Native Alaskan tribal communities. BOEM appreciates the opportunity to meet with Native Alaskan tribal members and values the discussions that were had during these consultations. BOEM has communicated the Native Alaskan tribal concerns to the decision-maker through consideration in the PEIS. Furthermore, BOEM will continue our dialogue about possible plans and activities on the Arctic OCS, including any potential lease sales in the future. In that spirit, BOEM welcomes the opportunity to meet with Native Alaskan tribal communities on a government-to-government basis, and BOEM values the ongoing dialogues with Native Alaskan communities.

8.4.4.4.23 Issue 4.23 Geohazards.

1. Several comments were specific to the text and figures in Sections 4.2.1.2 and 4.2.1.3:

    - Figures 4.2.1-2 and 4.2.1-4: state in the legend that only earthquakes of M 7.0 are plotted. Also show Cook Inlet folds (fault-cored anticlines) on the figure, based on Haessler et al. (2000).
    - Delete statement on Border Ranges fault as current thinking holds that it is not active.
    - Specify the magnitude threshold for the 1,200 earthquakes.
    - The text discusses floods but not liquefaction and direct-shaking effects on structures which are of greater significance. Even though they are discussed in greater detail in the following paragraph, they should at least be listed in the first paragraph.
    - Provide more information on the 1964 event, especially its impacts on oil- and gas-related facilities (which was minimal). Also include a discussion of earthquake potential in the Cook Inlet fold belt, since these are some of the primary tectonic sources in the region.
    - Discuss lahars, the 2009 Redoubt eruption, and their impacts on the Drift River Terminal.
    - For the text: "…where a glacier-dammed lake at the headwaters of the Snow River fails every two to 2–5 years" — note that Post and Mayo (1971) report that flooding takes place on Snow River every 2–3 years.

- For the text: "Historically, the Knik River near Palmer (at the northernmost end of Cook Inlet) has flooded when glacier-dammed Lake George fails" — move this sentence because the preceding and following sentences refer to the Kenai River and they should follow one another. Move this sentence in front of the previous sentence.
- It should be stated that there is the possibility for creep along "listric growth faults," similar to what occurs in the GOM. This creep could affect infrastructure.
- Describe the seismicity on the Beaufort Shelf in more detail. Summarize any evidence of seismicity. Also clarify what is meant by "no seismicity in recent times." What is meant by the term "recent"?
- Note that there have been numerous events on the southern Chukchi Shelf and a few off Wainwright.

Response: The following responses address the comments in the order they appear above:

- Please see the seismicity discussion in Section 4.2.1.2.2, which states that since 1973, more than 1,200 earthquakes have been recorded in the Cook Inlet region; 10 of which had magnitudes greater than 6.0. The text here refers to Figure 4.2.1-2 for plots of the two largest earthquakes (the 1999 and 2001 M 7.0 earthquakes on the Kodiak and Sitkalidak Islands); they are shown on Figure 4.2.1-4 for consistency. Neither of these figures was intended to show all earthquakes in the region, just the largest two. The maps show faults that would fall into USGS Class A (Quaternary) faults; the text has been revised to discuss anticlinal folds in the region and these features are now shown on Figures 4.2.1-2 and 4.2.1-4.
- The text states that there has been no movement on the Border Ranges Fault in the past 24 million years. This indicates that the fault is "inactive," therefore, the statement (which cites a publication of the Alaska Division of Geological and Geophysical Surveys; Stevens and Craw 2004) is correct. The text has been revised to state more explicitly that the fault is considered inactive.
- The 1,200 earthquakes referred to in the seismicity discussion for Cook Inlet include those greater than M 3.0; the text has been revised to indicate this.
- The order of these paragraphs discussing flooding due to earthquakes, liquefaction, and direct-shaking effects has been reversed to indicate the importance of liquefaction and direct-shaking effects relative to potential flooding.
- The text in the seismicity discussion for Cook Inlet has been revised to state that there was minimal damage to oil and gas structures as a result of the 1964 Alaska earthquake. Discussion of movement potential along folds has also been added.
- Lahars that inundated the Drift River valley and their effects on the Drift River Oil Terminal are discussed in the next paragraph.
- The 2 to 5 year range of the outburst floods at the headwaters of the Snow River encompasses the 2- to 3-year range cited by Post and Mayo (1971); therefore, the text has been retained. Reference to Post and Mayo (1971) has

been included in the section to strengthen the support for range of these events.

- The last sentence of the first paragraph (Cook Inlet) refers to both glacial lakes and the Kenai River — summarizing that in both cases, floods occur more frequently in the fall and can be especially severe if the lakes or the Kenai River are already high or frozen. Therefore, the text has been retained.
- The text in Section 4.2.1.3.2 of the PEIS (Arctic Region — Seismicity) has been revised to indicate that slow movement (creep) can occur along listric growth faults and affect the integrity of infrastructure over time.
- The text of the seismicity discussion for the Arctic Region has been revised to include additional discussion on possible Quaternary movement along faults in Harrison Bay (using a new reference, Craig and Thrasher [1982]). The term "recent times" refers to post-Quaternary time (i.e., Holocene); this has been indicated in the text.
- A reference to seismicity on the southern Chukchi Shelf (and off of Wainwright) has been added to the seismicity discussion for the Arctic Region as suggested (as documented by Avetisov 1996). Search results from an Alaska Earthquake Information Center database query for earthquakes along the Chukchi coastal zone were also included.

2. There are several additional sources of information that are available regarding subsea permafrost in the Arctic lease areas and these should be considered for the discussion in Section 4.2.2.2 (Subsea and Coastal Permafrost – Arctic Region). The sources include:

- For information on subsea permafrost, see: Map showing extent of subsea permafrost in circum-Arctic: Brown, et al., eds. 1997. Circum-Arctic map of permafrost and ground-ice conditions. Washington, DC: U.S. Geological Survey in Cooperation with the Circum-Pacific Council for Energy and Mineral Resources. Circum-Pacific Map Series CP-45, scale 1:10,000,000, 1 sheet.
- Osterkamp and Harrison (1982) state that "Subzero temperatures were found in all holes drilled in Kotzebue Sound, and in the Chukchi and Beaufort Seas. Holes drilled in the Chukchi Sea near Barrow suggest that the shore-line is stable, or nearly so, and that ice-bearing permafrost is probably thin or absent a kilometer or more off-shore." (See Osterkamp, E., and D. Harrison, 1982, "Temperature Measurements in Subsea Permafrost off the Coast of Alaska," in: Proc. 4th Can. Permafrost Conf. Calgary, Alberta, 1981, Natl. Res. Council, Ottawa, pp. 238–248.)
- MMS (2007) states that "the presence and distribution of subsea permafrost is largely unknown (Grantz et al., 1982; Thurston and Theiss, 1987). Subsea permafrost is not yet recognized in most seismic data from the Chukchi Sea (Sellman and Hopkins, 1984). Rogers and Morack (1982) recognized ice-bonded material from seismic data collected in 5 m of water north of Icy Cape." (See *Chukchi Sea Planning Area Oil and Gas Lease Sale 193 and Seismic Surveying Activities in the Chukchi Sea Final Environmental Impact Statement*, OCS EIS/EA MMS 2007-026, Alaska OCS Region. Available at

http://www.alaska.boemre.gov/ref/EIS%20EA/Chukchi_FEIS_193/LS%20193%20FEIS%20Vol%20I.pdf.)

- MMS (2007) also states that "The presence of extensive subsea permafrost on the Beaufort Shelf (Craig et al. 1985) suggests that some subsea permafrost may exist along the northwest coast of Alaska. However, no anomalous near-surface seismic velocities that would indicate the presence of ice-bonded sediments have been reported. The near-surface consolidated rock present throughout much of the Chukchi Shelf may have inhibited development of permafrost during lowered sea level (Grantz et al., 1982). Another explanation for the apparent lack of relict permafrost offshore is that it was melted by the relatively warm currents moving north from the Bering Sea." (MMS: Chukchi Sea Planning Area Oil and Gas Lease Sale 193 and Seismic Surveying Activities in the Chukchi Sea - Final Environmental Impact).

Response: The references cited above have been reviewed and the text in Section 4.2.2.2 (Subsea and Coastal Permafrost — Arctic Region) has been revised to incorporate the findings of these reports as applicable.

8.4.4.5 Issue 5 Cumulative Impacts

1. The cumulative impacts analysis should include a discussion of additive, multiplicative, and synergistic effects on resources; conclusions regarding impact levels should be clarified and better supported.

   Response: Additive, multiplicative, and synergistic effects are "interactive" effects in which the net adverse cumulative effect is greater than the sum of the individual effects (CEQ 1997: "Considering Cumulative Effects Under the NEPA"). Summaries discussing these types of effects on resources have been added to the end of Sections 4.6.2, 4.6.3, 4.6.4, and 4.6.5, and an overall summary is now provided in a new section, Section 4.6.6. Similarly, the PEIS has been revised to integrate the eco-region concepts presented in the Affected Environment chapter in the cumulative effects analysis. This integrating framework provides a useful lens to discuss additive, multiplicative, and synergistic effects in context of resilient and/or stressed ecosystems. The text has been revised to ensure that impact levels are clearly identified (according to the definitions provided in Section 4.1.4 of the PEIS) and substantiated. The relevance of uncertainty and incomplete information in context of impact conclusions is also addressed.

2. The cumulative impacts analysis must include a more substantial analysis of the effects of climate change; in areas of uncertainty (i.e., where information is unavailable or incomplete), include a summary of the existing scientific evidence and information on known trends.

   Response: Section 1.4.2 discusses incomplete and unavailable information and the analytical requirements for programmatic analyses and decisions. The PEIS presents a discussion of climate change and its effect on baseline environmental conditions, in Section 3.3. The effect of climate change on baseline conditions was also considered in the resource-by-resource impact discussions presented in Section 4.4 of the PEIS. This level of consideration and analysis is appropriate for a programmatic EIS and programmatic decision-making. The cumulative impacts analysis draws on the summary of climate change effects discussed in Section 3.3; climate change is also discussed in relation to the various resources (as it applies) throughout Chapter 3. The text in Section 4.6 (Environmental Impacts of the Cumulative Case) has been revised, as appropriate, to integrate this information. In cases where credible scientific evidence is not available (or complete enough) to support conclusions, the text has been revised to state that future research and monitoring may be required as part of the NEPA review at the lease sale or project level (in accordance with CEQ 1997). The references cited in these comments have been reviewed and incorporated into the discussion of cumulative impacts as appropriate.

3. The analysis of cumulative impacts in the Arctic Region is inadequate in the areas of subsistence resources (whales, seals, fish, and caribou), human health, noise effects on marine mammals, sociocultural systems (because large impacts are unacceptable), biological systems (including additive and synergistic effects), ice movement, transboundary effects (from Russian and Canadian offshore oil and gas activities), and climate change.

   Response: The cumulative impacts analyses, in Section 4.6, addressing resources in the Arctic region have been strengthened by improving content integration and including additional information from various sources (earlier sections of the PEIS, as well as additional literature on potential impacts related to climate change, subsistence, and oil spills). The cumulative effects analysis presents a clearer description of cumulative actions, defining the spatial and temporal bounds considered in the cumulative analysis. The PEIS provides additional clarification of and supporting documentation for the impact levels identified (including interactive effects of multiple actions), and clarifies the role of mitigation and monitoring at the lease sale level. The PEIS is a programmatic NEPA document and as such, is meant to encompass the full breadth of potential cumulative impacts on important resources in the Arctic region and other regions of development. It is intended to guide subsequent lease-specific analyses that will focus on the effects of a particular proposed action. The NEPA analyses associated with the various stages of OCS oil and gas development are shown in Table 1-1. Note also that specific mitigation measures and lease stipulations are determined in the more in-depth NEPA analyses required for lease sales and projects.

4. The cumulative impact analysis should include additional reasonably foreseeable future actions (e.g., LNG facilities and those proposed by Shell and ConocoPhillips) and correct, update or reconsider the descriptions of other actions (i.e., gold mining and vessel traffic) in the Arctic Region. The breadth of actions considered should be expanded to include subsistence, transportation, tourism, commercial fisheries, and the effects of offshore activities conducted by neighboring countries.

   Response: The cumulative impacts section has been revised to include additional reasonably foreseeable future actions and to correct and update the description of gold mining in the Arctic Region as commenters have suggested. Section 4.6 includes a new table with a comprehensive listing of the types of past, present (ongoing), and reasonably foreseeable future activities that could affect important resources in the planning regions — including those mentioned in comments received.

5. The cumulative impacts of noise on marine mammals presented in Section 4.6.4 have not been adequately assessed.

   Response: The cumulative impacts of noise on marine mammals presented in Section 4.6.4 have been revised to incorporate more information on the long-term effects of undersea noise (including seismic surveys) on a regional scale.

6. The Deepwater Horizon event undermines statements about the small impacts of small oil spills relative to existing seeps and potential spills from foreign tankers. Mitigation measures for spills and their impacts (especially large ones) should be described in the PEIS.

   Response: The cumulative impact analysis differentiates between the occurrence and impacts of small, large, and catastrophic spill sizes. The text in the discussions of cumulative impacts has been revised to address large and CDE spills. BOEM and BSEE have developed a robust regulatory framework to minimize spill occurrence (see Section 4.3.3 for recent regulatory reforms).

7. How many generations does the PEIS address (i.e., what is the time frame of the cumulative impacts analysis)?

   Response: The time frame for the cumulative impacts assessment for the PEIS is 40 to 50 years. This information is presented in Tables 4.6.1-1 and 4.6.1-2 and new Section 4.6.2.

8. The Federal Government should continue to support research in the Arctic region, including ecosystem-based research that can contribute to a better understanding of cumulative impacts.

   Response: BOEM is in agreement.

9. Section 4.6.4.3.4, on Invertebrates and Lower Trophic Levels, suggests that there would not likely be overall population-level effects on invertebrate resources because there are a relatively small proportion of habitats that would come into contact with released oil; however, it is possible that oil could be transported to the east by currents in such a way that biologically active areas in the Arctic region could also be exposed (such as where baleen cetaceans congregate in summer and krill are present during winter and early spring). These impacts could propagate up the food web to Arctic cod and baleen whales.

   Response: New text has been added to Section 4.6.4.3.4 to more clearly address the potential transport and fate of oil in sensitive ecosystems and spill-related contamination of krill and its implications for higher trophic levels. See also Section 4.4.7.1.3, which provides information on potential impacts to marine mammals from consuming oil-contaminated prey. Lease-specific NEPA analyses will address this issue in more detail.

10. NOAA had recommended that a discussion of the effect of pipelines and pipeline safety buffers be included in the cumulative effects section on coastal habitats because the presence of pipelines can reduce or eliminate suitable areas for borrow material needed for barrier island and wetland restoration projects. Pipeline safety buffers would reduce areas available for restoration. Pipelines and their safety buffers could also result in impacts to seabird nesting areas and sea turtle nesting beaches.

    Response: Very few new pipelines will come to shore in the GOM due to the 5-year Program (see Table 4.6.1-1). Pipeline disturbance widths are generally small with modern placement methods, and the rights-of-way should be less than 200 m (656.2 ft) in width. Pipeline placement would avoid nesting locations and would not occur during active nesting. Operators are interested in protecting pipelines from coastal erosion so a synergy could be developed with coastal restoration projects. Because of demand for OCS material for coastal restoration, BOEM is trying to cluster pipelines and to keep pipelines away from known marine mineral resources. This information has been incorporated into Section 4.6.3.1.1 with the appropriate BOEM citations.

11. NOAA had commented previously that the cumulative effects section on commercial and recreational fishing (Section 4.6.4.4.4) contained an oversimplification of the factors impacting abundance of fish species because it does not account for the management strategies that are currently in place to prevent overfishing. We recommend that the section be revised to reflect NOAA's findings that recreational catches in some fisheries can have a larger impact on abundance of fish species than commercial fishing practices. NOAA can provide information on the number of fish stocks/species that are overfished in all regions.

    Response: The original text, which states that "Sportfishing may also contribute significantly to cumulative effects on some fishery resources. As a consequence of the pressure fishing places on fishery resources, appropriate management is required to reduce the potential for depletion of stocks due to overharvesting. Even with management, the possibility of overfishing still exists." is compatible with NOAA comments. However, the text in Section 4.6.4.4.4 was revised to discuss additional factors affecting fish stocks. For additional information on commercial fisheries, see Section 4.6.5.1.3 (Commercial and Recreational Fisheries).

12. NOAA recommends that BOEM define terms such as "small" areas and "short" time period as they relate to the effects of oil spills to marine benthic and pelagic habitats in Section 4.6.3.3.2. Discuss the effects of spills that occur when ice covers the area (as opposed to the open water period).

    Response: Because recovery time is a function of the specific spill, environmental conditions, and the resource of interest, it cannot be quantified in a general way. However, the text in Section 4.6.3.3.2 has been modified to give a range of time for oil breakdown. Currently, drilling is not allowed during periods of ice cover.

13. A true measure of the cumulative effects of oil spills cannot be accounted for until the effects of the Deepwater Horizon event is better understood. BOEM should revise the PEIS to analyze the full impact of the Deepwater Horizon event.

    Response: The Affected Environment, effects analysis, and cumulative impacts sections have been updated to reflect the most recent information relevant to a description of the environmental baseline conditions and potential for compounding effects in the GOM. BOEM has also disclosed instances where incomplete and unavailable information exists and discussed its relevance to a choice among alternatives. Section 1.4.2 discusses incomplete and unavailable information. The reader is also referred to Section 4.3.3, which discusses the risk and fate of a low-probability, catastrophic discharge event. The text in the cumulative impacts analysis has been revised, as appropriate, to more fully integrate this information.

14. NOAA has previously commented on the cumulative effects on sea turtles (Section 4.6.4.1.4) that it is not aware of data to support the statement that OCS impacts would be minor relative to non-OCS impacts. It recommends including references.

    Response: The text in Section 4.6.4.1.4 has been revised to include an impact level based on the available scientific information (independent of its magnitude relative to non-OCS activities).

15. It would be helpful to have a quantitative estimate of the cumulative effects on marine mammals in Section 4.6.4.3.1. The document indicates the possible number of drill sites and their likely locations; combining this information with marine mammal density information and known “takes” of marine mammals could provide a quantitative estimate of expected cumulative impacts (at least for some species).

    Response: A quantitative estimate of cumulative marine mammal “takes” would need to account for all cumulative actions, including State oil and gas exploration and development and other non-oil activities. In support of the lease sale and plan stage NEPA documents and consultations, BOEM, NMFS and USFWS, working in collaboration, develop equivalent estimates of marine mammal density and potential take. This PEIS qualitatively describes the cumulative effects on marine mammals in Section 4.6.4.3.1, assuming on- or off-lease activities would comply with the requirements of the ESA, MMPA, and resulting authorizations, which may stipulate “take” limits.

16. Clarify the term “Northern fur sea lion.”

    Response: The text has been revised to “Northern fur seal” in Section 4.6.4.2.1.

17. Section 4.4.1.3: Clarify whether there would be regulatory prohibitions against tankering or marine transportation of produced hydrocarbons. The environmental consequences of reductions in sea ice and opening of new sea routes on current navigational and economic conditions have not been fully addressed.

Response: There are no current regulations prohibiting the tankering or marine transportation of produced hydrocarbons. The effects of sea ice reduction and opening of new sea routes on the current navigational and economic conditions of the Arctic region has been included in the cumulative impacts analysis.

18. The discussion of natural hazards is disjointed because it is addressed under several topics (geologic hazards, ice hazards, and physical oceanography) in the PEIS. The discussion of potential impacts from certain hazards such as fog, high winds, storm surges, extreme temperatures, and seasonal darkness is incomplete. In addition, substantial information on the difficulties of recovering oil in broken ice conditions has not been included. The discussion of these topics would be improved if they were included in a single section. The Oil Spill Prevention and Response report (Nov. 2010) for the U.S. Arctic Ocean is a good example.

    Response: Natural hazards are discussed only in Section 4.2 (which discusses both geologic hazards and sea ice and permafrost). The hazards are further broken down by planning regions to reflect the way the sections on the affected environment and impacts on the various resources are organized. The Arctic Ocean report commissioned by the Pew Environment Group was already referenced in Section 4.3.3, but has also been incorporated in the climate change and physical oceanography sections (Sections 3.3 and 4.2, respectively), as appropriate.

19. Provide a source for the statement in Section 4.6.4.3.2: "Oil contamination of food resources may influence recovery of a local population by affecting reproductive success and survival, with the degree of impact largely dependent on the patterns of prey distribution." This statement should take into account compensating dynamic factors that affect wildlife populations (e.g., when population is reduced, the survival and productivity rates among remaining birds often increase).

    Response: Section 4.6.4.3.2 has been revised to include additional scientific sources and to provide more information about the population-level impacts of oil spills on bird species.

20. The discussions of the Deepwater Horizon event should be updated or qualified by noting the oil estimates still at or below the water surface are current as of August 2010. Include a statement to clarify that oil continues to weather and that much of the oil reported by the Georgia Sea Grant Oil Spill Update has either dissolved or dispersed and was not recoverable.

    Response: Section 4.6.2 has been updated to reflect the most recent information available on the effects of the DWH event, including the references cited in the comment.

21 The statement in Section 4.6.3.1.1, "Although much of the oil remaining after cleanup is highly weathered, several constituents have the potential to cause toxicological effects (OSAT-2 2011)," should clarify that oil weathering depleted a large portion of the hydrocarbons in oil, including PAHs. Add two references by Boehm et al. (2011) which cite

the high rates of biodegradation of oil from the Deepwater Horizon event: (1) "Distribution and Fate of PAH and Chemical Dispersants in the Water Column Following the Deepwater Horizon Oil Spill," SETAC North America 32nd Annual Meeting (November 13-17); and (2) "Aromatic Hydrocarbon Concentrations in Seawater: Deepwater Horizon Oil Spill," International Oil Spill Conference (May 23-26, 2011)

Response: The references cited in this comment have been reviewed and additional information regarding the breakdown of volatile compounds during weathering has been incorporated into Section 4.6.3.1.1.

22. The PEIS should do a better analysis of the cumulative and synergistic impacts of climate change and ocean acidification. BOEM should consider the impacts on climate change from the analysis of oil and gas consumption resulting from the Program's lease sales. The statement in Section 1.4.5.5 "consumption of the refined oil is not considered because the scope of this PEIS is limited to issues that have a bearing on the decisions for the proposed leasing program" is an example of circular reasoning and therefore, does not substantiate the omission of an analysis of the impacts of hydrocarbon consumption.

    Response: Section 4.6 evaluates the effects of climate change, ocean acidification, and other global trends as cumulative actions. Consistent with judicial guidance, BOEM does not provide an analysis of the impacts of oil and gas consumption on various resources; the rationale is stated in Chapter 1 (as noted in the comment). However, regional and national emissions from fuel combustion sources are accounted for in the air quality impacts analyses in the cumulative impacts section. Summaries discussing the additive, multiplicative, and synergistic effects on resources have been added to the end of Sections 4.6.2, 4.6.3, 4.6.4, and 4.6.5, and an overall summary is now provided in a new section, Section 4.6.6.

23. The statement in Section 4.6.2.1.1 that "as of January 2011, oiling was still present on many shorelines and on barrier islands" should be revised to "… some shorelines …" because it gives the erroneous impression that many shorelines are still oiled. Also, the statement in Section 4.6.3.1.1 "On Grand Isle, Louisiana, and Bon Secour, Alabama, oil was found up to 105 cm (41 in.) below the surface…" should be revised to indicate that supertidal buried oil was found.

    Response: Section 4.6.2 has been updated to reflect the most recent information available on the effects of the DWH event.

8.4.4.6 Issue 6 Oil Spills

8.4.4.6.1 Issue 6.1 General Oil Spill Concerns.

1. USEPA requested information on the potential effectiveness and impacts of using large-scale berm construction as a spill response technique.

Response: The PEIS principally describes typical measures used to respond to oil spills. Following the DWH event, sand berms were constructed in the GOM in an attempt to contain spill and prevent transport of oil into back-barrier and wetland ecosystems. All such response measures require advance approval of the On-Scene Federal Coordinator, U.S. Coast Guard. Section 4.3.3 of the PEIS has been revised to include a general discussion of the possibility of non-traditional spill response measures, the approval process, and potential ramifications of untested response tactics.

2. The PEIS does not adequately characterize the occurrence risk or potential impacts of a catastrophic discharge event that could result from OCS exploration or development operations during the proposed leasing program.

   Response: The PEIS addresses the risks of oil spills, including the risk of catastrophic discharge event, in Sections 4.3.3 and 4.4.2. While the PEIS does not assume that a catastrophic discharge will occur, the potential for significant effects because of such an event are considered throughout Chapter 4 by environmental and socioeconomic resource.

3. The PEIS should include analyses of direct, indirect, and cumulative effects of catastrophic discharge events. This includes downstream effects resulting from spill response measures.

   Response: The catastrophic discharge event is analyzed across all resource sections in Chapter 4 of the PEIS. Additional reference content has been provided in each resource section to further support the analysis therein.

8.4.4.6.2 Issue 6.2 Oil Spill Assumptions and Risks.

1. Spill risk and spill-associated impacts are related to the volume of oil produced. Larger reservoirs may pose a greater spill risk.

   Response: Changes were made to the PEIS to clarify the underlying spill risk assumptions. The relationship between reservoir size and oil produced is characterized in the PEIS in Section 1.5.5.6.

2. The unpublished paper “Anderson (in preparation)” used to calculate spill risk must be made publicly available before it can be used as the basis for the spill risk analysis in the PEIS.

   Response: Anderson et al. (2012) is now available on BOEM’s web site. Additional information has been added to the PEIS that includes the spill rates for platforms, pipelines, and tankers for 1996-2010. The rates for 1996–2010 were used in the estimation of the number of spills in each Planning Area. The basic assumptions of that spill rate analysis are summarized in the footnotes of the table.

3. The PEIS should include relevant reform information and recommendations from the National Oil Spill Commission Report on the Deepwater Horizon Event, the National

Academy of Engineering/National Research Council report, and other pertinent reports following the DWH event that specifically address the assessment of oil spill risk. The PEIS should address what BOEM and BSEE have accomplished or plan to accomplish to address the identified deficiencies. Moreover, the PEIS should demonstrate that the reform measures will contribute to improvements in offshore safety.

Response: The PEIS has been revised in Sections 1.3, 2.9, and 4.3.3 to address this concern. In particular, Section 4.3.3 has been revised to include a more complete discussion of both governmental and industry reform efforts, in place and ongoing, that are being implemented to respond to the reform considerations and recommendations. BOEM and BSEE have implemented and continue to implement many of the expert recommendations in the various DWH event investigation reports. Many of these enhanced measures, such as improved blowout preventer (BOP) reliability, improved cementing and other secondary barrier programs, better-defined operational and risk assessment procedures, and integrated treatment of human risk factors, have been benchmarked against international standards and experience where these improvements have been shown to effectively reduce risk (See DNV 2010b in Section 4.7 references).

4. The PEIS inadequately evaluates the risk of the occurrence of oil spills. The PEIS risk analysis is overly simplistic and relies on the same flawed historical approach. Using that methodology, BOEM underestimates the actual risk of accidental spills, especially those potentially occurring during higher-risk drilling operations. BOEM should improve the quantitative risk assessment of oil spills, considering the different risk profiles of different OCS operations, disclose the greater risk of drilling in deep water and Arctic conditions, and incorporate lessons learned from the DWH event.

   Response: BOEM included a substantial treatment of the different factors that can contribute a different risk profile across different OCS oil exploration and development operations relative to different environmental conditions and operational circumstances. The reader is referred to that detailed discussion in Section 4.3.3. In addition, the PEIS has been revised to incorporate the best available information addressing occurrence of oil spills, including small, large, and potentially catastrophic spill sizes, across different operational phases and environments. Additional quantitative treatment of spill risk is included in Sections 4.3.3 and 4.4.2. BOEM maintains that the risk of large and potentially catastrophic discharge events is rare, including those resulting from loss of well control.

8.4.4.6.3 Issue 6.3 Arctic Oil Spill Concerns.

1. Many commenters emphasized the limitations of governmental and industry response capability currently in place to effectively contain, respond to and clean up oil spills in the harsh arctic environment. Comments commonly referenced the general lack of response planning, existing response support infrastructure, Arctic-specific containment and mechanical recovery technology, as well as the remoteness, extreme weather and sea state, cold temperatures, seasonal darkness, and presence of sea ice in the Arctic. Some of these

commenters indicated that leasing should not be pursued in the Arctic until sufficient response capability was in place.

Response: These general comments about spill response capability are already reflected in the PEIS in Section 4.3.3 and do not warrant additional changes to the PEIS. Related comments providing or requesting additional information are included and addressed in comments below.

2. Numerous commenters expressed serious concern over the risk of a large spill occurring in the Arctic and the possibility for severe long-term impacts on sensitive environmental resources and native communities.

   Response: BOEM appreciates that the risk of oil spills is in the Arctic is a fundamental concern. The PEIS acknowledges this risk throughout Chapter 4 of the PEIS. The reader is referred to the following sections of Chapter 4: 4.3.3, 4.4.2, and 4.6.

3. A number of comments differentiated the risk of a catastrophic discharge event in the Arctic from the risk of a catastrophic discharge event in deepwater GOM. The shallow-water wells and low-pressure geology found in the Arctic are less technically complex than the deepwater wells and high-pressure/high-temperature conditions in the GOM, and as a result, the risk of blowout and oil spills is less. A catastrophic discharge event is extremely rare, and with new requirements in place, industry is prepared for such a remote event with oil spill response plans appropriate for the nature and risk of operations.

   Response: Section 4.3.3 describes the various factors that contribute to the risk of blowouts and catastrophic discharge events, as well as regional spill containment and response capability if such an event were to occur.

4. The PEIS should accurately disclose the effectiveness of mechanical recovery techniques of spilled oil in the Arctic. Commenters assert that Shell has incorrectly asserted that they can successfully recover up to 95% of oil if a spill occurs in the Arctic.

   Response: Comment noted. See PEIS Section 4.3.3 for a discussion of the efficacy of mechanical recovery methods, including the potential for reduced effectiveness in ice conditions and narrow windows for physical recovery owing to ice state and ice breaking capability.

5. No one has yet determined how to clean up oil in pack ice, which covers the Arctic during eight months of the year. The Coast Guard possesses only three heavy ice breakers, one of which has been converted to a research vessel, another that is slated to be junked, and another that awaits a similar fate in Seattle. Skimmers — the main tool used in the BP spill — have been proven by Canadian researchers to be ineffective even when the water is clear of ice because of choppy conditions. We cannot answer all of these questions between now and when the lease sales open in 2015. The National Commission made recommendations on how to close the response and research gaps in the Arctic, including launching an immediate

Federal research effort to gather more scientific data about the Arctic Ocean, conducting annual stock assessments of species, and creating an interagency research program to focus on spill response and containment in the Arctic. Until we have more information, the Department cannot make a sound decision as to whether to drill in the Arctic Ocean. Especially in an era of acute Federal budget constraints, there is no guarantee that the work necessary to close these gaps will be completed. Until these efforts are completed, it is not possible to assess the true risks to the Arctic environment, or to the Native communities that depend on the resources of the Arctic for their survival.

Response: The PEIS reasonably discloses the potential for oil spills in the Arctic Planning Areas and fairly characterizes the existing spill response capability and challenges to well containment and oil response in various ice states. The PEIS also discusses the scope of recent oil spill response plans industry has prepared in support of proposed Arctic operations under recent lease sales. The commenter incorrectly presumes that OCS activities under the 2012-2017 Program that could result in the oil spill size of concern will occur instantaneously within the same time frame as the lease sale schedule. Instead, given recent precedent in industry investments, BOEM anticipates that first exploration drilling operation under the new program may not actually occur until after the end date of the 2012-2017 Program. In the intervening time, as characterized in Section 4.3.3, BOEM, BSEE, and the oil and gas industry are actively pursuing a sophisticated research program focused on oil spill response in the Arctic. Many of these efforts have been described in revisions to Section 4.3.3.

The Arctic lease sales included in the Preferred Alternative are intentionally scheduled late in the Program so that new research and practical experience garnered from exploration activities proposed in 2012 and 2013 under existing leases, provided they are approved by BOEM and BSEE, can better inform those decisions. The PEIS already considers no Arctic sales alternatives if the Secretary of the Interior wanted to pursue a course of action to avoid the potential for oil spills in the Arctic associated with 50-year implementation of the 2012-2017 Program. That being said, it would still be possible for spills to occur during exploration and development operations under leases acquired under previous programs. At any time, the Secretary maintains the discretion to cancel or further delay the sales if new information suggests it is prudent to do so, or conversely, if the absence of information warrants a more precautionary approach. Similarly, the Secretary maintains the discretion to issue suspension orders for given exploration or development operations provided the need.

8.4.4.6.4 Issue 6.4 A Catastrophic Discharge Event.

1. The references are incorrect or are missing from Section 4.3.4 in the Draft PEIS.

   Response: The references cited in Section 4.3.3 were inadvertently not included in the reference section for Chapter 4. The PEIS includes all references relevant to the discussion of the risk of a low probability, catastrophic discharge event.

2. Section 4.3.4 of the Draft PEIS should reference the best available North Sea research efforts and demonstration projects regarding oil spill response measures and capability in ice conditions.

   Response: Section 4.3.3 of the PEIS has been revised to include additional information concerning oil spill response research in the North Sea. In addition, the PEIS includes information about ongoing BSEE, U.S. Coast Guard, National Research Council, and Joint Industry Project efforts to study and improve oil spill response capability in the Arctic.

3. Section 4.3.4.3.1 of the Draft PEIS needs to provide more detailed information about the assumptions underlying the catastrophic discharge event scenarios in each OCS Planning Area. This includes a more robust discussion of the likelihood of occurrence of such an event in context of new prevention and containment requirements. An estimate of the frequency of major spills could include factors such as historical domestic and international catastrophic spill occurrences, environmental factors, number of platforms, pipelines, and oil tankers, as well as the volume of production. Additionally, the PEIS should make reference to other rare events and the nature of impacts that can be expected.

   Response: Section 4.3.3 of the PEIS has been revised to better describe the methodologies used to derive the spill scenarios, clarifies the likelihood of occurrence, and identifies comparable spill examples. The PEIS indicates that the likelihood of occurrence of a catastrophic discharge event is small. BOEM maintains that the introduction of new prevention and containment requirements should further reduce the likelihood of occurrence, but, at the 5-year program stage, there is no definitive way to quantify that improvement given well-specific variables. BOEM has conservatively assumed for the purpose of its 40 CFR 1502.22 analysis that new prevention and containment requirements are not effective. Those assumptions are clearly specified in Section 4.3.3. The specific resource area analyses in Chapter 4 of the PEIS summarize the scale of possible environmental effects for small and large oil spills (which the analytical scenario assumes), as well as a low-probability catastrophic discharge event (which is unexpected).

4. The Northwest Arctic Borough expressed concern over the possibility of a catastrophic oil spill. Northwest Arctic Borough stressed the importance of spill prevention and response, including the need to have proven cleanup capabilities tested and deployed before any OCS activities begin. The Northwest Arctic Borough comments indicated that there were a range of deficiencies in the Draft PEIS. The Draft PEIS underestimated the likelihood of occurrence such a spill and the potential impacts from such a spill. Similarly, the Draft PEIS overestimated the response capabilities for such a spill. Table 4.3.4-1 failed to mention weather or broken ice conditions as factors that could lead to a catastrophic event. Northwest Arctic Borough questioned the accuracy of estimates that a catastrophic discharge would be contained within 40–75 days in the Chukchi Sea, as compared to greater estimates in the Beaufort, especially since the Chukchi Sea is further from infrastructure than either of the other two Alaska planning areas. NWAB requested that the PEIS clarify the reference to the 2010 SINTEF report on the Joint Industry Program on Oil Spill Response for Arctic Waters. The Joint Industry Program study used field trials to improve oil spill response techniques for in situ burning of oil and use of dispersants and mechanical recovery. The PEIS should have

indicated that the trials involved prepositioning of equipment and deployment during controlled conditions. The PEIS should also have emphasized the current challenges faced by the Coast Guard in the Arctic in terms of human and resource capital to respond to a spill in ice conditions.

Response: BOEM revised Section 4.3.3 to address the technical aspects of this comment. The reader is also referred to Section 4.2.2 for a characterization of the potential interactions between sea ice and oil and gas infrastructure on the OCS and the resulting risk potential. BOEM has also clarified the underlying assumptions about the duration of a catastrophic discharge event in the Chukchi region. The PEIS includes an expanded discussion of the current regulatory regime for spill response planning and implementation, as well as the regional spill response capability.

5. NOAA recommended that BOEM broaden the scope of its analysis to consider the impacts of all activities, including potential oil spills and the use of chemical dispersants in any oil spill response efforts, to Essential Fish Habitat and other vulnerable deep-water habitats such as deep-sea corals. NOAA also suggested that BOEM evaluate the potential impacts to EFH for each life stage of each managed species, as well as impacts to other vulnerable habitats, from a worst-case scenario oil spill, including impacts to benthic and pelagic coastal and offshore habitats, and prepare proposed mitigation requirements for such a spill.

   Response: Sections 4.4.6.4 and 4.4.7.3 of the PEIS include an analysis of potential impacts to EFH and fish appropriate for a programmatic NEPA document. Under CEQ requirements, the PEIS does not need to include an analysis of a worst-case oil spill. Rather, under the requirements of 40 CFR 1502.22, the PEIS must address reasonably foreseeable significant adverse effects resulting from a proposed action even if the probability of occurrence is low. To comply with this requirement, BOEM has analyzed the effects of a "catastrophic discharge scenario" for each Planning Area under consideration. The effects analysis for each resource in Chapter 4 considers events and impacts which may have catastrophic consequences, including population-level effects for sensitive biological resources and chronic disturbance to vulnerable or sensitive habitats. BOEM's overall approach to region-specific or plan-specific mitigation is explained in detail throughout the document, most notably in Section 1.3.1. BOEM refers the commenter to BSEE regulations at 30 CFR Part 254 and the 2010 Certification NTL (NTL 2010-N10) that require that OCS operations have an oil spill response plan that is adequate to contain the worst-case discharge for an individual exploration or development plan. The worst-case discharge under the BSEE regulations should not be confused with the NEPA requirement described above.

6. NOAA recommended that BOEM provide further analysis and support for the statement that oil in Arctic waters can be "suspended" in the water column. NOAA also cautioned against the language here regarding the benefits of ice in confining or cleaning-up spilled oil. NOAA disagreed with any characterization that oil trapped in ice prevents the oil from affecting sensitive habitats and from spreading.

Response: The PEIS has been revised to more accurately describe the potential for oil to be entrained in the water column. The PEIS does not indicate that there are explicit benefits to oil being confined to ice. Section 4.3.3 states that ice may either facilitate or hinder the clean-up of oil or the scale of cleanup operations in the Arctic, depending on the circumstances.

7. The PEIS only addressed well-control issues and associated technological applications. Because sub-sea pipelines are envisioned for product delivery, NOAA recommended the PEIS include a similar analysis of pipeline spills. Such spills may have relatively large volumes and may be considered catastrophic. Pipelines may transit the spring lead system through which thousands of marine mammals migrate each spring, and any spill may occur under ice — presenting challenges for timely detection.

   Response: BOEM acknowledges that pipeline spills can have sufficiently large volumes to contribute to significant environmental effects. However, the volume and duration of those spills will not be as large and long as spills that could potentially occur following loss of well control. BOEM has treated the likely frequency and size of pipeline spills in the small and large accidental spill analysis in Section 4.4.2 and throughout the Chapter 4 effects analyses. To comply with 40 CFR 1502.22 requirements, BOEM has deliberately used a long-duration loss of well control so as not to underestimate the potential spill size and duration of a low-probability catastrophic discharge event, and analyzed the potential for environmental effects from such an event. In general, the distance between two safety valves would not allow the volume to be catastrophic even from a rupture or equivalent occurrence. Subsea pipelines must be designed and constructed to operate safely in the harsh environment on the Arctic OCS where ice scour is prevalent. Arctic pipeline designs are based on extensive pipeline experience onshore in Arctic environments and offshore experiences in the Beaufort Sea and other parts of the world. The design goal for any pipeline is ultimately zero discharge of oil, and it must be in compliance with BSEE and U.S. Department of Transportation pipeline safety regulations. Any offshore pipeline system in the Beaufort and Chukchi Seas would be designed according to these codes, standards, and specifications. Should development be proposed, a joint technical review of the pipeline design by the BSEE and State Pipeline Coordinator's Office would be conducted in conjunction with the review processes for the right-of-way application. The pipeline would be hydrostatically tested before operation begins, have three leak-detection systems, and be monitored by pigging to ensure safe operations. During the development plan phase, mitigation can be considered to reduce the potential impacts of a spill further if determined to be necessary. For example, during the Northstar Development Project, British Petroleum proposed using a supplemental leak-detection system, LEOS, that increases the probability of detecting a pinhole leak from the pipeline under the ice that could potentially be below the pressure-point analysis and mass-balance line-pack compensation threshold.

8. In addition to ice, extreme temperatures, and shortness of the ice-free season mentioned here, seasonally limited available daylight is also likely to be a major constraint to a spill response, as aerial efforts are important to locate and track surface oil, direct response operations, and assess response effectiveness (aerial efforts are a requisite for certain response tactics).

BOEM should consider the limited infrastructure currently available in the Arctic to support large-scale response operations in the event of a well or pipeline blowout.

Response: BOEM has revised Section 4.3.3 to address and provide more detail about the unique challenges of oil spill response operations in the Arctic, including human capital and infrastructure needs.

9. In Section 4.3.4.2.2, the Draft PEIS states "since the toxicity of dispersants is an important consideration, mechanical containment methods are the preferred initial response. Very large spills may require immediate application of dispersants." This discussion should be expanded to discuss the fact that although mechanical response is preferred, it is not always adequate and that dispersant use involves trade-offs and can provide a net benefit.

Response: Section 4.4.3 of the PEIS has been revised to include a more inclusive discussion of the trade-offs of dispersant application.

10. Many risk factors for catastrophic discharge events positively correlate with water depth. Thus, water depth is not simply one variable among others that needs to be considered in regulating OCS oil and gas operations. Instead, water depth is broadly representative of the risk of offshore drilling. While water depth is not the only risk factor that should be considered for catastrophic discharges, environmental impacts may be significantly different in deepwater leasing, and as such, that possibility underscores the need to consider an alternative in which deepwater leasing would be deferred.

Response: The PEIS considers the various factors that potentially contribute to the risk of occurrence of loss of well control and potential consequences of such an event. Recent research has indicated that water depth is not or is either marginally correlated with safety incidents — not spill or pollution events. The principal factor associated with downhole risk is the true vertical depth of the well, which in turn drives borehole pressure conditions. Moreover, it is not uniformly true that all wells drilled in deepwater are drilled to a greater final depth than in shallow water. Section 4.3.3 of the PEIS includes a robust discussion of the risk potential that deepwater and ultra-deepwater operations introduce. Despite the conjecture offered in the comment, there is no definitive evidence that water depth actually contributes to significantly different effects, although it does complicate spill containment and response operations as already disclosed in the PEIS. Consider the following example. A given exploration well spudded in shallow water may be drilled to a true vertical depth greater than a given deepwater well, despite the fact that the deepwater well is in a water depth more than several hundred meters. The geology overlying and formation and reservoir pressure conditions in the reservoir in a shallow water well may be comparatively riskier. The proximity to the coast, assuming a blowout and spill does occur, may present the potential for greater environmental impacts because of the likelihood of wide-spread and immediate contact with coastal and estuarine resources. Section 4.3.3 addresses the relative importance of fate considerations and spill proximity to sensitive resources. As explained in the PEIS, BOEM's exploration and development scenario projects that the lion's share of oil from the GOM will be produced most economically from deepwater. Excluding deepwater is therefore inconsistent with the purpose and need of the proposed action which requires the Secretary to both develop OCS resources and protect the environment. Chapter 2 presents a detailed justification of why BOEM has not analyzed an alternative excluding deepwater leasing.

11. The PEIS overstates the relative risks associated with deepwater operations and fails to include important blowout and BOP pressure test data. Minerals Management Service studies indicate a significantly lower blowout rate for deepwater drilling operations. West Engineering, SINTEF, and OOC (Offshore Operators Committee) pressure test data show that critical pressure test failures are 19 to 27 times higher for surface BOPs than for subsurface stacks.

    Response: BOEM has incorporated the references suggested and clarified the point being made in the PEIS. Although blowout events in the deepwater GOM are limited, the most comprehensive blowout frequency analysis, based on SINTEF's international database of blowout events, suggests that there is a greater relative frequency of blowouts in high-pressure/high-temperature conditions.

12. In Section 4.3.4.2.1 of the Draft PEIS, the statement "in shallow water, the relatively lower formation pressure typically results in a higher margin of safety, although encountering shallow gas represents a substantial hazard" is misleading and should be revised. With regard to formation pressures, well depth (not water depth) is the primary consideration. While ultra-deep (subsurface) shelf wells like those at the Blackbeard prospect typically encounter very high formation pressures, the ultra-deepwater Perdido field has low reservoir pressures. In this section, the Draft PEIS also states that "deepwater drilling rigs are multi-point moored to the sea floor or, more recently, dynamically positioned" is incorrect. DP [dynamic positioning] systems have been in use for 40 years. The Glomar Challenger had a full DP system for coring operations in 1968, and the Sedco 445 had a DP system for drilling in 1971. In this section, the Draft PEIS also states that "the technologically advanced BP Thunder Horse platform, for instance, intended to be BP's largest producer in the GOM, flooded because of the backward installation of a valve" does not relate to the discussion.

    Response: Section 4.3.3 of the PEIS has been revised to address or clarify the text in the draft.

13. The PEIS states that "the number of incidents reported increases with more complex operations, in particular with deepwater operations which, by their very nature, often entail greater scale, expansion, and complexity (Cohen and Krupnick 2011)." Citing a reference is not helpful unless that reference includes data that substantiate the conclusions. Increased production from fewer manned surface facilities tends to reduce safety risks and the potential for operational failures, not increase them.

    Response: BOEM inadvertently cited the wrong reference. The correct reference is Muehlenbachs et al. (2011). BOEM has clarified the statement and provided additional references to support the principal idea.

14. In Section 4.3.4.3.4, the Draft PEIS states that "the DWH event demonstrated that advances in drilling, safety, and spill response did not keep pace with increasingly complex operations by raising the standards for drilling and workplace safety, spill containment, and spill response." This statement is not representative of the views of industry in general and should be removed. The Macondo incident has caused everyone to evaluate their operations. However, Macondo is not the sole performance measure for all operations and an entire industry. USDOI data indicate that drilling operations have been getting safer and that the blowout rate has decreased. In addition, since the DWH event, a number of regulatory, policy, and industry-led initiatives have been developed and implemented. Together, these initiatives will work to further reduce the risk of future incidents and improve the offshore industry's ability to respond to any accidents or oil spills that might occur in the future.

    Response: The PEIS has been revised. Section 4.3.3 includes a detailed discussion of recent and ongoing governmental and industry reforms. The language in question has been revised.

15. In Section 4.3.4.2.1 of the Draft PEIS, the measure used to quantify the three largest spills prior to the DWH event is not provided.

    Response: The PEIS has been revised to indicate that the spill sizes are expressed in barrels (bbl).

16. Table 4.3.4-1 of the Draft PEIS should be revised by removing the term "vs." from "capping at the well vs. drilling relief well vs. chemical and mechanical response" since the current structure suggests that there are different trade-offs amongst each.

    Response: Table 4.3.3-2 in the PEIS has been revised to clarify the intent. However, there are trade-offs associated with some of different response strategies, especially in chemical and mechanical response.

17. While catastrophic discharge event may be classified as a "spill of national significance," spills that may not be classified as a catastrophic discharge event may still be classified as a "spill of national significance." A discharge may be classified as a spill of national significance (SONS) by the Administrator of the USEPA for discharges occurring in the inland zone and the Commandant of the U.S. Coast Guard (USCG) for discharges occurring in the coastal zone (40 CFR 300.323). USEPA recommends that BOEM consider clarifying that a SONS may not necessarily be a "catastrophic discharge event."

    Response: Section 4.3.3 of the PEIS has been revised to clarify that a SONS may not necessarily be a catastrophic discharge event.

18. It is not enough that the PEIS lists potential hazards that could lead to an oil spill; it must analyze and describe how the hazards could cause a spill, and most importantly, whether and how these hazards could be mitigated to avoid a spill. For example, in Section 4.2, which describes the relationship of the physical environment to oil and gas operations, the PEIS describes seismic faults, weather conditions, and geological hazards in the Arctic that "may

present a risk to offshore oil and gas activities," but does not specify what those risks are, nor does it make recommendations as to whether or how these hazards can be treated to avoid those risks. In sum, the PEIS is not sufficient without a reasonable analysis of the significant impacts oil spills may have on the regions proposed for leasing, the state and availability of current technologies and infrastructure to effectively contain and clean up a major or catastrophic spill in the different regions, and of whether and how the risks and impacts of such a spill can be mitigated.

Response: BOEM believes the PEIS does sufficiently link geological, operational, and other hazards to the occurrence of a spill or other incidental events. The reader is referred to Sections 4.2 and 4.3.3 for a complete discussion of risk. While the exact cause of the spill may vary, Chapter 4 of the PEIS fully analyzes the effects of small, large, and very large oil spills and differentiates between the intensity and context of potential impacts.

19. In Section 4.3.4.2.2, the Draft PEIS discusses the Marine Well Containment Company's seabed containment system. The PEIS states "this system is intended to address the weakness of the BP containment dome that caused its failure during the DWH event. The system can inject antifreeze-like chemicals to inhibit natural gas hydrate build-up, which created spill containment complications during the DWH event. Of course, whether Marine Well Containment Company's system will work as effectively as it claims will not be known until another blowout event occurs." The commenter asked BOEM to revise this section of the document to note that the DWH response deployed other, more advanced systems later in the response that did have methane injection capabilities to control hydrate formation. Additionally, the capping and control systems deployed during the response in June 2010 were effective in capturing a significant portion of the released oil and gas. Accordingly, it has been shown that similar systems can be effective in similar situations.

    Response: Section 4.3.3 of the PEIS has been revised to reference the improved capability for containment after BP's containment dome was modified.

20. In Section 4.3.4.2.1, the Draft PEIS states "deepwater wells require subsea BOP placement at depths unreachable for human service; ROVs [remote operating vehicles] become necessary." This statement insinuates that there is an increased likelihood in spill occurrence or failure in well control or containment. The effective use of ROVs at deepwater sites has been clearly demonstrated.

    Response: BOEM provides additional reference to the Mide (2010) study that addresses the reliability of ROVs to clarify the dependency on ROVs for physical intervention on deepwater well equipment and associated risk.

21. In Section 4.3.4.2.1, the Draft PEIS states "important technology includes the acoustic backup system, which communicates with the BOP system in the event of electrical and hydraulic connection loss with the wellhead. DNV (2010) reported a 25% reliability of current acoustic backup systems. ROV activation of the BOP using the secondary control system had a 75% success rate." Why is the acoustic backup system highlighted as important

when it has significantly lower reliability than ROV activation? Acoustic backup systems are likely to have even lower reliability during turbulent blowout conditions.

Response: Section 4.3.3 of the PEIS has been revised to clarify the statement in question and to address the reliability of other primary and secondary control systems.

22. It is not clear if the effects analysis considers the new reforms that require industry to have plans in place for a worst-case discharge and the circumstance that a spill cannot be contained with the containment technology. Even with the new safeguards in place, there is always a chance that capping or other methods of containment will not be successful.

    Response: As stated in Section 4.3.3, the PEIS includes an effects analysis that assumes a catastrophic discharge event has occurred and, despite the new requirement for containment capability, containment is not possible or effective so the spill continues to until a relief well is drilled or the well naturally bridges. The effects analysis is provided by resource and region in Section 4.4.

23. In Section 4.3.4.3.4 of the Draft PEIS, the bulleted list characterizing the Certification NTL is incomplete.

    Response: The PEIS has been revised to clarify the requirements of the Certification NTL in Section 4.3.3.

24. Section 4.3.4.3.1 of the PEIS needs to provide more detailed information about the assumptions underlying the catastrophic discharge event scenarios in each OCS Planning Area. This includes a more robust discussion of the likelihood of occurrence of such an event in context of new prevention and containment requirements. An estimate of the frequency of major spills could include factors such as historical domestic and international catastrophic spill occurrences, environmental factors, number of platforms, pipelines, and oil tankers, as well as the volume of production. Additionally, the PEIS should make reference to other rare events and the nature of impacts that can be expected.

    There is no definition or the context for what is considered a reasonably foreseeable spill. Some comments criticized that the catastrophic discharge event scenarios were not reasonable because they failed to take into account new technology and procedures and instead were based on the time required to drill a relief well. In light of the new well containment capabilities, it is very likely that the oil flow would be stopped or substantially reduced in less than the minimum durations specified for GOM and Alaska OCS oil blowouts.

    Response: Section 4.3.3 of the PEIS has been revised to describe the methodologies used to derive the spill scenarios and clarifies the likelihood of occurrence. In Section 4.3.3, BOEM provides a clearer explanation of its conservative assumptions regarding an oil spill. The specific resource analyses in Chapter 4 of the PEIS summarize the scale of possible environmental effects for small and large oil spills (which our scenario assumes), as well as a low-probability catastrophic discharge event (which is unexpected). Consistent with the requirements of 40 CFR 1502.22, the PEIS includes an analysis of impacts with have catastrophic consequences even if their probability of occurrence is low.

25. The PEIS does not contain adequate information concerning the regulatory protocols, effectiveness of, and impacts of subsea dispersant injection as a method to minimize the fate and effects of an oil spill. Subsea physical containment technologies should still be required for OCS operators until the environmental consequences of subsea dispersants have been investigated.

    Response: The PEIS has been revised to provide additional information on the protocols and effectiveness of dispersant use in Section 4.3.3. Subsea physical containment is required under BSEE regulations and clarified by NTLs.

26. The PEIS does not adequately characterize the persistence of and re-exposure to spilled oil from a catastrophic discharge event.

    Response: Section 4.3.3 has been revised to describe the potential for the persistence and re-exposure of oil in the marine and coastal environment. Also, Sections 4.4.6 and 4.4.7 discuss the potential for oil spill impacts on coastal and marine habitat and associated fauna.

27. The effects analyses in the PEIS are premised on a flawed assumption concerning the potential occurrence or likelihood of occurrence of a catastrophic spill in each OCS Planning Area. BOEM should provide more detailed analysis of the likelihood of occurrence and scale of effects associated with such an event, especially in the Arctic. Otherwise, the effects analysis violates the NEPA requirement to provide a full and fair discussion of environmental impacts.

    Response: Assigning accurate probabilities to rare events is difficult as acknowledged in the PEIS. BOEM has expanded the analysis in the PEIS in an attempt to better characterize the risk of occurrence, although absolute quantification remains difficult given the relatively limited number of historical observations for both loss of well control and major pollution events and wide-ranging exposure variables. Even then, reliance on historical data presents its own set of challenges as the historical data may represent a trend associated with a different regulatory regime or industry practices. Quantitative risk assessment becomes most practical at the well design phase, much later in the phased OCSLA process, when the combined reliability of primary and secondary barriers or barrier-failure modes can be analyzed within a fault-tree approach. At the exploration and development phase, worst-case discharge is also calculated on a site-specific basis and can be useful in determining the potential scale of effects.

28. In Section 4.3.4.3.1, the Draft PEIS estimates the probabilities for risk for a 150,000 bbl spill in the Arctic and GOM to be 3.94×10^{-4} and 3.42×10^{-4} respectively. The fact that these risk probabilities are so similar, despite the many differences between these areas, is surprising. What "Arctic specific variables" are factored into the Bercha estimate?

Response: The PEIS (see Section 4.3.3.3.1) has been revised to include updated information and a description of the fault-tree approach used by the Bercha Group.

29. The Arctic Ocean is a unique operating environment. As discussed in the PEIS, the characteristics of the Arctic OCS — rough seas, dynamic sea ice, extreme cold, limited visibility and daylight — exacerbate the risks and consequences of an oil spill, while also complicating cleanup. Oil is also likely to persist in cold environments. Section 4.3.4 of the Draft PEIS needs to be updated to include more relevant information about spill response capability in the Arctic, including major challenges to timely and effective spill response, as well as recent planning and capability improvements to address those challenges. An updated discussion of the U.S. Coast Guard presence, ice-breaking capacity, and other support infrastructure needs to be provided. The PEIS needs to demonstrate the adequacy of existing preparedness and response capabilities. In the absence of this, the PEIS fails to demonstrate why the risk is acceptable and leasing is warranted.

    Response: Containment and response in the Arctic must plan for the challenges of mobilizing, staging, and delivering technology and equipment and the ability to deploy it and get it on location in a timely manner in remote locations. The PEIS analysis includes assumptions that are consistent with recent exploration plans and oil spill response plans approved by BOEM and BSEE that include unprecedented measures. All operations in the Arctic must comply with oil spill containment and preparedness requirements in BSEE regulations and Notices to Lessees, such as the Certification NTL described in Section 4.3.3. Current practices for oil spill response plans are largely based on the type, location, season, and duration for each exploration activity. If development and production from the Alaska OCS Region were proposed, additional requirements and practices for conducting oil spill response would be developed commensurate with the type, location, and scope of proposed activities.

    Secretary Salazar highlighted the work of U.S. agencies to ensure that the full scope of Federal command and control capabilities are in place in the event that an accident occurred during the limited period allowed for potential exploratory drilling in the Arctic. If drilling is allowed to go forward, the U.S. Coast Guard would be in charge of overall command and control activities. For example, the Coast Guard has committed to an on-scene, at-sea presence, with land-based support, in the event that exploratory drilling goes forward this summer. The Coast Guard's command and control activities, supported by BSEE, the USEPA, NOAA, and other Federal agencies, would proceed in conformance with federally mandated contingency plans for the North Slope area that have recently been revised and updated. Those plans include the identification of sensitive ecological resources in the region and outline protection strategies.

    Preparedness and response exercises are essential to actual response effectiveness. For the last several summers, the Coast Guard has deployed vessels, aircraft and personnel to North Slope areas to practice operations in the area and work with local officials and citizens. On December 8, 2011, members of the Coast Guard and the State of Alaska conducted an Incident Command Post workshop with Shell personnel to improve oil spill preparedness. BSEE coordinated a table-top exercise with Shell and Federal, State, and local representatives in May 2012. In addition, the Alaska Regional Response Team (ARRT), which is made up of 12 Federal agencies and the State of Alaska, is planning an exercise that will test ARRT processes for responding to an incident. Finally, BSEE will conduct a deployment test of a company's capping stack prior to the approval of their drilling permit application, as well as on-site unannounced inspections of deployed spill response equipment.

In its regulatory role, BSEE is proactively working with NOAA, USCG, State of Alaska, international bodies, and joint industry programs to review oil-spill response plans and preparedness by the oil-and-gas and maritime industries prior to exploration and development activities. BOEM and BSEE do not disagree that spill response preparedness and response capability may be improved by further research, planning, and regulatory reform. BOEM is only considering adding the Arctic Planning Areas to the 5-year Program, under which any drilling activity would not likely occur until sometime after 2020 following a number of subsequent NEPA analyses and project-specific approvals. In the intervening time, BOEM, BSEE, other governmental agencies, and industry may make significant strides and advances in Arctic spill preparedness. If exploration drilling occurs under past lease sales, valuable lessons and experience can be applied in context of OCS operations potentially conducted under this 5-year Program. Including the lease sales in the 5-year Program does not guarantee the lease sales will occur. However, excluding lease sales at this point may prematurely postpone the development of valuable oil and gas resources on the basis of the current state of preparedness as compared to what it will be at the timeframe relevant to actual operations.

30. In cold environments, there is the potential for oil to persist. Scientific studies documenting that phenomenon for the Exxon Valdez spill were provided.

    Response: Section 4.3.3 of the PEIS addresses the fate of oil in cold environments and in ice, including the potential for persistence and repeated exposure to biological resources. BOEM has supplemented the discussion with the references provided: Peterson, C.H., S.D. Rice, J.W. Short, D. Esler, J.L. Bodkin, B.E. Ballachey, and D.B. Irons, 2002, "Long-Term Ecosystem Response to the *Exxon Valdez* Oil Spill," *Science*:302 (5653), 2082–2086. Short, J.W., M.R. Lindeberg, P.M Harris, J.M. Maselko, J.J. Pella, S.D. Rice, 2004, "Estimate of Oil Persisting on the Beaches of Prince William Sound 12 Years after the *Exxon Valdez* Oil Spill," *Environmental Science and Technology* 38:19–25. Siron, R., et al., 2003, "Fate and Effects of Dispersed Crude Oil under Icy Conditions Simulated in Mesocosms," 35 *Marine Environmental Research* 273.

31. The last public "spill drill" in the Arctic, which tested booms and skimmers and other conventional methods of oil spill cleanup in only partial sea ice conditions was in 2000 and was deemed a failure. Since offshore exploration work has to be done in the short summer when the ice cap has melted, it is unlikely that an oil spill could be cleaned up before the sea freezes over in the fall, making clean-up essentially impossible until the next summer. If an oil leak continued after freeze up, the oil would freeze into the ice and be carried potentially great distances as the ice continues to move all winter. The oil industry has never conducted an offshore oil spill response drill in the Chukchi Sea to test its equipment and procedures.

Ice can clog skimmers, make vessel operations more challenging and make it difficult to deploy equipment. Oil spreads under ice, making it more difficult to track and clean up. Field exercises in the Beaufort Sea in 2000 showed that sea ice could shut down on-water recovery at very low concentrations.

Response: The PEIS discusses the importance of timing of OCS activities relative to the fate and transport of spilled oil and effectiveness of clean-up operations during ice conditions in the Arctic in Section 4.3.3. Nuka Research Planning Group and Pearson Consulting (2010) and Potter et al. (2012) describe more recent field drills and trials in the Arctic. Section 4.3.3 of the PEIS has been revised to include new information about spill response drills and research, including the new International Association of Oil and Gas Producers (OGP) Arctic Oil Spill Response Technology Joint Industry Program. BSEE and the U.S. Coast Guard are actively engaged in capacity-building with respect to oil spill preparedness and response capabilities.

32. The last time that clean-up was tested in the Arctic was in 2000 when BP Exploration tested the response tactics and strategies for North Slope Operations. BP's studies showed that the maximum oil expected to be recovered in calm seas with minimum icy Arctic conditions would be 0–1% in fall ice conditions, 10% in spring ice concentrations without ice management, and 30% in spring ice concentrations with extensive ice management. The trials also identified many mechanical response limitations in broken ice conditions. They discovered that booms do not work effectively in ice. Skimmers do not work effectively in broken ice.

    Response: The 2000 broken ice trials in the Alaska Beaufort Sea demonstrated that the actual operating limits for a barge-based mechanical recovery system using conventional booms and skimmers. A follow-up trial testing the barge-based tactic, conducted in 2002, showed no major improvements and was followed shortly thereafter by the removal of that barge (the Endeavor) from the Alaska North Slope spill response equipment. The PEIS has been revised to incorporate additional information about the expected physical recovery of oil in different ice states assuming different ice management practices. See Section 4.3.3 of the PEIS.

33. The Canadian National Energy Board has analyzed the Arctic response gap with the finding that cleanup would not be possible on average three to five days of each week during some timeframes during a given year. Cleanup would not be at all possible from 44 to 84% of the time during the short Arctic drilling open-water season. For seven to eight months out of the year during the winter, no spill clean-up would be possible. Shell's recent exploration plan acknowledges that if Shell cannot achieve well control or remove all oil before freeze-up, the operator would abandon the well and leave the oil uncontained under the ice until spring thaw. Shell then proposes to develop a clean-up plan during the winter months and initiate response activities after spring breakup. This is not a plan.

    Response: The PEIS has been revised to incorporate information about the potential response gap given the time of year. Although the recent Shell exploration plan and oil spill response plan include unprecedented measures in preparedness, it is possible that containment measures would be unsuccessful prior to ice-over. This assumption is implicit in the catastrophic discharge scenario and subsequent effects analysis. See Sections 4.3.3 and 4.4.2 of the PEIS.

34. The International Tanker Owners Pollution Federation has noted that "containment and recovery at sea rarely results in the removal of more than a relatively small portion of a large spill, at best only 10–15% and often considerably less." The US Arctic Research Commission recently echoed these concerns for the Arctic.

    Response: This comment is consistent with the discussion in Section 4.3.3 addressing the efficacy of containment and mechanical recovery of oil.

35. During the DWH event in 2010, 20,000 to 60,000 people were involved in the cleanup operations. There is an obvious human capital and resources problem with mobilizing that number of people to the North Slope and accommodating their needs with existing infrastructure. That further reality underscores the importance of prevention and containment.

    Response: The PEIS has been revised to incorporate the human capital challenges involved in mobilizing a large workforce into a remote area. Such a challenge underscores the fundamental importance of prevention and containment, the principal focus of BOEM, BSEE, and industry reform following the DWH event. See Section 4.3.3 of the PEIS.

36. The Proposed Program states that "the Beaufort Sea Planning Area has well-developed oil and gas infrastructure on adjacent land and in State waters." However, this superficial conclusion fails to take into account the fact that existing infrastructure in this region is concentrated on land at Prudhoe Bay and is not sufficient to support response and cleanup of an oil spill in marine waters. Transportation-related infrastructure is minimal, and what exists is concentrated in the Prudhoe Bay oil field area. Heavy lift cranes and protected small boat shelters are found only at Prudhoe Bay's West Dock. Getting this limited equipment to needed locations would be difficult given that the communities within this region are not connected by a permanent road system and airports and related facilities are limited. Airports at Barrow, Kotzebue, and Deadhorse have scheduled jet service and are owned and maintained by the State of Alaska.

    Response: Although this specific assertion is not made in the PEIS, BOEM acknowledges the limited existing infrastructure (Section 3.11) and the need for advance logistical planning by OCS operators to mobilize the necessary technology, human capital, and equipment in advance of operations (Section 4.3.3). The distribution and scale of infrastructure needed for mobilization and deployment of containment and response efforts substantially constrains timely mobilization of such resources after a major spill has occurred. The PEIS has been revised to incorporate this concern.

37. An oil spill response stipulation exists for the GOM (Appendix B.1.4); however, a similar stipulation does not exist for Alaska OCS Planning Areas. Nonetheless, operators in the Arctic have developed practices specifically for the Arctic operating conditions. Operator efforts to address these challenges have also included more than 30 years of laboratory studies, simulation in test tanks and field experiments under carefully managed conditions in the U.S. and Canadian waters of the Beaufort Sea, in the Norwegian High Arctic, in the Barents Sea, and around Svalbard Island. Many of these projects have involved collaboration with the MMS.

    Response: Additional information about ongoing research and relevant industry practices has been incorporated in the discussion of spill response in Section 4.3.3.

8.4.4.7 Issue 7 Mitigation

1. Appendix B provides only minimal and generic information on specific mitigation measures to be applied for reducing impacts. Although it is understood that this is a Programmatic document, a presentation of each regulatory rule or guidance (e.g., NTL No. 2010-G40, etc.), or a reference for accessing these, in place for reducing impacts should be provided in this appendix. Although many of these may be provided or generally discussed in the text of the document, it would aid the reader if all were provided comprehensively in Appendix B. The mitigation measures employed to reduce or eliminate impacts are critical to impact-level conclusions reached throughout the document. BOEM should provide a more comprehensive approach for disseminating these to the public. Furthermore, BOEM should specify the minimum required mitigation measures now rather than waiting for some later date to impose those conditions.

    Response: The PEIS establishes an environmental baseline in Chapter 3 and then analyzes the impact factors associated with OCS development according to a reasonable scenario of activity and mitigation. Mitigation and other protective measures include those required by statute and regulation, or those deemed necessary by BOEM policy and practice for each planning area considered in the proposed 2012-2017 Program (see Appendix B: Assumed Mitigation and Other Protective Measures). At this programmatic stage, we can commit to those general mitigation measures imposed by statute or regulations, but it is premature to make absolute commitments about more site-specific mitigation without the detailed analyses that occur at the lease sale phase. However, we believe the analysis in this PEIS provides a reasonable framework for future evaluation of mitigation measures at subsequent phases in the proposed 5-year Program, such as, for example, the lease sale phase or the exploration plan submittal phase. Appendix B has been expanded to include other protective measures commonly applied through laws and regulations, as they pertain to the analyses in Chapter 4 of the PEIS.

2. The Bureau of Land Management (BLM) has developed a method to address existing data gaps for the National Petroleum Reserve Area (NPR-A). In some instances, the BLM has required pre-activity, multi-year, site-specific studies, when relevant or recent data are not otherwise available, for the purpose of helping develop mitigation measures. BOEM should

make the same commitments for OCS areas identified in the Programmatic EIS for offshore energy development in the Arctic.

Response: Decisions regarding the relevance of missing scientific information, or the need for specific mitigation to minimize potentially adverse environmental effects, are best addressed at the lease sale or plan phase, when the specific issue or concern can be well-defined and addressed in the requisite detail and analytical rigor. The BLM's Northeast NPR-A Supplemental Integrated Activity Plan process cited by the North Slope Borough is more comparable to the lease sale planning step in the OCSLA-phased process. BOEM does not generally adopt or prescribe mitigation within the framework of the national 5-year PEIS, or make commitments to multi-year, site-specific study without first defining the need and purpose, which, generally speaking, is not sufficiently characterized or formulated within the 5-year framework. BOEM does not disagree that additional scientific information may be needed to enhance mitigation and otherwise refine program implementation in individual Planning Areas. In fact, in the Proposed Program and Proposed Final Program, the Secretary of the Interior has intentionally scheduled single Chukchi Sea and Beaufort Sea lease sales late in the Program to provide additional time to identify information gaps and gather pertinent scientific data, including the need for additional site-specific study or mitigation development, to better inform lease sale, exploration, and development plan decisions. As reflected in the 2011 U.S. Geological Survey report, *An Evaluation of the Science Needs to Inform Decisions on Outer Continental Shelf Energy Development in the Chukchi and Beaufort Seas, Alaska,* BOEM's Environmental Studies Program continues to be a principal mechanism in defining and meeting those information needs. BOEM is collaborating with Federal partners in government-wide research programs such as Synthesis of Arctic Research (SOAR), Arctic Science Engineering Education for Sustainability (ARCSEES) program, North Pacific Research Board, Interagency Arctic Research Policy Committee, and National Academy of Sciences Polar Research Board research initiatives, as well as the National Research Council "Responding to Oil Spills in the Arctic Environment" review. Similarly, industry has been proactive in funding site-specific studies in the Arctic; in the case of Shell, they have funded millions of dollars in independent studies to characterize the environmental baseline, oceanographic conditions, potential effects on sensitive marine species, and define mitigation/monitoring needs and protocols.

At this preliminary planning stage, BOEM maintains that it is premature to define information and study needs when the analytic granularity is too coarse for site-specific or resource-specific decisions, when information from new or ongoing scientific research may be available at the time of the lease sale, and new and needed consultation and coordination will have occurred with resource agencies, such as Fish and Wildlife Service and National Marine Fisheries Service. However, BOEM does not want to downplay the underlying concern expressed in these comments, especially when there is apprehension that the point being made is ignored and unfairly treated in a tiered analytical and decision framework. BOEM has included a new section in the Issues of Programmatic Concern (see Section 4.3.2) to memorialize the issue and better explain the process of considering and evaluating different alternatives and mitigation strategies that may need to be applied at appropriate program decision points. BOEM encourages North Slope Borough to provide this same recommendation during scoping for potential Arctic lease sales.

3. The Draft PEIS failed to include a discussion of planning area-specific mitigation measures, such as seasonal restrictions in the Arctic and protected species observer programs. BOEM's analysis also rests on the assumption that the mitigation measures in Appendix B are effective; Appendix B essentially outlines the stipulations contained in leases, without analyzing whether they are, in fact, sufficient to minimize negative environmental impacts. BOEM's inclusion of mitigation measures at the PEIS level also violates CEQ's requirement that there be actual capacity to implement the mitigation measures by the Federal agency that proposes said mitigation measures in the PEIS.

   Response: Mitigation and other protective measures are developed during the implementation phases of the Program. For analytical purposes only, this PEIS considers mitigation and other protective measures already established and required by existing statutes or regulations, as well as sale-specific measures (stipulations) that were commonly adopted in past sales and that will likely be implemented for any lease sales that would occur under the Program. However, it is at the lease sale stage that more detailed and geographically focused analyses are conducted to evaluate the magnitude of potential impacts and, if needed, to develop effective mitigation strategies to reduce the magnitude of those potential impacts to acceptable levels.

   The 5-year PEIS is a programmatic NEPA document that analyzes the "size, timing, and location" of possible lease sales in the next five years. In the phased OCSLA and tiered NEPA process, the 5-year program is followed by lease sale or plan where more focused NEPA analyses are performed. In this framework, BOEM fully considers the need for and development of mitigation, effectiveness of the mitigation in terms of its stated purpose, as well as the potential effects associated with implementation of the mitigation. Appendix B has been revised to clarify the protective measures required by law, regulation, or historical practice that are assumed for analytical purposes in the 5-year PEIS. The mitigation and other protective measures considered in Appendix B have generally been developed over a long period of time and/or historically implemented. The mitigation has been codified because of its historical effectiveness, or as best practice at the bequest of resource agencies external to BOEM or its predecessor bureaus.

   Monitoring the effectiveness of mitigation involves tracking the success of a mitigation effort in achieving expected outcomes and environmental effects. Consistent with CEQ's January 2011 guidance on "Appropriate Use of Mitigation," BOEM relies on scientific staff and outside experts familiar with the predicted environmental impacts to develop the means to monitor mitigation effectiveness, in the same way that BOEM also relies on agency and outside experts to develop and evaluate the effectiveness of mitigation. Implementation of mitigation and monitoring necessarily draws on the expertise of resource agencies with whom BOEM consults, such as U.S. Fish and Wildlife Service and National Marine Fisheries Service.

   One of the more tangible vehicles BOEM uses to evaluate the effectiveness of regulations and mitigations is through the linked environmental study and assessment process. For example, BOEM has been studying and monitoring conditions at the Flower Garden Banks through its Environmental Studies Program for more than two decades, although initial monitoring efforts date to the 1970s. By continually monitoring and assessing stipulations or mitigation measures that are based upon studies results, BOEM is positioned to change or strengthen environmental requirements. A clear-cut example of this is seen in BOEM's studies of deep-sea corals in the GOM. When it became apparent (due to new study results) that extensive deep-sea coral habitats were not being included in environmental reviews because they occurred slightly shallower than existing review triggers, BOEM moved quickly to notify operators of new guidance to avoid these sensitive communities. This type of adaptive reevaluation is continual and vitally important to the protection of our nation's precious offshore environments and resources. The same is true in the Arctic. An example is the ongoing BOEM study, entitled "Aggregate Effects Research and Environmental Mitigation Monitoring of Oil Industry Operations in the Vicinity of Nuiqsut." This study is using social science research methods to evaluate the effectiveness of specific mitigation measures being implemented to manage conflicts relative to onshore and offshore oil and gas exploration and development in the vicinity of subsistence use areas for the village of Nuiqsut. The added value from such studies can lead to new mitigation applied at the lease sale phase.

The implementation of mitigation by BOEM is also questioned in the comment. Following the October 2011 re-organization of BOEMRE, BOEM is now responsible for environmental analyses for all activities associated with leasing, authorization of on- and off-lease geological and geophysical surveys, and approvals of exploration and development plans. BOEM will develop and adaptively manage environmental protection measures specific to these activities. BSEE is responsible for environmental compliance related to issuing permits associated with plans (i.e., Applications for Permits to Drill), inspections of environmental measures, and enforcement for non-compliance. BSEE also reviews industry reporting and works with BOEM to adaptively manage environmental mitigation measures to ensure their effectiveness and enforceability. Under the new Safety and Environmental Management System (SEMS) requirements (clarified in BSEE National NTL 11-N09), OCS operators must address environmental information in all aspects of their SEMS program and specifically address requirements as set forth in regulation, lease stipulation, plan conditions of approval, etc. This includes verification and corrective actions and continual improvement related to mitigation measures. BSEE provides the regulatory oversight focused on compliance by operators with environmental regulations, as well as making sure operators comply with the measures required by BOEM.

The comment suggests that sufficient authority is not vested in BOEM to require mitigation in the 5-year PEIS. To be clear, the PEIS is not adopting specific mitigation within the 5-year Program decision, but rather, assumes it to be in place for analytical purposes because the mitigation has already been codified and/or is generally considered a matter of practice.

Further, CEQ requirements regarding mitigation do not specifically require that BOEM have express authority to require mitigation for it to be relevant to the decision. Consistent with CEQ's January 2011 guidance on the "Appropriate Use of Mitigation," BOEM is not making any commitments to mitigation without sufficient legal authority now or at a later stage. BOEM would like to point out that the bureau's underlying authority may provide the basis for its commitment to implement and monitor the mitigation at the lease sale or plan phase. However, the authority for the mitigation may also derive from legal requirements that are enforced by other Federal, State, or local government entities (e.g., air or water permits administered by local or State agencies). Both scenarios generally apply during implementation of the 5-year program when mitigation is applied through lease sale stipulations or plan approvals. BSEE will take an active role in clarifying and enforcing those requirements.

4. BOEM needs to ensure that mitigation measures to protect subsistence activities are negotiated between subsistence communities and oil and gas companies through vehicles like Conflict Avoidance Agreements (CAA) that the Alaska Eskimo Whaling Commission (AEWC) negotiates with oil and gas companies each year.

   Response: The 5-year PEIS is a programmatic NEPA document that analyzes the "size, timing, and location" of possible lease sales in the next five years. In the phased OCSLA and tiered NEPA process, the 5-year program is followed by lease sale- or plan-specific NEPA documents in which more focused NEPA analyses are performed and mitigation needs are identified and analyzed. This includes the effectiveness of the mitigation to achieve its stated purpose, as well as the effects of the mitigation. BOEM has not historically developed systematic or specific mitigation through the 5-year PEIS process. Instead, in the 5-year PEIS, BOEM assumes that certain mitigation and other protective measures already required by existing regulation or BOEM requirement/practice will be in place (see PEIS Chapter 1 and Appendix B). While BOEM believes mitigation is properly developed and analyzed in the phased OCSLA process — lease sale, exploration plan, development plan — the Bureau appreciates the importance of subsistence activities in the Arctic and stresses on that longstanding way of life. In recent years, oil and gas companies, such as Shell, have been proactively working with the Native communities and community interest groups to negotiate conflict avoidance agreements in advance of activities. Consistent with the framework of Coastal and Marine Spatial Planning, BOEM encourages multi-use and environmental conflict resolution. In the 5-year programmatic analytical approach, this issue is best addressed at the lease sale or plan phase when the spatial and temporal aspects can be defined and addressed in the requisite detail and analytical rigor. BOEM has included a new section in the Issues of Programmatic Concern (see Section 4.3.2) to memorialize the issue and better explain the process of considering and evaluating different alternatives and mitigation strategies that may need to be applied at appropriate program decision points. BOEM encourages the Alaska Eskimo Whaling Commission to provide this same recommendation during scoping for potential Arctic lease sales.

5. Noise impact mitigation measures should be included. Underwater noise is, as the USDOI has stated in the past, one of the most prevalent forms of environmental impact from offshore exploration, development, and production activities. (Preliminary Revised 5-year OCS Oil & Gas Leasing Program for 2007-2012 (2010)). It requires honest analysis, dedicated research, robust protected areas, and substantial mitigation of both acute and cumulative effects well beyond current practice. While BOEM and NMFS are considering mitigation measures for seismic surveys in the EISs for GOM, Arctic, and Atlantic planning areas, it is important — for purposes of consistency and resource allocation — for BOEM to address a number of mitigation alternatives at the leasing program stage.

Response: The PEIS establishes an environmental baseline in Chapter 3 and then analyzes the impact factors associated with OCS development according to a reasonable scenario of activity and mitigation. Section 4.1 of the PEIS describes the potential impact-producing factors, including noise. Mitigation measures, considered in the PEIS, including those required by statute and regulation, or those deemed necessary by BOEM policy and practice for each planning area are described in Appendix B: Assumed Mitigation and Other Protective Measures. At this programmatic stage, we can commit to those general mitigation measures imposed by statute or regulations, but it is premature to make absolute commitments about more site-specific mitigation without the detailed analyses that occur at the lease sale phase. As the comment acknowledges, BOEM is actively pursuing Programmatic Environmental Impact Statements in the GOM, Mid- and South Atlantic, and Arctic in collaboration with the National Marine Fisheries Service in specific recognition of the potential for environmental impacts from noise in the marine environment. Those deliberative, multi-year processes are still ongoing at this time, such that the outcomes are not yet available to incorporate in the 5-year planning process. The PEIS for the Arctic was published in January 2012. The PEIS for the Mid- and South Atlantic was published in March 2012. The PEIS for the GOM is expected to be published in late 2012. Absent specific decisions, BOEM is confident that some of the mitigation strategies proposed within the framework of those documents will ultimately be adopted and applied in context of exploration activities that may occur under leases in the 2012-2017 Program in the GOM and Alaska Planning Areas. However, we believe the analysis in this PEIS provides a reasonable framework for future evaluation of mitigation measures at subsequent phases in the proposed 5-year Program, such as, for example, during geophysical permitting, the lease sale phase, or the exploration plan phase.

8.4.4.8 Issue 8 Regulations and Safety

1. Many commenters requested BOEM and BSEE to reform their regulations and practices based on the numerous recommendations from various reports prepared following the DWH event, including the National Oil Spill Commission Report on the Deepwater Horizon Event, the National Academy of Engineering Report, the National Research Council Report, the Deepwater Horizon Joint Investigation Team Report, USDOI's Report Regarding the Causes of the April 20, 2010 Macondo Well Blowout, etc.

   Response: Both BOEM and BSEE are proactively addressing the opportunities and needs at the heart of the recommendations of the various reports written following the DWH event. BOEM and BSEE have reviewed all the reports, already incorporated many recommendations, and continue to pursue and implement aggressive regulatory reform that addresses many of these recommendations or underlying need for reform or regulatory changes. As discussed in Section 4.3.3, BOEM and BSEE have focused on drilling safety reforms, especially on loss of well control prevention and well containment. BOEM has revised Section 4.3.3 of the PEIS to provide a more detailed presentation of the ongoing governmental reform process, in addition to new measures that have already been processed or implemented since publication of the Draft. Section 4.3.3 was also revised to include pertinent information about ongoing reform being pursued by industry, such as new safety, risk assessment, and spill research initiatives. Please refer to Section 4.3.3 of the PEIS for more information.

2. BOEM should present a more balanced discussion of new safety and environmental regulations and other safety measures implemented since the DWH event, including ongoing challenges of reform implementation. The effectiveness of the regulatory framework and reform measures is relatively untested.

   Response: BOEM appreciates these comments and recognizes that a proactive government and industry are critical to ensure safe and environmentally sound OCS oil and gas operations. BOEM has revised Section 4.3.3 of the PEIS to clarify the bases of recent and ongoing reform measures, referencing reform reports, benchmarked international standards, and international trends following comparable regulatory overhauls. Section 4.3.3 presents a focused discussion of (1) ongoing reforms in BOEM, BSEE, other Federal agencies, and industry and (2) promising safety, risk assessment, and oil spill response research.

3. One comment requested that BOEM present in the PEIS a risk assessment of the 5-year Program drilling activities to aid in decision-making. The risk assessment should consist of a formal probabilistic risk analysis that evaluates human, environmental, and economic risks associated with drilling, well construction, temporary well abandonment, oil and gas production, and eventual well abandonment.

   Response: BOEM has focused its analytical effort in the PEIS on the occurrence and consequence of an oil spill, as compared to drilling-related safety incidences, or costs or losses of productive time. Section 4.3.3 includes a robust discussion of the various factors that may contribute to risk during drilling operations. The PEIS characterizes the risk of oil spills in Section 4.3.3 and 4.4.2 in detail appropriate for the proposed action. Quantification of the risk of oil spills, especially very large, unexpected spills, remains a challenging problem for the reasons explained in Section 4.3.3. The same section also includes a discussion of how risk is evaluated by both government and industry through the phased OCSLA process from the 5-year Program through site-specific drilling plans.

   BOEM appreciates this comment and recognizes that a proactive government and industry are critical to ensure safe and environmentally sound OCS oil and gas operations. BOEM has revised the PEIS (see Section 4.3.3) to elaborate on recent and ongoing reform measures, referencing reform reports, benchmarked international standards, and international trends following comparable regulatory overhauls. Specific to the issue of risk assessment for OCS drilling activities, Section 4.3.3 also presents a discussion of recent joint BSEE-industry research regarding the development of a blowout risk assessment methodology, model, and risk assessment tool for OCS drilling planning and operations in the GOM.

4. The PEIS is thorough in its presentation of the regulatory and policy reforms that BOEM and BSEE have undertaken subsequent to the DWH event to improve safety and environmental outcomes.

Response: The recognition of BOEM's concerted effort to treat this topic in the PEIS is appreciated. However, since many commenters requested further clarity and information on this topic, BOEM revised Section 4.3.3 of the PEIS to provide more information about previously implemented, and ongoing reforms, including those being pursued by BSEE and industry.

5. A commenter suggested the PEIS make specific reference to substantial reform measures implemented by industry to improve offshore exploration and development operations following the DWH event. These reforms include new and revised standards, recommended practices, and guidelines that incorporate lessons learned from the DWH event.

   Response: BOEM has updated the PEIS (see Section 4.3.3) to include new and/or revised industry standards, recommended practices, guidelines, etc., such as API Standard 65-Part 1 and 2, API RP 96, API Well Construction Interface Document Guidelines, API RP 53, API Specification Q2, and API Specification 16A. Similarly, the PEIS presents updated information about the reform initiatives of other joint industry efforts and task forces.

6. Many commenters expressed concern that BOEM, BSEE, and the U.S. Coast Guard does not have adequate oil spill planning and response measures in place to support oil and gas leasing on the OCS. BSEE should better reform its regulations and guidance to minimize the likelihood of a major oil spill and to enhance oil spill planning and response measures, ensuring adequate containment resources, oil spill response capability, and proven containment and clean-up technologies are in place to respond to a major oil spill, before allowing leasing, especially in the Beaufort and Chukchi Sea Planning Areas.

   Response: BSEE and the U.S. Coast Guard, among other Federal and State entities, are responsible for oil spill planning and response efforts on the OCS. Adjacent coastal States also bring substantial expertise and resources to spill planning and response. BOEM and BSEE regulations under Subpart B of 30 CFR Part 550 and 30 CFR Part 254, respectively, require industry to demonstrate adequate spill planning and response capability, including the need to respond to a major spill in remote areas such as the Arctic Ocean.

   Following the DWH event, BOEM and BSEE put into place new requirements regarding spill containment and response planning and capability. BSEE continues to participate in regional planning exercises, evaluate new spill response technologies, invest in new innovative spill response research, etc. Both BOEM and BSEE are funding a new NRC study that considers oil spill response capability in the Arctic. Section 4.3.3 of the PEIS provides information about ongoing spill planning and response reforms in government and industry.

7. Several commenters called for reform of, and improvement in, the governmental process used to evaluate oil spill prevention and response plans. Many comments questioned industry's ability to implement oil spill response measures in the event of a significant spill, suggesting that plans need to be benchmarked against the best international standards and/or real-world demonstrations of the effectiveness of planning exercises. The commenters expressed the need for BSEE to rigorously review operators' oil spill response plans prior to

approval in a manner that ensures adequate technical input. The review and approval process should ensure that plans include spill scenario information, such as containment and response capabilities. Oil spill response plans should be subject to review and approval by not only USDOI, but other agencies with relevant operational expertise, including the USCG, USEPA, and NOAA. The plans should be available to the public for comment.

BOEM and BSEE should routinely evaluate and continually improve oil spill prevention and response measures, especially in the Arctic. In the effort toward continual improvement, BOEM and BSEE should consider adopting the recommendations from the National Commission on the BP Deepwater Horizon Oil Spill and Offshore Drilling and the National Academy of Engineering/ National Research Council. For example, operators should be required to employ best-available technologies and practices; provide detailed plans for source control; redesign blowout preventer systems "to provide robust and reliable cutting, sealing, and separation capabilities for the drilling environment to which they are being applied and under all foreseeable operating conditions of the rig on which they are installed;" establish test and maintenance procedures "to ensure operability and reliability appropriate to their environment of application"; and seek approval of proposed well design to demonstrate that (1) well components are equipped with sensors or other tools to obtain accurate diagnostic information and (2) wells are designed to mitigate risks to well integrity during post-blowout containment efforts.

Response: BOEM and BSEE recognize the importance of routinely evaluating and continually improving oil spill prevention and response capabilities and measures. The implementing regulations found in 30 CFR Part 550 and 30 CFR Part 250 require industry to conduct OCS operations using best-available technology and following established best practices. BSEE continues to pursue and implement a systematic regulatory reform that, in part, responds to the various reform recommendations. With increased inspection and spill response resources, BSEE plans to enhance inspections and drills, such as rigorous announced and unannounced oil spill response drills. BSEE currently has a robust process for the review and approval of industry oil spill response plans that includes appropriate technical expert input. Oil spill response plans are required to include a description of operator containment and response methodologies and capabilities per recent NTL requirements. In addition, BSEE conducts a robust research portfolio of studies each year to analyze various aspects of oil spill containment, fate, and response. The results of this research are used to continually improve oil spill prevention and response measures.

As part of the Department's broad and continuing reform efforts, BSEE created a number of Implementation Teams to evaluate and, as warranted, pursue implementation of the various reform recommendations following the DWH event. The ongoing work of these teams lays the foundation for lasting change in the way the BSEE and BOEM will implement oil spill prevention and response measures in the future. The Oil Spill Response Team at BSEE is also conducting a comprehensive review of spill response and the adequacy of operators' oil spill response plans. This team is working closely with the U.S. Coast Guard and other Federal agencies on developing enhanced spill response plans and more effective reviews of those plans in light of lessons learned from the DWH event response. Similarly, industry, through the establishment of the Center for Offshore Safety, new joint industry task forces, and joint industry research programs, is proactively engaged in advancing oil spill prevention and response capabilities.

BOEM has revised the PEIS to provide more information about oil spill response planning roles and responsibilities, ongoing regulatory reforms, enhanced governmental and industry practices, and new spill response research and technology development (see Section 4.3.3).

8. Several commenters assert that prior to consideration of leasing in the Arctic OCS Planning Areas, BOEM should (1) add a stipulation to all Arctic leases requiring a certification for Oil Spill Response Organizations (OSROs) to verify their capability to respond given the environmental conditions and challenges in the Arctic, (2) require operators to have trained response personnel and Arctic-grade response equipment pre-staged along vulnerable Arctic coastlines, and (3) require key oil spill containment and response equipment be designed for and tested in Arctic conditions.

   Response: This comment is ripe for response at the lease sale phase when mitigation requirements are evaluated and, in part, determined. Even though this is not a regulatory requirement, the need for such certification can be analyzed at the lease sale phase as appropriate (refer to the PEIS Section 4.3.2, Programmatic Deferrals and Mitigations). Moreover, BOEM also considers spill response capability during exploration and/or development plan evaluation under 30 CFR Part 550, Subpart B. Under its authority, 30 CFR Part 254, BSEE must also evaluate the merit of an operator's oil spill response plan.

   A wide range of comments were submitted on the regulatory framework for oil spill planning and response, as well as the general state of capability. For a more detailed discussion, the reader is referred to Section 4.3.3.

9. A commenter stated that operators must obtain any necessary approvals and environmental permits from the appropriate State agency, if the project results in a discharge to waters of the State. Additionally, all precautions should be observed to control nonpoint source pollution from construction activities on the OCS.

   Response: Both BOEM and BSEE are aware of the water quality permits required from affected coastal States for OCS activities. Operators also have to obtain NPDES permits under the requirements of the Clean Water Act. BOEM evaluates the need for other precautions and mitigation related to pollution control and water quality at the lease sale or plan stages.

10. Since pipelines installed and anchored on the Arctic seafloor will be decommissioned by capping in place, a commenter suggested that BOEM reference the standards to which industry will be held to that ensure the pipelines will be cleaned and pollution will not result.

    Response: BSEE regulates the decommissioning of pipelines under 30 CFR Part 250, Subpart J, and pipeline decommissioning is addressed specifically in 30 CFR 250.1006 and 30 CFR 250.1750 through 250.1754. 30 CFR 250.1006 states that pipelines out of service for less than one year must be isolated with a blind flange or a closed block valve at each end. Pipelines out of service for more than one year but less than five years must be flushed and filled with inhibited seawater. Pipelines out of service for five years or more are addressed under 30 CFR 250.1750 through 250.1754, which states that operators "may decommission a pipeline in place when the Regional Supervisor determines that the pipeline does not constitute a hazard (obstruction) to navigation and commercial fishing operations, unduly interfere with other uses of the OCS, or have adverse environmental effects." 30 CFR 250.1751 describes the details of the pipeline decommissioning application process, including the information requirements to be submitted with the application. Section 4.1.1.4 of the PEIS has been updated with a summary of the pipeline decommissioning requirements.

8.4.4.9 Issue 9 Statutory Compliance

1. Appendix C (Federal Laws and Executive Orders) of the PEIS is missing several environmental statues and Executive Orders.

   Response: BOEM added the Migratory Bird Treaty Act of 1918, Executive Order 11990 — Protection of Wetlands, as well as other statues that were missing from Appendix C of the PEIS. The list of environmental statutes and Executive Orders added to Appendix C is as follows:

   - Rivers and Harbors Act (RHA) of 1899 (Sections 9 and 10) – 33 USC sec. 401 *et seq*.
   - Migratory Bird Treaty Act (MBTA) of 1968, as amended (1936, 1972, 1976, 2006) – 16 USC 703 *et seq*.
   - The new BOEM authorities in Alaska under the Clean Air Act (CAA) of 1963, as amended (1990, 2004) 42 USC sec. 7401 *et seq*.
   - Executive Orders:
     - Executive Order 11988, Floodplain Management (May 24, 1977), amended by EO 12148 (July 20, 1979)
     - Executive Order 11990: Wetlands Protection (May 24, 1977), amended by EO 12608 (September 9, 1987)
     - Executive Order 13175, Consultation and Coordination With Indian Tribal Governments
     - Executive Order 13186: Responsibilities of Federal Agencies To Protect Migratory Birds (January 10, 2001)

2. Commenters stated that the PEIS is not in compliance with or fails to adequately explain the provisions of various environmental statutes. One commenter expressed that an Alaska National Interest Lands Conservation Act Section 810 review for pipeline routes from the Chukchi Sea and Beaufort Sea to the Trans-Alaska Pipeline System needs to be conducted for the PEIS.

   Response: BOEM updated Appendix C, Section C.1.4 The Alaska National Interest Lands Conservation Act (ANILCA) accordingly to show that pipeline routes in State waters are subject to ANILCA requirements.

3. Another commenter expressed that all OCS activities in waters adjacent to Alabama's coast must be carried out in full compliance with relevant Alabama laws, rules, and regulations, and in a manner that is fully compliant and consistent with the Coastal Zone Management Act (CZMA).

   Response: All OCS activities that may affect Alabama's coastal resources will be conducted in a manner that is fully compliant and consistent with the CZMA. BOEM will comply with CZMA requirements at the lease sale phase of the 5-year Program. Please refer to Appendix C, Section C.1.7 The Coastal Zone Management Act (CZMA) and the Coastal Zone Reauthorization Amendments of 1990, for more information.

4. Several commenters expressed concern that the PEIS does not adequately address how BOEM complies with the Endangered Species Act (ESA) and Marine Mammal Protection Act (MMPA) for the 5-year Program.

   Response: BOEM will consult with the USFWS and NMFS under Section 7 of the ESA at the lease sale phase during implementation of the 5-year Program. BOEM revised the section heading for Section 1.4.5.4 of the PEIS from "Biological Assessment and Opinion for Threatened and Endangered Species" to "Endangered Species Act Section 7 Consultations for Threatened and Endangered Species" to clarify when BOEM will undertake these consultations with the USFWS and NMFS under Section 7 of the ESA. Please refer to Sections 1.4.5.4 and 4.4.7.1 of the PEIS for more detail.

5. One commenter expressed concern that the PEIS does not adequately address how BOEM complies with the Magnuson-Stevens Fishery Conservation and Management Act (FCMA) for the 5-year Program.

   Response: BOEM consults with NMFS under the Magnuson-Stevens FCMA for the western portion of the Eastern Planning Area of the GOM using a different mechanism than that used for the Western and Central GOM. Appendix C, Section C.1.9 The Magnuson-Stevens Fishery Conservation and Management Act, has been revised to clarify this difference in these consultations across the GOM Planning Areas.

6. One commenter requested the references to the incidental harassment authorization and letters of agreement be added to Section 4.4.5.4 of the PEIS. The inclusion of the conflict avoidance agreements (CAA) could be added but must note that the CAA is voluntary and the terms negotiated between individual operators and communities and subsistence user groups vary widely.

   Response: Since details like incidental harassment authorization and conflict avoidance agreements are more appropriate for inclusion in the lease sale NEPA documents, BOEM has not added the requested information to the PEIS. However, oil and gas activities on the Arctic OCS are subject to compliance with the MMPA and ESA. Compliance with these acts collectively ensures that (1) there is no more than a negligible impact on marine mammals; (2) there is no unmitigatable adverse impact on subsistence uses of marine mammals; and

(3) there is no jeopardy to ESA-listed species or adverse modification to any critical habitat designated for ESA-listed species. Authorizations under the MMPA and ESA contain mitigation and monitoring measures to ensure these thresholds are not exceeded. Examples of such authorizations can be found at the following websites:

- USFWS
  - http://alaska.fws.gov/fisheries/mmm/Beaufort_Sea/76FR47010.pdf
  - http://alaska.fws.gov/fisheries/mmm/Chukchi_Sea/pdf/73FR33212.pdf
  - http://alaska.fws.gov/fisheries/mmm/itr.htm
- NMFS
  - http://www.nmfs.noaa.gov/pr/permits/incidental.htm
- BOEM
  - http://www.alaska.boemre.gov/ref/Biological_opinions_evaluations.htm
  - http://www.alaska.boemre.gov/ref/eis_ea.htm.

7. Industry practices as mandated by the USFWS and NMFS include maintaining 1-mile exclusion zones around known polar bear dens, use of aerial FLIR surveys to identify polar bear dens, and Incidental Harassment Authorization and Polar Bear and Wildlife Interaction Plans, which specify the means by which industry minimizes contact, conflict, or stress upon the Polar Bears. These industry and regulatory practices should be specified to demonstrate protection of the polar bears. The PEIS should also note a prior USFWS finding that "documented impacts on polar bears by the oil and gas industry during the past 30 years are minimal" and "historically, oil and gas activities have resulted in little direct mortality to polar bears." (72 *Fed. Reg.* at 1,079).

   Response: Details such as specified exclusion zones for polar bears are more appropriate for inclusion and discussion at the lease sale phase; therefore, BOEM has not added the requested information to the PEIS. However, BOEM concurs that there are existing mitigation and monitoring measures as well as industry practices that are directed at minimizing or eliminating impacts to polar bears from oil/gas activities. The USFWS promulgated regulations under the MMPA that require a suite of mitigation measures in order to ensure a negligible impact (as defined under the MMPA) on polar bears. These regulations can be found at http://alaska.fws.gov/fisheries/mmm/Beaufort_Sea/76FR47010.pdf and http://alaska.fws.gov/fisheries/mmm/Chukchi_Sea/pdf/73FR33212.pdf. Additional detail on implementation of these measures can be found at http://alaska.fws.gov/fisheries/mmm/itr.htm. Further, the USFWS has also completed a consultation with BOEM under the Endangered Species Act that further ensures oil/gas activities permitted by BOEM do not result in jeopardizing the continued existence of polar bears (see http://www.nmfs.noaa.gov/pr/permits/incidental.htm).

8. Coastal and Marine Spatial Planning (CMSP) should not be characterized as a "national zoning plan."

   Response: The language has been revised in Section 4.3.1: Multiple Use Issues and Marine Spatial Planning, to read as follows, "In recent years, Coastal and Marine Spatial Planning (CMSP) has emerged as a new paradigm and planning strategy for coordinating all marine and coastal activities within an ecosystem-based framework."

9. Commenters expressed that the Executive Order instituting the National Ocean Policy and CMSP directly conflicts with the Congressionally-established OCSLA.

   Response: BOEM appreciates the concern over the overlapping requirements of the OCSLA and National Ocean Policy EO 13547. BOEM sees the planning frameworks of the OCSLA and CMSP as complementary. Please refer to Section 4.3.1: Multiple Use Issues and Marine Spatial Planning, of the PEIS for more information.

10. Several commenters suggested that the PEIS and 5-year Program should better integrate the National Policy for Stewardship of the Ocean, Our Coasts and the Great Lakes (referred to as NOP). Implementation of the NOP by using CMSP will help resolve issues of conflicting use.

    Response: BOEM has incorporated the requirements of the National Ocean Policy EO 13547 into its 5-year Program, which includes CMSP. Please refer to Section 4.3.1: Multiple Use Issues and Marine Spatial Planning, of the PEIS for more information.

11. The PEIS mentions participation of all GOM States in the Federal coastal management program, but it fails to mention Alaska's withdrawal from the program and how the sunset of the Alaska Coastal Management Program (ACMP) may affect regulation of oil and gas activities in the Alaska DCS (Drilling, Completion, and Stimulation) Program. Until July of 2011, the statewide ACMP standards included the statutes and regulations of the Alaska Department of Environmental Conservation which were more stringent than Federal requirements. The Final EIS should include an analysis of the impacts of the loss of the ACMP.

    Response: In 2011, the Alaska State Legislature did not pass legislation that would have extended the ACMP established under Section 303 of the CZMA. The ACMP expires in July 2011. Without a Federal Consistency Program and a supporting State regulatory regime in effect, BOEM will no longer have to coordinate under appropriate subparts of the CZMA consistency regulations, 15 CFR Part 930. However, under other Federal environmental mandates, including but not limited to NEPA and the OCSLA, BOEM must still consider the direct, indirect, and cumulative environmental effects on coastal resources on State lands or submerged lands from the proposed and connected actions. Under Section 19 of the OCSLA, any affected State may submit recommendations to the Secretary of the Interior regarding the size, timing, or location of a proposed lease sale or with respect to a proposed development and production plan (OCSLA Section 25). The lease sale phase is the usual decision-point for BOEM to evaluate the need for any mitigation that is now necessary absent former State requirements, applied pursuant to Section 307 of the CZMA, that were in place to avoid or minimize impacts to acceptable levels.

TABLE 8.4-1 Stakeholders Providing Issue-Specific Comments on the PEIS

Issue 1 — NEPA Process	
John Mueller	Natural Resources Defense Council
USACitizen1	Northwest Arctic Borough
World Wildlife Fund, U.S. Arctic Field Program	National Oceanic and Atmospheric Administration
Eleanore Huffins	Alaska Wilderness League
Pamela Miller	Alaska’s Big Village Network
Alaska Department of Natural Resources	International Dark Sky Association
Jason Brune	North Slope Borough
Tom Hendrix	Defenders of Wildlife
Center for Water Advocacy	Eyak Preservation Council
Oceana	Center for Biological Diversity
Qaiyaan Su’esu’e	Northern Alaska Environmental Center
Harry Brower	Pacific Environment
Heather Dingman	Republicans for Environmental Protection
Inupiat Community of the Arctic Slope	Sierra Club
Mobile Bay Sierra Club	The Wilderness Society
Carol Admans-Davis	Mobile Baykeeper
Darcie Warden	Ocean Conservancy
The Wilderness Society, Lois Epstein	National Audubon Society
Catherine Shed	Pew Environmental Group
Carla Sims Kayotuk	Gulf Restoration Network
Don McKie	
Issue 2 — NEPA Analysis	
US Fish and Wildlife Service, Southeast Region	North Slope Borough, Department of Wildlife Management
J. Capozzelli	Natural Resources Defense Council
Reed Secord	Natural Resources Development Council
U.S. Environmental Protection Agency	Sierra Club
Ted Tupper	Oceana
Isaac Blume	Lih Young
John Hocevar	Jenna Hertz
Henri Fourroux	Charles Edwardson
Rosemary Ahtuangaruak	Pamela Miller
Tidewater, Incorporated	Rick Steiner
Audubon Alaska	Jason Brune
Carl Portman	Tom Lohman
Tina Robinson	Kiersten Lippmann
Marjorie Ahnupkana	Leandra de Sousa
Isaac Nukapigak	Benjamin Craft-Rendon
George Edwardson	Billy Nashoalook
Bill Tracey, Sr	Native Village of Point Hope
Qaiyaan Su’esu’e	Kristi Frankson
Louisa Riley	Lois Epstein
Shell Exploration and Production Company	National Oceanic and Atmospheric Administration
Gulf Restoration Network	Chad Nordlum
Katharyn Reiser	Northwest Arctic Borough
Oasis Earth	Alaska Wilderness League
Marybeth Holleman	Alaska’s Big Village Network
Ted Tupper	Surfrider Foundation
Aleut Corporation	Center for Water Advocacy
Christopher Lish	Defenders of Wildlife
Alaska Oil and Gas Association	Eyak Preservation Council

TABLE 8.4-1 (Cont.)

National Ocean Industries Association	World Wildlife Fund Petition
Statoil USA E&P Inc.	Pew Environmental Group
The Nature Conservancy	Pacific Environment
American Petroleum Institute	Republicans for Environmental Protection
The Wilderness Society	Alaska Oil and Gas Association
World Wildlife Fund, U.S. Arctic Field Program	Independent Petroleum Association of America
International Association of Drilling Contractors	International Association of Geophysical Contractors
U.S. Oil and Gas Association	North Slope Borough
Northern Alaska Environmental Center	Center for Biological Diversity
Resource Development Council	Alaska Eskimo Whaling Commission
Ocean Conservancy	Iñupiat Community of the Arctic Slope
National Audubon Society	Arctic Slope Regional Corporation

Issue 3 — Alternatives

U.S. Environmental Protection Agency	Republicans for Environmental Protection
Michelle Waters	Sierra Club
Donny Williams	The Wilderness Society
Holly Hanks	Gulf Restoration Network
Natural Resources Development Council	Pacific Environment
Oceana	Alaska's Big Village Network
Rosemary Ahtuangaruak	Northern Alaska Environmental Center
Natural Resources Defense Council	Center for Water Advocacy
Northwest Arctic Borough	Defenders of Wildlife
National Oceanic and Atmospheric Administration	World Wildlife Fund, U.S. Arctic Field Program
Alaska Wilderness League	Ocean Conservation Research
Center for Biological Diversity	Sierra Club
Eyak Preservation Council	Alaska Oil and Gas Association

9 LIST OF PREPARERS

Name	Education/Expertise	Contribution
Bureau of Ocean Energy Management		
Tamara Arzt	J.D./M.PA., NEPA, Environmental Law and Policy; 12 years of experience working on a variety of national, State, and local environmental policy and legal issues.	NEPA compliance reviewer
Gene Augustine	M.S., Biology, aquatic ecology concentration; B.S. Biology, environmental biology; 34 years of impact assessment and natural resource planning and management, including 30 years of experience in Alaska ecosystems.	NEPA coordinator for the Alaska region and technical review
Melissa Batum	M.S., Geology; 14 years of experience in the field of geology.	Project Coordinator, oil spill risk reform, Reviewer; physical environmental, geological hazards
Gregory Boland	M.S., Biological Oceanography; 37 years of experience in offshore environmental research, primarily benthic biology including coral reef and deep-sea ecology.	Reviewer; benthic habitat
Perry Boudreaux	M.S., Marine and Environmental Biology; 6 years of experience in wetland impact analysis and environmental assessment.	NEPA coordinator for the Gulf of Mexico region (Draft PEIS phase)
Jerry Brian	M.S., Applied Economics and Management with a focus on environmental and resource economics; 9 years of experience in socioeconomic research and environmental analysis.	Reviewer; socioeconomics
Megan Butterworth	M.S., Marine Science; B.S., Marine Science; B.S., Biology; 4 years of experience in biological oceanography and marine science.	Reviewer; human health impacts; marine mammals, reptiles, invertebrates, fish, EFH, Areas of Special Concern, water quality
Chris Campbell	M.A., Anthropology Cultural Resources; 40 years of experience in Alaskan anthropological research and field work; 33 years of NEPA experience.	Reviewer; socioeconomic, sociocultural, subsistence, environmental justice, archaeology
Bob Cameron	M.S., Meteorology; 30+ years of experience in meteorology and climate issues.	Reviewer; climate change

Name	Education/Expertise	Contribution
Sidney F. Chaky	M.A., Sociology; 19 years of experience.	Reviewer; land use and infrastructure, scenario
Douglas Choromanski	B.S., Geology; 30 years of experience in site clearance shallow hazards surveys.	Reviewer; site clearance surveys
Catherine Coon	M.S., Fishery Biology; 20 years of fisheries, habitat ecology, and spatial statistics of Alaska marine resources.	Reviewer; EFH, fish, lower trophics
James Craig	Ph.D., Geology; 29 years of experience in Alaska geology, E&D scenarios, costs, and fair market value evaluations.	Reviewer; provided exploration & development scenarios and schedules, inputs for both the MAG_PLAN and OECM models
Deborah Cranswick	32 years with OCS Program; 20 years NEPA; 9 years AK Region; 7 years EAS chief	NEPA compliance and OCS program reviewer
Christopher Crews	B.S., Wildlife Biology, minor Natural Resources; B.S. Biological Sciences; 6 years analytical experience (NEPA), 4 years landscape/grazing management	Reviewer; terrestrial mammals, pinnipeds
Jennifer Culbertson	Ph.D., Biology; 11 years of experience in coastal biology/chemistry and applied ecology	Reviewer; marine and coastal habitats; water quality; ecoregions
Jeffrey Denton	M.S., Wildlife Management; 38 years of experience in wildlife and wildlife habitat management, research, and environmental assessment.	Reviewer of biological resources
Nancy Deschu	B.A., Zoology/M.S., Civil Engineering (water resources).	Reviewer; water quality, fish, EFH
Norman Froomer	Ph.D., Geography and Environmental Engineering; 35 years of experience in coastal research and environmental assessment.	Project manager; purpose and need, alternatives, scenarios, marine spatial planning
Jeffrey Gleason	Ph.D., Zoology (avian ecology); 7 years of experience in analysis.	Reviewer; birds
Donald (Tre) W. Glenn, III	Ph.D., Environmental Engineering; 10 years of experience in impact analysis.	Reviewer; reptiles and marine mammals
Kelly Hammerle	MPA, Environmental Policy emphasis; B.S. Fisheries and Wildlife; 7 years of experience in environmental assessment.	Project manager, logistics coordinator, NEPA compliance, comment analysis and response, purpose and need, Alternatives, Reviewer

Name	Education/Expertise	Contribution
Larry Hartzog	M.S., Fisheries Limnology; 34 years of experience as environmental scientist preparing environmental impact analysis, endangered species coordination/ consultation and mitigation planning.	Reviewer; coastal and marine habitats and fish
Louis Heying	Obtaining B.S. in Geography and Environmental Planning; 4 months internship experience	Comment analysis
Dirk Herkhof	M.S., Meteorology; 36 years of experience in air quality impact analysis, meteorological and air quality studies, and NEPA.	Reviewer; air quality and climate; air emissions estimates
Tim Holder	Master of Urban Planning; 12 years of experience in urban planning, 19 years working for MMS in Alaska, 2 years for MMS in the GOM as a socioeconomic specialist, and 2 years in MMS/BOEMRE HQ as Arctic Liaison.	Coordinating with Alaska cooperating agencies; reviewer; sociocultural
Dan Holiday	Ph.D., Physical Sciences and Biological Oceanography; 8 years of experience in environmental modeling of primary productivity, and the biology and ecology of oceanographic and estuarine trophic systems.	Reviewer; lower trophics, vegetation and wetlands, oceanography, climate, and cumulative effects
Mark Jensen	M.S. Economics; 10 years of experience in economic analysis, research, and document preparation.	Reviewer; sociocultural, tourism/recreation, commercial/recreational fishing, Areas of Special Concern
Walter Johnson	Ph.D., Marine Science, Physical Oceanography; 30 years of experience in coastal oceanography and numerical ocean modeling; 22 years of oil spill modeling.	Reviewer; oil spill-related information
Brian Jordan	Ph.D., Natural Resource Science and Management; M.S., Forestry with specialization in wood science; B.A. Anthropology with a minor in classical studies; 18 years of experience in underwater archaeology, submerged cultural resource management, historic preservation, and marine policy.	Reviewer; sociocultural
Arie R. Kaller	Ph.D., Oceanography and Coastal Sciences; 11 years of experience in coastal vegetation and nekton research, and 2 years of NEPA document preparation.	Reviewer; coastal and marine habitats, EFH, and fish

Name	Education/Expertise	Contribution
Elizabeth Leonard	B.S., Agriculture; 28 years of agricultural, environmental, flood control, and navigation economic experience; 2 years as a Coastal Impact Assistance Project Officer, and 1 year of environmental science experience.	NEPA coordinator for the Gulf of Mexico region (Final PEIS phase)
Jill Lewandowski	M.S. Environmental Science and Policy; Ph.D. in progress; 15 years of experience in protected species assessment.	Reviewer; marine mammals, sea turtles, and acoustic environment
James Lima	Ph.D., Political Science; Socioeconomic Specialist; 25 years of experience in marine-related social science research, ocean and coastal management, and environmental assessment.	Reviewer; socioeconomics
Matthew Lux	B.S., Geography.	Reviewer; GIS data/maps
Robert Martinson	M.S., Zoology; B.S., Biological Science; 32 years NEPA and environmental compliance experience with particular emphasis on wetlands and aquatic and coastal ecology.	Reviewer and comment resolution for purpose and need; alternatives
Tershara Matthews	Ph.D. candidate, Coastal Sciences; 16 years of experience and research in coastal research.	Reviewer
Lori Monroe	J.D.; 26 years of legal experience, including preparing and reviewing legal documents, both environmental and non-environmental in nature.	Reviewer; legal review
Dave Moran	M.S., Zoology; 27 years professional experience in applied environmental science.	Reviewer; invertebrates and lower trophic levels
Constance Murphy	B.S., Soil Science; 16 years in environmental science, consulting, assessment, and remediation; 3 years in editing.	Administrative Record
Michelle K. Nannen	M.S., Marine Environmental Science; 10 years of experience in benthic and fisheries ecological studies and environmental assessment.	Reviewer; marine benthic habitats and marine pelagic habitats
S.E. O'Reilly	Ph.D., Environmental Geochemistry; 9 years of experience in mineralogy/ (bio) geochemistry as related to water quality.	Reviewer; water quality

Name	Education/Expertise	Contribution
Robert Peterson	M.S., Geology; 32 years offshore oil and gas experience; Chief Resource and Economic Analysis Section, AKOCS.	Reviewer; economic impacts
Richard Prentki	Ph.D., Chemical Oceanography; 30 years in Agency as OSRA Coordinator and COR.	Reviewer; geohazards
John Primo	Ph.D., MA Ecological and Applied Anthropology; marine, aquatic and coastal social science; experience with community and regional profiling (i.e., fishing communities, lakeside communities); experienced researcher; research portfolio and project management background.	Reviewer; sociocultural systems, environmental justice, and archaeological and historic resources
Virginia Raps	M.S., Aeronautical Science; B.S., Mathematics and Meteorology; 16 years of NEPA planning experience focusing on air quality impact analysis; 17 years of experience National Weather Service and Naval Weather Service surface and upper air analysis.	Reviewer; meteorology, climate change, and air quality impacts
Rick Raymond	M.S., Environmental Sciences; 23 years fish and wildlife analysis, wetlands, NEPA and environmental assessment.	Reviewer; avian sections for Alaska
Michael Routhier	J.D., M.S.E.L.; 3 years of experience in environmental planning and regulatory compliance.	NEPA reviewer
Mark Schroeder	M.S., Wildlife Biology; 25 years of government experience.	Reviewer
Lois Simenson	M.S., Environmental Science; 13 years of experience in coastal research and environmental assessment.	Coastal Zone Management Coordinator, BOEM Alaska
James Sinclair	M.S., Biological Sciences; 17 years of experience with coastal and offshore organisms and ecosystems research.	Reviewer; ecoregional settings
David Sire	B.S. Forest management; 23 years of experience in preparing and reviewing NEPA compliance documents.	NEPA compliance reviewer
Kimberly Skrupky	B.S., Environmental Science, Wildlife Conservation; 13 years of experience in environmental policy and marine biology.	Reviewer; marine mammals, sea turtles, and acoustic environment

Name	Education/Expertise	Contribution
Caryn Smith	M.S., Oceanography; 23 years of experience oil spill risk analysis and environmental assessment.	Reviewer; Alaska OCS region oceanography and sea ice, oil spill analysis
Bill Swears	M.A., English; 20 years of experience in reading, writing, and editing Federal technical documents and regulations.	Accuracy checking; language consistency: purpose and need, alternatives
Lisa Treichel	M.S., Technology Management, Environmental and Waste Management Option/B.S., Forestry and Wildlife; 24 years environmental experience.	NEPA compliance reviewer
Poojan Tripathi	M.S., Plant and Soil Science; 7 years of experience as an interdisciplinary environmental science with expertise hydrology, water quality, wetlands, and NEPA.	Comment analysis and response, Reviewer; water quality, purpose and need, alternatives
Sally Valdes	Ph.D., aquatic ecology; 25 years of science/science policy experience.	Reviewer; biological resources, commercial fisheries
Jeffrey Walker	B.S., Geological Engineering; 35 years of experience managing oil and gas projects on the Alaska OCS.	Reviewer
Sharon Warren	Program Analysis Officer; 10+ years of experience in review of environmental analyses related to land management and oil and gas activities in Alaska.	Reviewer
Kate Wedemeyer	M.S., Fisheries; M.S., Natural Resource Management; 24+ years in Alaskan fish and habitat management and related environmental assessments.	Reviewer; fisheries
Geoffrey Wikel	M.S., Marine Science; MPP; 11 years of experience in coastal geomorphology and oceanography.	Project manager, risk of a catastrophic discharge event, comment analysis and response, purpose and need, alternatives; Reviewer
James Woehr	Ph.D., Ecology, avian ecologist; 30+ years in avian research and management.	Reviewer; birds

APPENDIX A

GLOSSARY

This page intentionally left blank.

APPENDIX A

GLOSSARY

anadromous fish – fish that migrate up river from the sea to breed in fresh water.

anthropogenic – coming from human sources, relating to the effect of man on nature.

aphotic zone – zone where the levels of light entering through the surface are not sufficient for photosynthesis or for animal response.

archaeological interest – capable of providing scientific or humanistic understanding of past human behavior, cultural adaptation, and related topics through the application of scientific or scholarly techniques, such as controlled observation, contextual measurement, controlled collection, analysis, interpretation, and explanation.

archaeological resource – any material remains of human life or activities that are at least 50 years of age and that are of archaeological interest.

aromatic – applied to a class of organic compounds containing benzene rings or benzenoid structures.

attainment area – an area that is classified by the U.S. Environmental Protection Agency (USEPA) as meeting the primary or secondary ambient air quality standards for a particular air pollutant based on monitored data.

barrel – equal to 42 U.S. gallons or 158.99 liters.

benthic – bottom dwelling, associated with (in or on) the seafloor.

benthos – organisms that dwell in or on the seafloor, the organisms living in or associated with the benthic (or bottom) environment.

biological opinion – an appraisal from either the U.S. Fish and Wildlife Service (USFWS) or the National Marine Fisheries Service (NMFS) evaluating the impact of a proposed Federal action, if it is likely to jeopardize the continued existence of a listed species or result in the destruction or adverse modification of critical habitat, as required by Section 7 of the Endangered Species Act.

bivalves – general term for two-shelled mollusks (clams, oysters, scallops, mussels).

carrying capacity – the maximum number or weight of individuals that can exist in a given habitat; an appraisal from either USFWS or NMFS evaluating the impact of a proposed activity on endangered and threatened species.

cetacean – any of an order (Cetacea) of aquatic mostly marine mammals including the whales, dolphins, porpoises, and related forms with a large head, fusiform nearly hairless body, paddle-shaped forelimbs, vestigial concealed hind limbs, and horizontal flukes (tails).

chemosynthetic – organisms that obtain their energy from the oxidation of various inorganic compounds rather than from light (photosynthesis).

coastal wetlands – forested and nonforested habitats, mangroves, and all marsh islands that are exposed to coastal waters. Included in forested wetlands are hardwood hammocks, cypress-tupelogum swamps, and fluvial vegetation/bottomland hardwoods. Nonforested wetlands include fresh, brackish, and salt marshes. These areas directly contribute to the high biological productivity of coastal water by input of detritus and nutrients, by providing nursery and feeding areas for shellfish and finfish, by serving as habitat for many birds and other animals, and by providing waterfowl hunting and fur trapping.

coastal zone – the coastal waters (including the lands therein and thereunder) and the adjacent shore lands (including the waters therein and thereunder) strongly influenced by each other and in proximity to the shorelines of the several coastal States; and including islands, transitional and intertidal areas, salt marshes, wetlands, and beaches. The zone extends seaward to the outer limit of the United States territorial sea. The zone extends inland from the shorelines only the extent necessary to control shore lands, the uses of which have a direct and significant impact on the coastal waters. Excluded from the coastal zone are lands the use of which are by law subject to the discretion of or which are held in trust by the Federal Government, its officers, or agents. (The State land and water area officially designated by the State as “coastal zone” in its State coastal zone program as approved by the U.S. Department of Commerce under the Coastal Zone Management Act [CZMA].)

coastal zone consistency review – State review of direct Federal activities or private individual activities requiring Federal licenses or permits, and outer continental shelf (OCS) plans pursuant to the CZMA to determine if the activity is consistent with the enforceable policies of the State’s federally approved Coastal Zone Management (CZM) program.

continental shelf – a broad, gently sloping, shallow feature extending from the shore to the continental slope, generally considered to exist to the depth of 200 m (656 ft); that part of the continental margin between the continental shelf and the continental rise (or oceanic trench).

continental slope – a relatively steep, narrow feature paralleling the continental shelf; the region in which the steepest descent to the ocean bottom occurs.

contingency plan – a plan for possible offshore emergencies prepared and submitted by the oil or gas operator as part of the plan of development and production, and which may be required for part of the plan of exploration.

critical habitat – a designated area that is essential to the conservation of an endangered or threatened species that may require special management considerations or protection.

crude oil – petroleum in its natural state as it emerges from a well, or after it passes through a gas-oil separator but before refining or distillation.

crustaceans – any aquatic invertebrate with jointed legs, such as crabs, shrimp, lobster, barnacles, amphipods, isopods, etc.; primarily an aquatic group.

deferral – action taken by the Secretary of the Interior or delegated official to remove certain areas/blocks from leasing.

delineation well – an exploratory well drilled to define the areal extent of a field. Also referred to as an "expendable well."

development – activities that take place following discovery of minerals in paying quantities, including geophysical activity, drilling, platform construction, and operation of all onshore support facilities, and that are for the purpose of ultimately producing the minerals discovered.

development and production plan (DPP) – a plan describing the specific work to be performed on an offshore lease, including all development and production activities that the lessee proposes to undertake during the time period covered by the plan and all actions to be undertaken up to and including the commencement of sustained production. The plan also includes descriptions of facilities and operations to be used, well locations, current geological and geophysical information, environmental safeguards, safety standards and features, time schedules, and other relevant information. All lease operators are required to formulate and obtain approval of such plans by the Bureau of Ocean Energy Management (BOEM) before development and production activities may begin; requirements for submittal of DPP are wholly identified in 30 CFR 250.34.

development well – a well drilled into a known producing formation in a previously discovered field, to be distinguished from a wildcat, exploratory, or offset well.

dilution – the reduction in the concentration of dissolved or suspended substances by mixing with water.

discharge – something that is emitted; flow rate of a fluid at a given instant expressed as volume per unit of time.

dispersion – a distribution of finely divided particles in a medium.

drillship – a self-propelled, self-contained vessel equipped with a derrick amidships for drilling wells in deep water.

drilling mud – a special mixture of clay, water, or refined oil, and chemical additives pumped downhole through the drill pipe and drill bit. The mud cools the rapidly rotating bit, lubricates the drill pipe as it turns in the wellbore, carries rock cuttings to the surface, serves to keep the hole from crumbling or collapsing, and provides the weight or hydrostatic head to prevent extraneous fluids from entering the wellbore and to control downhole pressures that may be encountered (drilling fluid).

effluent – the liquid waste of sewage and industrial processing.

emission offset – emission reductions obtained from facilities, either onshore or offshore, other than the facility or facilities covered by the proposed exploration plan or development and production plan. The emission reductions achieved must be sufficient so that there will be no net increase in emissions for the area.

endangered and threatened species (endangered species) – any species that is in danger of extinction throughout all or a significant portion of its range and has been officially listed by the appropriate Federal or State agency; a species is determined to be endangered (or threatened) because of any of the following factors: (1) the present or threatened destruction, modification, or curtailment of its habitat or range; (2) over utilization for commercial, sporting, scientific, or educational purposes; (3) disease or predation; (4) the inadequacy of existing regulatory mechanisms; or (5) other natural or man-made factors affecting its continued existence.

environmental assessment – a concise public document required by the National Environmental Policy Act of 1969 (NEPA). In the document, a Federal agency proposing (or reviewing) an action provides evidence and analysis for determining whether it must prepare an environmental impact statement (EIS) or whether it finds there is no significant impact (i.e., Finding of No Significant Impact [FONSI]).

environmental effect – a measurable alteration or change in environmental conditions.

environmental impact statement (EIS) – a statement required by the NEPA or similar State law in relation to any major action significantly affecting the environment; a NEPA document.

essential habitat – specific areas crucial to the conservation of a species that may necessitate special considerations.

essential fish habitat (EFH) – those waters and substrate necessary to fish for spawning, breeding, feeding, or growth to maturity. This includes areas that are currently or historically used by fish, or that have substrate such as sediment, hard bottom, bottom structures, or associated biological communities required to support a sustainable fishery.

estuary – semi-enclosed coastal body of water that has a free connection with the open sea and within which seawater is measurably diluted with freshwater.

Exclusive Economic Zone (EEZ) – the maritime region adjacent to the territorial sea, extending 200 nautical miles from the baseline of the territorial sea, in which the United States has exclusive rights and jurisdiction over living and nonliving natural resources.

exploration – the process of searching for minerals. Exploration activities include:
(1) geophysical surveys where magnetic, gravity, seismic, or other systems are used to detect or infer the presence of such minerals; and (2) any drilling, except development drilling, whether on or off known geological structures. Exploration also includes the drilling of a well in which a discovery of oil or natural gas in paying quantities is made, and the drilling, after such a discovery, of any additional well that is needed to delineate a reservoir and to enable the lessee to determine whether to proceed with development and production.

exploration plan (EP) – a plan submitted by a lessee (30 CFR 250.33) that identifies all the potential hydrocarbon accumulations and wells that the lessee proposes to drill to evaluate the accumulations within the lease or unit area covered by the plan. All lease operators are required to obtain approval of such a plan by a BOEM Regional Supervisor before exploration activities may commence.

exploratory well – a well drilled in unproven or semi-proven territory for the purpose of ascertaining the presence underground of a commercially producible deposit of petroleum or natural gas.

fault – a fracture in the earth's crust accompanied by a displacement of one side of the fracture with respect to the other.

fauna – the animals of a particular region or time.

fixed or bottom founded – permanently or temporarily attached to the seafloor.

flyway – an established air route of migratory birds.

formation – a bed or deposit sufficiently homogeneous to be distinctive as a unit. Each different formation is given a name, frequently as a result of the study of the formation outcrop at the surface and sometimes based on fossils found in the formation.

fugitive emissions – emission into the atmosphere that could not reasonably pass through a stack, chimney, vent or other functionally equivalent opening.

geochemical – of or relating to the science dealing with the chemical composition of and the actual or possible chemical changes in the crust of the earth.

geologic hazard – a feature or condition that, if unmitigated, may seriously jeopardize offshore oil and gas exploration and development activities. Mitigation may necessitate special engineering procedures or relocation of a well.

geophysical – of or relating to the physics of the earth, especially the measurement and interpretation of geophysical properties of the rocks in an area.

geophysical data – facts, statistics, or samples that have not been analyzed or processed, pertaining to gravity, magnetic, seismic, or other surveys/systems.

geophysical survey – the exploration of an area during which geophysical properties and relationships unique to the area are measured by one or more geophysical methods.

habitat – a specific type of place that is occupied by an organism, a population, or a community; a specific type of place defined by its physical or biological environment that is occupied by an organism, a population, or a community.

harassment – an intentional or negligent act or omission that creates the likelihood of injury to wildlife by annoying it to such an extent as to significantly disrupt normal behavioral patterns that include, but are not limited to, feeding or sheltering.

haulout area – specific locations where pinnipeds come ashore and concentrate in numbers to rest, breed, and/or bear young.

herbivores – animals whose diet consists of plant material.

hydrocarbon – any of a large class of organic compounds containing primarily carbon and hydrogen; comprising paraffins, olefins, members of the acetylene series, alicyclic hydrocarbons, and aromatic hydrocarbons; and occurring, in many cases, in petroleum, natural gas, coal, and bitumens.

hypothermia – subnormal temperature of the body, usually due to excessive heat loss.

hypoxia – depressed levels of dissolved oxygen in water, usually resulting in decreased metabolism.

incidental take – take of a threatened or endangered fish or wildlife species that results from, but is not the purpose of, carrying out an otherwise lawful activity conducted by a Federal agency or applicant (see take).

indirect effects – effects caused by activities that are stimulated by an action but not directly related to it.

industry infrastructure – the facilities associated with oil and gas development (e.g., refineries, gas processing plants, etc.).

information to lessees – information included in the Notice of Sale to alert lessees and operators of special concerns in or near a sale area of regulatory provisions enforceable by Federal or State agencies.

jack-up rig – a barge-like floating platform with legs at each corner that can be lowered to the sea bottom to raise the platform above the water; a drilling platform with retractable legs that can be lowered to the sea bottom to raise the platform above the water.

landfall – the site at which a marine pipeline comes to shore.

lay barge – a shallow-draft, barge-like vessel used in the construction and laying of underwater pipelines.

lighter – a barge or small tanker used to move cargo from a large ship to port; also, to transport by lighter.

macroinvertebrate – animals such as worms, clams, or crabs that are large enough to be seen without the aid of a microscope.

mariculture – the breeding or growth of marine animals and plants to increase their stocks.

marine sanctuary – area protected under the Marine Protection, Research, and Sanctuaries Act of 1972.

marshes – persistent, emergent nonforested wetlands characterized by vegetation consisting predominantly of cordgrasses, rushes, and cattails.

microcrustacean – any relatively small crustacean (may range from microscopic to slightly over one centimeter in size) including organisms such as beach hoppers (amphipods), copepods, ostracods, isopods, and mysids.

military warning area – an area established by the U.S. Department of Defense within which the public is warned that military activities take place.

minerals – as used in this document, minerals include oil, gas, sulfur, and associated resources, and all other minerals authorized by an Act of Congress to be produced from public lands, as defined in Section 103 of the Federal Land Policy and Management Act of 1976.

mollusks – animal phylum characterized by soft body parts including clams, mussels, snails, squid, and octopus.

mud – the liquid circulated through the wellbore during rotary drilling operations. In addition to its function of bringing cuttings to the surface, drilling mud cools and lubricates the bit and drill stem, protects against blowouts by holding back subsurface pressures, and deposits a mud cake on the wall of the borehole to prevent loss of fluids to the formations; also called drilling mud or drilling fluid; also a sediment designation composed of silt and clay-sized particles.

mysids – small shrimp-like organisms, also known as opossum shrimp due to their method of egg incubation.

natural gas – hydrocarbons that are in a gaseous phase under atmospheric conditions of temperature and pressure.

nearshore waters – offshore open waters that extend from the shoreline out to the limit of the territorial seas (12 nautical miles).

nonattainment area – an area that is shown by monitoring data or air quality modeling calculations to exceed primary or secondary ambient air quality standards established by the USEPA.

offloading – another name for unloading; offloading refers more specifically to liquid cargo, crude oil, and refined products.

oil spill contingency plan – a plan submitted by the lease or unit operator along with or prior to a submission of a plan of exploration or a development/production plan that details provisions for fully defined specific actions to be taken following discovery and notification of an oil spill occurrence.

operational discharge – a release of oil that is part of the routine operation of a function.

operator – the person or company engaged in the business of drilling for, producing, or processing oil, gas, or other minerals and recognized by BOEM as the official contact and responsible for the lease activities or operations.

organic matter – material derived from living plant or animal organisms.

Outer Continental Shelf (OCS) – all submerged lands that comprise the continental margin adjacent to the United States and seaward of State offshore lands.

petroleum – an oily, flammable, bituminous liquid that occurs in many places in the upper strata of the earth, either in seepages or in reservoirs; essentially a complex mixture of hydrocarbons of different types with small amounts of other substances; any of various substances (as natural gas or shale oil) similar in composition to petroleum.

phytoplankton – plant (photosynthetic) plankton; microscopic, freefloating, photosynthetic organisms that drift passively in the water.

pinniped – any of a suborder (Pinnipedia) of aquatic carnivorous mammals (e.g., seals, sea lions, sea otters, walruses) with all four limbs modified into flippers.

plankton – passively floating or weakly motile aquatic plants and animals.

planning area – a subdivision of an offshore area used as the initial basis for considering blocks to be offered for lease in the U.S. Department of the Interior’s areawide offshore oil and gas leasing program.

platform – a steel, concrete, or gravel structure from which offshore development wells are drilled.

postlease – any activity on a block or blocks after the issuance of a lease on said block or blocks.

potential impact (effect) – the range of alterations or changes to environmental conditions that could be caused by an action.

primary production – production of carbon by a plant through photosynthesis over a given period of time; oil and gas production that occurs from the reservoir energy inherent in the formation.

produced water – total water produced from the oil and gas extraction process; the water may be discharged after treatment or reinjected; production water or production brine.

production – activities that take place after the successful completion, by any means, of the removal of minerals, including such removal, field operations, transfer of minerals to shore, operation monitoring, maintenance, and workover drilling.

production well – a well that is drilled for the purpose of producing oil or gas reserves; it is sometimes termed a development well.

prospect – an untested geologic feature having the potential for trapping and accumulating hydrocarbons.

recoverable reserves – portion of the identified oil or gas resources that can be economically extracted under current technological constraints.

recoverable resource estimate – an assessment of oil and gas resources that takes into account the fact that physical and technological constraints dictate that only a portion of resources or reserves can be brought to the surface.

refining – fractional distillation, usually followed by other processing (e.g., cracking).

reserves – portion of the identified oil or gas resource that can be economically extracted.

reservoir – a subsurface, porous, permeable rock body in which hydrocarbons have accumulated.

resources – concentrations of naturally occurring solid, liquid, or gaseous materials in or on the earth's crust some part of which is currently or potentially extractable. These include both identified and undiscovered resources.

rig – a structure used for drilling an oil or gas well.

right-of-way – a legal right of passage, an easement; the specific area or route for which permission has been granted to place a pipeline, (and) ancillary facilities, and for normal maintenance thereafter.

rookery – the nesting or breeding grounds of gregarious (i.e., social) birds or mammals; also a colony of such birds or mammals.

sale area – the geographical area of the OCS being offered for lease for the exploration, development, and production of mineral resources.

scoping – the process prior to EIS preparation to determine the range and significance of issues to be addressed in the EIS for each proposed major Federal action.

seagrass beds – more or less continuous mats of submerged, rooted marine flowering vascular plants occurring in shallow tropical and temperate waters. Seagrass beds provide habitat, including breeding and feeding grounds, for adults and/or juveniles of many of the economically important shellfish and finfish.

sediment – material that has been transported and deposited by water, wind, glacier, precipitation, or gravity; a mass of deposited material.

seeps (hydrocarbon) – gas or oil that reaches the surface along bedding planes, fractures, unconformities, or fault planes through connected porous rocks.

seismic – pertaining to, characteristic of, or produced by earthquakes or earth vibration; having to do with elastic waves in the earth; also geophysical when applied to surveys.

semisubmersible – a floating offshore drilling structure that has hulls submerged in the water but not resting on the seafloor.

shunting – a method used in offshore oil and gas drilling activities where expended drill cuttings and fluids are discharged near the ocean seafloor rather than at the surface, as in the case of normal offshore drilling operations.

significant archaeological resource – those archaeological resources that meet the criteria of significance for eligibility to the *National Register of Historic Places* as defined in 36 CFR 60.4 or its successor.

stipulations – specific measures imposed upon a lessee that apply to a lease. Stipulations are attached as a provision of a lease; they may apply to some or all tracts in a sale. For example, a stipulation might limit drilling to a certain time period of the year or certain areas.

subsistence uses – the customary and traditional uses by rural residents of wild, renewable resources for direct personal or family consumption as food, shelter, fuel, clothing, tools, or transportation; for making and selling of handcraft articles out of nonedible byproducts of fish and wildlife resources taken for personal or family consumption; for barter, or sharing for personal or family consumption; and for customary trade.

supply boat – a vessel that ferries food, water, fuel, and drilling supplies and equipment to a rig and returns to land with refuse that cannot be disposed of at sea.

take – to harass, harm, pursue, hunt, shoot, wound, kill, capture, or collect a threatened or endangered fish or wildlife species, or attempt to engage in any such conduct. (Harm includes habitat modification that impairs behavioral patterns, and harass includes actions that create the likelihood of injury to an extent that normal behavior patterns are disrupted.)

threatened species – any species that is likely to become an endangered species within the foreseeable future throughout all or a significant portion of its range, and which has been officially listed by the appropriate Federal agency. Criteria for determination of threatened status can be found under "endangered species."

trawl – a large, tapered fishing net of flattened, conical shape that is typically towed along the sea bottom.

trophic – trophic levels refer to the hierarchy of organisms from photosynthetic plants to carnivores, such as man; feeding trophic levels refer to the hierarchy of organisms from photosynthetic plants to carnivores in which organisms at one level are fed upon by those at the next higher level (e.g., phytoplankton eaten by zooplankton eaten by fish).

turbidity – reduced water clarity resulting from the presence of suspended matter.

vascular plants – plants containing food and water conducting structures; higher plants that reproduce by seeds.

volatile organic compound (VOC) – any reactive organic compound that is emitted to the atmosphere as a vapor. The definition does not include methane.

vulnerability – the likelihood of being damaged by external influences. Vulnerability implies sensitivity of a system plus the risk of a damaging influence occurring.

weathering – the aging of oil due to its exposure to the atmosphere and environment causing marked alterations in its physical and chemical makeup.

wetlands – areas periodically inundated or saturated by surface or groundwater and predominantly supporting vegetation typically adapted for life in saturated soil conditions.

zooplankton – animal plankton, mostly dependent on phytoplankton for its food source; small, free-floating animals, may be passive drifters or motile, dependent on phytoplankton as a food source.

APPENDIX B

ASSUMED MITIGATION AND OTHER PROTECTIVE MEASURES

This page intentionally left blank.

APPENDIX B

ASSUMED MITIGATION AND OTHER PROTECTIVE MEASURES

All Bureau of Ocean Energy Management (BOEM) sale proposals include rules and regulations prescribing environmental controls to be imposed on lease operators. Lease stipulations, Outer Continental Shelf (OCS) regulations, and other measures provide a regulatory base for implementing environmental protection on leases issued as a result of a sale. The BOEM Environmental Studies Program and the analyses and monitoring of activities in a sale area provide information used in formulating the agency's regulatory control over the activities that occur during the life of the leases.

The Bureau of Safety and Environmental Enforcement (BSEE) has broad permitting and monitoring authority to ensure safe operations and environmental protection. Use of the best available and safest technologies during exploration, development, and production, as well as the adopted stipulations, are just a few of the measures designed to prevent environmental damage. BSEE also monitors operations after drilling has begun and carries out periodic inspections of facilities (in certain instances, in conjunction with other Federal agencies such as the U.S. Environmental Protection Agency) to ensure safe and clean operations over the life of the leases.

The analyses in the environmental impact statement assume the implementation of all impact-reducing mechanisms required by statute or regulation. In addition, the impact analysis assumes that sale-specific stipulations that were commonly adopted in past lease sales are in effect. The following is a brief description of the sale-specific stipulations or other impact-reducing mechanisms assumed in the analysis of potential effects of the proposed action. Because over 100 individual mitigations can be applied to exploration and development activities in the Gulf of Mexico region, only common lease stipulations are described individually. Both the lease stipulations and other protective environmental measures issued through Information to Lessees (ITL) in Alaska are described.

B.1 GULF OF MEXICO REGION

B.1.1 Lease Stipulations

B.1.1.1 Topographic Features

This stipulation designates a "No Activity Zone" around several underwater topographic features commonly called "banks" whose crests may contain biological communities including corals. The No Activity Zone is designed to protect the biota of these features from adverse effects of routine offshore oil and gas activities by preventing the emplacement of platforms, or the anchoring of service vessels or mobile drilling units, directly on the banks and requiring that drilling discharges be shunted in such a manner that they do not settle on the biota.

B.1.1.2 Live Bottom (Pinnacle Trend)

This stipulation is intended to protect the pinnacle trend area and the associated hard-bottom communities from damage from oil and gas activities. If the required live bottom survey report determines that the live bottom may be adversely impacted by the proposed activity, certain measures, such as relocation or monitoring, may be required.

B.1.1.3 Live Bottom (Low Relief)

This stipulation is intended to protect hard-bottom communities not associated with bathymetric features on the sea bottom. Biological communities such as seagrass beds, sponges, and corals may occur on smooth topography. If the required live bottom survey report determines that the live bottom may be adversely impacted by the proposed activity, certain measures, such as relocation or monitoring, may be required.

B.1.1.4 Oil-Spill Response (Eastern Gulf of Mexico)

This stipulation is intended to minimize the risk of oil spills reaching Florida State waters by requiring the staging of state-of-the-art mechanical oil-spill response equipment within specified timeframes and by requiring that oil dispersant chemicals and equipment be maintained in a state of readiness.

B.1.1.5 Military Areas

This stipulation has three sections: hold harmless, electromagnetic emissions, and operational. The hold harmless section serves to protect the U.S. Government from liability in the event of an accident involving a lessee and military activities. The electromagnetic emissions section requires the lessee and its agents to reduce and curtail the use of equipment emitting electromagnetic energy in certain areas. This reduces the impact of offshore oil and gas activities on military communications and missile testing. The operational section requires prior notification of the military when offshore oil and gas activities are scheduled within a military use area to assist in scheduling activities and to prevent potential conflicts.

A second stipulation requires the evacuation, upon the receipt of a directive from the BSEE Regional Director, of all personnel from all structures on the lease and the shutting in and securing of all wells and other equipment, including pipelines, on the lease.

Two additional stipulations are applied to leases in the Eastern Gulf of Mexico Planning Area only. In cooperation with the U.S. Air Force, “drilling windows” are established for

6-month periods during which exploratory operations or workover operations may be conducted on leases. This time-sharing arrangement allows military operations to proceed in areas containing leases without being disrupted by oil and gas activities, and without undue disturbance to the exploratory activity and workover operations.

An additional stipulation has been included for the Western Gulf of Mexico Planning Area only. The Naval Mine Warfare Stipulation is intended to eliminate potential impacts from multiple-use conflicts in the Western Planning Area, Mustang Island Area East Addition, Blocks 732, 733, and 734. The U.S. Department of the Navy has identified these blocks as needed for testing equipment and for training mine warfare personnel.

B.1.2 Other Mitigations Categories

B.1.2.1 Air Quality

This category includes eight mitigations that apply to offshore exploration, development, and pipeline activities.

B.1.2.2 Archaeology

There are 18 mitigations describing procedures for conducting archaeological surveys before bottom-disturbing activities can occur on a lease; the procedures operators must follow these to avoid impacts on potential prehistoric and shipwreck sites.

B.1.2.3 Artificial Reefs

Five mitigations exist to avoid impacts on artificial reef sites and permit areas.

B.1.2.4 Chemosynthetic Communities

There are five mitigations to avoid impacts on chemosynthetic communities in deepwater areas of the Gulf of Mexico.

B.1.2.5 Coastal Zone Management

Five mitigations describe the conditions of approval in each of the Gulf Coast States.

B.1.2.6 Topographic Features, Live Bottoms, and the Flower Garden Banks

There are 13 mitigations to protect the health and stability of these benthic features.

B.1.2.7 Miscellaneous Mitigations

These apply to space-use conflicts, oil spill preparedness, remote operating vehicle surveys in deep water, essential fish habitat, hydrogen sulfide, and other issues.

B.2 ALASKA REGION

B.2.1 Lease Stipulations

B.2.1.1 Orientation Program

This stipulation is designed to provide an increased understanding of, and appreciation for, local community values, customs, and lifestyles of Alaska Native communities. The required orientation program must be designed in sufficient detail to inform individuals working on OCS projects of specific types of environmental, social, and cultural concerns in the area. The orientation program must provide information to industry employees on protected species, biological resources used for commercial and subsistence purposes, archaeological resources of the area and appropriate ways to protect them, and reducing industrial noise and disturbance effects on marine mammals and marine and coastal birds. The program must also include information about avoiding conflicts with subsistence activities.

B.2.1.2 Protection of Biological Resources

This stipulation provides for identifying and protecting previously unknown important or unique biological populations or habitats that may occur in a lease area. If previously unknown sensitive biological resources are identified during the conduct of lease activities under an approved Plan of Exploration or Development and Production Plan, the lessee will be required to modify operations, if necessary, to minimize adverse impacts on those biological populations or habitats.

B.2.1.3 Protection of Fisheries (Cook Inlet Planning Area)

This stipulation is designed to minimize spatial conflicts between OCS activities and commercial, sport, and subsistence fishing activities. Lease-related uses will be restricted, if determined necessary by the BOEM Alaska Regional Supervisor for Field Operations, to prevent unreasonable conflicts with fishing operations. The stipulation requires the lessee to review planned exploration and development activities (including plans for seismic surveys, drilling rig transportation, or other vessel traffic) with potentially affected fishing organizations, subsistence communities, and port authorities to prevent unreasonable fishing gear conflicts.

B.2.1.4 Transportation of Hydrocarbons

This stipulation informs lessees that (1) BOEM reserves the right to require the placement of pipelines in certain designated management areas, (2) pipelines must be designed and constructed to withstand the hazardous conditions that may be encountered in the sale area, and (3) pipeline construction and associated activities must comply with regulations. This stipulation requires the use of pipelines if (1) pipeline rights-of-way can be determined and obtained; (2) laying such pipelines is technologically feasible and environmentally preferable; and (3) in the opinion of the lessor, pipelines can be laid without net social loss, taking into account any incremental costs of pipelines over alternative methods of transportation and any incremental benefits in the form of increased environmental protection or reduced multiple-use conflicts.

B.2.1.5 Industry Site-Specific Monitoring Program for Marine Mammal Subsistence Resources (Arctic Planning Areas)

This stipulation requires industry to conduct a site-specific monitoring program to determine when marine mammals are present in the vicinity of exploration operations, including ancillary seismic surveys, during periods of subsistence use. The monitoring program and review process required for Marine Mammal Protection Act authorization will satisfy the requirements of this stipulation. The monitoring plan must provide for reports on marine mammal sightings and the extent of observed behavioral effects because of lease activities. It also provides a formal mechanism for the oil and gas industry to coordinate logistics activities with the BOEM Bowhead Whale Aerial Survey Program. The stipulation provides for an opportunity for recognized co-management organizations to review and comment on the proposed monitoring plan before BOEM approval. The stipulation requires the lessee to fund an independent peer review of the proposed monitoring plan and the draft reports on the results of the monitoring program. No monitoring program will be required if the BOEM Alaska Regional Supervisor for Field Operations, in consultation with the appropriate agencies and co-management organizations, determines that a monitoring program is not necessary based on the size, timing, duration, and scope of the proposed operations.

B.2.1.6 Conflict Avoidance Mechanisms to Protect Subsistence Whaling and Other Marine Mammal Subsistence Activities (Arctic Planning Areas)

This stipulation is designed to reduce disturbance effects on Alaska Native subsistence practices from OCS oil and gas industry activities by requiring industry to make reasonable efforts to conduct all aspects of their operations in a manner that recognizes Alaska Native subsistence requirements and avoids conflict with local subsistence harvest activities. The stipulation applies to both on-lease operations and to support activities, such as vessel and aircraft traffic. The stipulation also requires industry to consult with directly affected subsistence communities, the North Slope Borough, and the recognized co-management organizations to discuss possible siting and timing conflicts and to assure that exploration, development, and production activities do not result in unreasonable conflicts with subsistence whaling and other subsistence harvests. The stipulation also provides a mechanism to address unresolved conflicts between the oil and gas industry and subsistence activities.

B.2.1.7 Measures to Minimize Effects on Spectacled and Steller's Eiders During Exploration Activities (Arctic Planning Areas)

This stipulation is designed to minimize the likelihood that spectacled or Steller's eiders will strike drilling structures or vessels. The stipulation requires specific lighting protocols for structures and vessels, a plan for recording and reporting bird strikes, and avoidance of specified blocks by OCS-related vessels engaged in exploration activities.

B.3 INFORMATION TO LESSEE

Several ITLs have been developed to notify lessees and operators about environmental, social, and cultural concerns.

Past ITLs have provided lessees information or advisories on the following:

- Community participation in operations planning;
- Bird and marine mammal protection laws;
- Endangered, threatened, and candidate species and designated critical habitat under the Endangered Species Act;
- Consideration in Oil Spill Response Plans of river deltas of the Beaufort Sea coastal plain that have been identified by the U.S. Fish and Wildlife Service as special habitats for bird nesting, fish overwintering, or for other species' use;
- Possible prohibition of shore-based facilities in river deltas that have been identified as special habitats;
- Potential effects of seismic surveys on marine mammals and subsistence activities;
- Requirements on the availability of bowhead whales for subsistence whaling;
- The BOEM bowhead whale aerial monitoring program;

- The possibility that BOEM may limit or modify operations if they could result in significant effects on the availability of bowhead whales for subsistence use;

- Requirements for protection of polar bears and to limit potential encounters and interactions between lease operations and polar bears;

- Requirements for archaeological and shallow geologic hazards reports in support of exploration and development plans;

- Navigational safety;

- Requirements for air quality permits;

- Designated Class I air quality areas;

- Requirements for National Pollutant Discharge Elimination System permits for discharge of produced water, drilling fluids, and cuttings;

- Sensitive areas to be considered when developing oil-spill contingency plans;

- Requirements for BSEE approval of Oil Spill Reponses Plans;

- Requirements for establishing and maintaining oil-spill financial responsibility;

- BOEM encouragement of the use of existing pads and islands wherever feasible;

- The importance of the area around Cross Island for Nuiqsut subsistence whaling activities;

- Requirements for mitigation of unreasonable conflicts with subsistence activities; and

- BOEM encouragement of industry to establish of a Good Neighbor Policy to provide an immediate compensation system to minimize disruption to subsistence activities and provide resources to relocate subsistence hunters to alternate hunting areas or provide temporary food supplies in the event an accidental oil spill adversely affects the harvest of marine subsistence resources.

B.4 OTHER PROTECTIVE MEASURES APPLIED THROUGH LAWS AND REGULATIONS

BOEM also assumes in this programmatic environmental impact statement (PEIS), for analytical purposes only, other protective measures that are most commonly applied through laws and regulations. BOEM assumes OCS activities will occur in compliance with all laws and regulations and that other protective measures will be applied through those laws and regulations. Though not exhaustive, below is a list of those measures that are most applicable to the resource areas fully analyzed in this PEIS. For more information on the related laws and regulations, see Appendix C. For more information on how these protective measures were analytically utilized in this PEIS, see Chapter 4.

- National Ambient Air Quality Standards (NAAQS) as required by the Clean Air Act and administered by the Environmental Protection Agency (EPA).

- Prevention of Significant Deterioration (PSD) Program for air pollutant concentrations as administered by the EPA.

- National Pollution Discharge Elimination System (NPDES) permitting as administered by the EPA.

- Liability and compensation for oil spill-related damages as required by the Oil Pollution Act (OPA) and administered by the U.S. Coast Guard.

- Endangered Species Act (ESA) and Marine Mammal Protection Act (MMPA) mitigation measures as applied through ESA and MMPA consultations with U.S. Fish and Wildlife Service (USFWS) and National Marine Fisheries Service (NMFS) aimed to ensure the protection of any endangered or threatened species, marine mammal, and their critical habitat. Examples of ESA/MMPA protective measures for OCS oil and gas activities are (but are not limited to):
  - Pre-activity survey requirements,
  - Activity ramp-up procedures,
  - Marine mammal observers,
  - Speed restrictions,
  - Activity exclusion zones, and
  - Incidental take authorizations.

- Archaeological survey and mitigation as required by the National Historic Preservation Act, State Historic Preservation Offices, and BOEM and BSEE regulations.

- Fishery management plans as required by the Magnuson-Stevens Fishery Conservation and Management Act (FCMA).

- Essential Fish Habitat designations and protections as required by FCMA and administered by NMFS.

This page intentionally left blank.

APPENDIX C

FEDERAL LAWS AND EXECUTIVE ORDERS

This page intentionally left blank.

APPENDIX C

FEDERAL LAWS AND EXECUTIVE ORDERS

C.1 FEDERAL LAWS

C.1.1 The Outer Continental Shelf Lands Act (OCSLA)

The Outer Continental Shelf Lands Act of 1953 (OCSLA) authorized the Secretary of the Interior to grant mineral leases and to prescribe regulations governing oil and gas activities on Outer Continental Shelf (OCS) lands. The OCSLA defines the OCS as:

> *. . . all submerged lands lying seaward and outside of the areas lands beneath navigable waters as defined in section 2 of the Submerged Lands Act and of which the subsoil and seabed appertain to the United States and are subject to its jurisdiction and control.*

The pertinent provision of the Submerged Lands Act defines "navigable waters" as:

> *. . . all lands permanently or periodically covered by tidal waters up to but not above the line of mean high tide and seaward to a line three geographical miles distant from the coast line of each such State and to the boundary line of each such State where in any case such boundary as it existed at the time such State became a member of the Union, or as heretofore approved by Congress, extends seaward (or into the Gulf of Mexico) beyond three geographical miles* . . . .

Under the OCSLA, the U.S. Department of the Interior (USDOI) is required to:

- Manage the orderly leasing, exploration, development, and production of oil and gas resources on the Federal OCS;
- Ensure the protection of the human, marine, and coastal environments;
- Ensure that the public receives a fair and equitable return for these resources; and
- Ensure that free-market competition is maintained.

Within the USDOI, the Bureau of Ocean Energy Management (BOEM) and Bureau of Safety and Environmental Enforcement (BSSE) are charged with the responsibility of managing and regulating the development of OCS oil and gas resources in accordance with the provisions of the OCSLA. BOEM and BSEE oil and gas operating regulations are presented in Chapter 30, Code of Federal Regulations (CFR), Parts 250 and 550.

C.1.2 The National Environment Policy Act (NEPA)

The National Environmental Policy Act of 1969 (NEPA) is the foundation of environmental policymaking in the United States. The NEPA process is intended to help public officials make decisions based on an understanding of environmental consequences and take actions that protect, restore, and enhance the environment. The NEPA established two primary mechanisms for this purpose:

- The Council on Environmental Quality (CEQ) was established to advise Agencies on the environmental decision making process and to oversee and coordinate the development of Federal environmental policy.

- Agencies must include an environmental review process early in the planning for proposed actions.

The CEQ issued regulations in 1978 implementing NEPA. The regulations include procedures to be used by Federal Agencies for the environmental review process. These regulations provide for the use of the NEPA process to identify and assess reasonable alternatives to proposed actions that avoid or minimize adverse effects of these actions upon the quality of the human environment. Scoping is used to identify the scope and significance of important environmental issues associated with a proposed Federal action through coordination with Federal, State, and local agencies; the general public; and any interested individual or organization prior to the development of an impact statement. The process also identifies and eliminates from further detailed study issues that are not significant or that have been covered by prior environmental review.

The NEPA requires all Federal Agencies to use a systematic, interdisciplinary approach to protect the human environment. Such an approach ensures the integrated use of natural and social sciences in any planning and decision making that may have an impact on the environment. The NEPA also requires the preparation of a detailed environmental impact statement (EIS) on any major Federal action that may have a significant impact on the environment. The EIS must address any adverse environmental effects that cannot be avoided or mitigated, alternatives to the proposed action, the relationship between short-term resources and long-term productivity, and irreversible and irretrievable commitments of resources. Environmental assessments (EAs) are prepared to determine whether significant impacts may occur. If an EA finds that significant impacts may occur, NEPA requires preparation of an EIS. The briefest form of NEPA review is the categorical exclusion review (CER). The purpose of a CER is to verify that neither an EA nor an EIS is needed prior to making a decision on the activity being considered for approval.

C.1.3 The Energy Policy Act of 2005

This law, enacted in 2005, gives BOEM new responsibilities over Federal offshore renewable energy and related uses of the OCS. Section 388 of the Act gives the Secretary of the Interior the authority to grant leases, easements, or rights-of-way for renewable energy-related uses on the Federal OCS, and to monitor and regulate the facilities used for energy production and energy support services.

C.1.4 The Alaska National Interest Lands Conservation Act (ANILCA)

In 1980, the Alaska National Interest Lands Conservation Act (ANILCA) created over 40 million ha (100 million ac) of new national parks, refuges, monuments, conservation areas, recreation areas, forests, and wild and scenic rivers in the State of Alaska for the preservation of "nationally significant" natural resources. To address special issues and needs arising from the new land designations, ANILCA contains numerous provisions and special rules for managing Alaska's public lands and nationally important resource development potential. ANILCA requires Federal land managers to balance the national interest in Alaska's scenic and wildlife resources with recognition of Alaska's economy and infrastructure, and its distinctive rural way of life. Title VIII of ANILCA requires that subsistence uses by "rural" Alaska residents be given a priority over all other (sport and commercial) uses of fish and game on Federal public lands in Alaska. As a compromise, Congress allowed the State to continue managing fish and game uses on Federal public lands, but only on the condition that the State of Alaska adopt a statute that made the new Title VIII "rural" subsistence priority applicable on State, as well as on Federal lands. If the State ever fell out of compliance with Title VIII, Congress required the Secretary of the Interior to reassume management of fish and game on the Federal public lands. Section 810 of ANILCA creates special steps a Federal agency must take before it decides to "withdraw, reserve, lease, or otherwise permit the use, occupancy, or disposition of public land."

Specifically, the Federal agency must first evaluate three factors: the effect of its action on subsistence uses and needs; the availability of other lands for the purposes sought to be achieved; and alternatives that would "reduce or eliminate the use, occupancy, or disposition of public lands needed for subsistence purposes." If the Federal agency concludes that its action "would significantly restrict subsistence uses," it must notify the appropriate State agency, regional council, and local committee. It then must hold a hearing in the vicinity of the area involved, and must make the following findings:

- Such significant restriction of subsistence uses is necessary and consistent with sound management principles for the utilization of public lands.

- The proposed activity will involve the minimal amount of public lands necessary to accomplish the purpose of such use, occupancy, or other disposition.

- Reasonable steps will be taken to minimize adverse impacts upon subsistence uses and resources resulting from such actions (16 USC 3120(a)(3)).

In *Amoco Production v. Village of Gambell*, 480 U.S. 531 (1987), the U.S. Supreme Court ruled that ANILCA applies only to Federal lands within the State of Alaska's boundaries. The Act defines "public lands" to mean Federal lands situated "in Alaska," which the Court ruled to mean within the territorial boundaries of the State, which ends in coastal waters to a point

4.8 km (3 mi) from the coastline. Therefore, the OCS is not encompassed by the words "in Alaska" and pipelines on the OCS are not subject to ANILCA. However, the sections of these pipelines that eventually go into State waters are subject to ANILCA.

C.1.5 The Clean Air Act (CAA)

The Clean Air Act (CAA), as amended, delineates jurisdiction of air quality between the U.S. Environmental Protection Agency (USEPA) and BOEM. For OCS operations in the Gulf of Mexico, those west of 87.5°W longitude are subject to BOEM air quality regulations; operations east of 87.5°W longitude are subject to the USEPA air quality regulations. In December 2011, Congress passed the Consolidated Appropriations Act of 2012, which amended the CAA by transferring air quality permitting authority for the OCS off the North Slope Borough of Alaska from the USEPA to BOEM. This area includes the Beaufort Sea and Chukchi Sea OCS Planning Areas and the northern part of the Hope Basin OCS Planning Area.

Under the CAA, the Secretary of the Interior is required to consult with the USEPA Administrator "to assure coordination of air pollution control regulations for OCS emissions and emissions in adjacent onshore areas." BOEM implementing regulations established to comply with the CAA are 30 CFR 550.218, 550.249, 550.302, 550.303, and 550.304. The regulated pollutants include carbon monoxide, particulates, sulfur dioxide, nitrogen oxides, and volatile organic compounds (as a precursor to ozone). BOEM regulations allow for the collection of information about potential sources of pollution for the purpose of determining whether the projected emissions of air pollutants from a facility could result in ambient onshore air pollutant concentrations above maximum levels provided in the regulations. These regulations also stipulate appropriate emissions controls deemed necessary to prevent accidents and air quality deterioration.

C.1.6 The Federal Water Pollution Control Act (FWPCA) and Clean Water Act (CWA)

The Federal Water Pollution Control Act (FWPCA) establishes water pollution control activities to restore and maintain the chemical, physical, and biological integrity of the Nation's waters. The Clean Water Act of 1977 (CWA) amended the FWPCA. Title III of the CWA requires the USEPA to establish national effluent limitation standards for existing point sources of wastewater discharges that reflect the application of the best practical control technology currently available. These standards apply to existing OCS exploratory drillships, semisubmersible vessels, and jack-up rigs used in exploration activities. The CWA also requires the USEPA to establish regulations for effluent limitations for categories and classes of point sources that require the application of "best available control technology economically achievable."

Section 311 of the CWA, as amended, prohibits the discharge of oil or hazardous substances into the navigable waters of the United States that may affect natural resources, except under limited circumstances, and establishes civil penalty liability and enforcement procedures to be administered by the U.S. Coast Guard (USCG). The CWA Title IV establishes requirements for Federal permits and licenses to conduct an activity (including construction or operation of facilities) that may result in any discharges into navigable waters. Section 402 of the CWA gives the USEPA the authority to issue National Pollutant Discharge Elimination System (NPDES) permits for the discharge of pollutants. The NPDES permits apply to all sources of wastewater discharges from exploratory vessels and production platforms operating on the OCS.

C.1.7 The Coastal Zone Management Act (CZMA) and the Coastal Zone Reauthorization Amendments of 1990

Congress passed the Coastal Zone Management Act (CZMA) and created the Coastal Zone Management Program to improve the management of our Nation's coastal areas. The program, a voluntary partnership between the Federal Government and the coastal States and territories, is administered at the Federal level by the National Oceanic and Atmospheric Administration (NOAA) within the U.S. Department of Commerce (USDOC). The program's goal is to reduce potential conflicts between environmental and economic interests in the coastal area through the use of federally approved coastal management programs (CMPs).

The CZMA allows a coastal State or territory, with a federally approved CMP, to review Federal activities for Federal consistency. Federal consistency is the CZMA requirement that all Federal actions that are reasonably likely to affect any land or water use or natural resource of the coastal zone be consistent with the enforceable policies of a State's/territory's CMP. Section 307 of the CZMA contains the Federal consistency provisions that impose certain requirements on Federal agencies to comply with enforceable policies detailed in the federally approved CMPs:

- Section 307(c)(1) requires that any direct Federal agency activities affecting any land or water use or natural resources of the coastal zone be consistent, to the maximum extent practicable, with enforceable policies of the State's CMP. This section applies to OCS lease sales.

- Section 307(c)(3)(A) requires that any Federal licenses/permit affecting any land or water use or natural resources of the coastal zone be consistent with enforceable policies of the State's CMP. This section applies to geological and geophysical permits. In addition, this section prohibits the Federal agency from issuing the license/permit until the affected State(s) has concurred with or presumed to concur with the applicant's consistency certification or until the Secretary of Commerce has overridden the State's consistency objection to the licensed/permitted activity.

- Section 307(c)(3)(B) requires that activities affecting any land or water use or natural resources of the coastal zone, described in detail in OCS exploration or development and production plans, be consistent with enforceable policies of the State's CMP. MMS is prohibited from approving an OCS plan until the affected State(s) has concurred with, or is presumed to concur with, the applicant's consistency certification or until the Secretary of Commerce has overridden the State's consistency objection.

C.1.8 The Endangered Species Act (ESA)

The Endangered Species Act of 1973 (ESA) establishes policy to protect and conserve threatened and endangered species and the ecosystems upon which they depend. The ESA is administered by the USDOI, U.S. Fish and Wildlife Service (USFWS), and the USDOC, National Marine Fisheries Service (NMFS). Section 7 of the ESA mandates that all Federal agencies consult with the USFWS or NMFS to ensure that any agency action is not likely to do the following:

- Jeopardize the continued existence of any endangered or threatened species, and/or

- Destroy or adversely modify an endangered or threatened species' critical habitat.

The ESA requires Federal agencies to formally consult when there is reason to believe that a listed (or proposed to be listed) species may be affected by a proposed action. Formal endangered species consultations provide a threshold examination and a biological opinion on the likelihood that the proposed activity will or will not jeopardize the continued existence of the resource, and on the effect of the proposed activity on the endangered species. The biological opinion may include recommendations for modification of the proposed activity. The USFWS or NMFS notifies the Federal agency in writing when insufficient information is available to conclude that the proposed activity is not likely to jeopardize the species or its habitat. In such cases, the Federal agency must obtain additional information, and, if recommended by the USFWS or NMFS, conduct appropriate biological surveys or studies to determine how the proposed activity may affect the endangered species or its critical habitat. After such additional information is received, the USFWS or NMFS would conclude the consultation process by issuing a formal biological opinion.

For OCS activities in the Western and Central Gulf of Mexico Planning Areas, BOEM consults with the USFWS and/or NMFS at the multisale stage. This consultation covers OCS activities from lease sale through the exploration, development, production, and decommission stages. For other OCS areas, BOEM consults with the USFWS and/or NMFS at the lease sale stage; however, this consultation only covers leasing and exploration activities. A separate consultation is conducted for development, production, and decommissioning stages.

C.1.9 The Magnuson-Stevens Fishery Conservation and Management Act (FCMA)

The Magnuson-Stevens Fishery Conservation and Management Act of 1976 (FCMA) established and delineated an area from the States' seaward boundary to approximately 200 nautical miles out as a fisheries conservation zone for the United States and its possessions.

The FCMA created eight regional fishery management councils (FMCs) and mandated a continuing planning program for marine fisheries management by the FMCs. In addition, the FCMA requires the FMC to prepare a fishery management plan (FMP), based upon the best available scientific and economic data, for each commercial species (or related group of species) of fish in need of conservation and management within each respective region.

When the Sustainable Fisheries Act of 1996 reauthorized the FCMA, Congress required NMFS to designate and conserve essential fish habitat (EFH) for those species managed under an existing FMP. By designating EFH, Congress hoped to minimize any adverse effects on habitat caused by fishing or nonfishing activities and to identify other actions to encourage the conservation and enhancement of such habitat. The phrase "essential fish habitat" encompasses "those waters and substrate necessary to fishes for spawning, breeding, feeding, or growth to maturity." As a result of this change, Federal agencies must consult with NMFS on those activities that may have direct (e.g., physical disruption) or indirect (e.g., loss of prey species) adverse effects on EFH. For OCS activities in the Western and Central Gulf of Mexico Planning Areas, BOEM consults with NMFS at the multisale stage. The proposed action includes OCS activities from lease sale through the exploration, development, production, and decommission stages for the Western and Central Gulf of Mexico Planning Areas. For the Eastern Planning Area in the GOM, BOEM initiates EFH consultation with NMFS individually for individual lease sales, exploration plans, or development and production plans.

C.1.10 The Migratory Bird Treaty Act (MBTA)

The Migratory Bird Treaty Act (MBTA) prohibits the take of migratory birds, in which it is unlawful to "pursue, hunt, take, capture, kill, attempt to take, capture or kill, possess, offer for sale, sell, offer to purchase, purchase, deliver for shipment, ship, cause to be shipped, deliver for transportation, transport, cause to be transported, carry, or cause to be carried by any means whatever, receive for shipment, transportation or carriage, or export, at any time, or in any manner, any covered migratory bird … or any part, nest, or egg of any such bird." The USDOI Secretary via the USFWS may authorize the otherwise prohibited take of migratory birds through regulations. Current USFWS regulations authorize the taking of migratory birds for specific purposes, such as hunting, depredation, and scientific study; however, the regulations do not expressly address the incidental take of migratory birds.

The Minerals Management Service (MMS), now BOEM, entered into a Memorandum of Understanding (MOU) with the USFWS to meet the requirements under Section 3 of Executive Order 13186 (66 FR 3853, January 17, 2001) (refer to C.2.10 below for full discussion) concerning the responsibilities of Federal agencies to protect migratory birds. The Executive Order directs executive departments and agencies to take certain actions to further implement the MBTA. The purpose of this MOU is to strengthen migratory bird conservation through enhanced collaboration between BOEM and the USFWS. The MOU identifies specific areas in which cooperation between the parties will substantially contribute to the conservation and management of migratory birds and their habitats.

C.1.11 The Marine Mammal Protection Act (MMPA)

The Marine Mammal Protection Act (MMPA) was enacted in 1972 to ensure that marine mammals are maintained at, or in some cases restored to, healthy population levels. Jurisdiction over marine mammals under the MMPA is split between two Federal Agencies, the USFWS and NMFS. The USFWS has jurisdiction over sea otters, polar bears, manatees, dugongs, and walrus, while NMFS has jurisdiction over all other marine mammals.

The MMPA established a moratorium on the taking or importing of marine mammals except during certain activities that are regulated and permitted. Such activities include scientific research, public display, commercial and educational photography, import and export of marine mammal parts, commercial fishing authorizations, and take incidental to non-fishing commercial activities. Taking is defined as "to harass, hunt, capture, or kill or attempt to harass, hunt, capture, or kill any marine mammal." Harass is defined as any act of pursuit, torment, or annoyance that has the potential to do the following:

- Injure a marine mammal or marine mammal stock in the wild, or

- Disturb a marine mammal or marine mammal stock in the wild by disrupting behavioral patterns (e.g., breathing, nursing, breeding).

Upon request, the Secretary (of either the USDOI or the USDOC, depending on jurisdiction) can authorize the unintentional taking of small numbers of marine mammals incidental to activities other than commercial fishing (e.g., offshore oil and gas exploration and development) for a period of 1–5 yr, depending on the level of anticipated take. To authorize the taking, the Secretary must find that the total of the taking during the 5-yr period (or less) would have a negligible impact on the affected species. In addition, the Secretary shall withdraw or suspend permission to take marine mammals incidental to oil and gas production, and other activities when the following take place:

- The applicable regulations concerning the methods of taking, monitoring, or reporting are not being complied with; or

- The taking is having, or may be having, more than a negligible impact on the affected species or stock.

BOEM coordinates with the USFWS and NMFS to ensure that BOEM and offshore operators comply with the MMPA, and to identify mitigation and monitoring requirements for permits or approvals for activities like seismic surveys and platform removals.

C.1.12 The International Convention of the Prevention of Pollution from Ships (MARPOL) and Marine Plastic Pollution Research and Control Act (MPPRCA)

In 1978, the International Convention of the Prevention of Pollution from Ships (MARPOL) was updated to include five annexes on ocean dumping. By signing onto MARPOL, countries agree to enforce Annexes I and II (oil and noxious liquid substances) of the treaty. Annexes III (hazardous substances), IV (sewage), and V (plastics) are optional. The United States is signatory to two of the optional MARPOL Annexes, III and V. Annex V is of particular importance to the maritime community (e.g., shippers, oil platform personnel, fishers, recreational boaters) because it prohibits the disposal of plastic at sea and regulates the disposal of other types of garbage at sea. The USCG is the enforcement agency for MARPOL Annex V within the U.S. Exclusive Economic Zone (EEZ) (within 322 km [200 mi] of the U.S. shoreline).

The Marine Plastic Pollution Research and Control Act (MPPRCA) is the Federal law implementing MARPOL Annex V in all U.S. waters. Under the MPPRCA, it is illegal to throw plastic trash off any vessel within the EEZ. It is also illegal to throw any other garbage (e.g., orange peels, paper plates, glass jars, and monofilament fishing line) overboard while navigating in inland waters or within 5 km (3 mi) offshore. The greater the distance from shore, the fewer restrictions apply to nonplastic garbage. However, dumping plastics overboard in any waters anywhere is illegal at anytime. Fixed and floating platforms, drilling rigs, manned production platforms, and support vessels operating under a Federal oil and gas lease are required to develop waste management plans and to post placards reflecting discharge limitations and restrictions. Garbage must be brought ashore and properly disposed of in a trash can, dumpster, or recycling container. Docks and marinas are required to provide facilities to handle normal amounts of garbage from their paying customers. Violations of MARPOL or MPPRCA may result in a fine of up to $50,000 for each incident. If criminal intent can be proven, an individual may be fined up to $250,000 and/or imprisoned up to 6 yr. If an organization is responsible, it may be fined up to $500,000 and/or be subject to 6 yr of imprisonment.

C.1.13 The Marine Protection, Research, and Sanctuaries Act (MPRSA)

The Marine Protection, Research, and Sanctuaries Act of 1972 (MPRSA) regulates the ocean dumping of waste, provides for a research program on ocean dumping, and provides for the designation and regulation of marine sanctuaries. Also known as the Ocean Dumping Act, it regulates the ocean dumping of all material beyond the territorial limit (5 km [3 mi] from shore) and prevents or strictly limits dumping material that "would adversely affect human health, welfare, or amenities, or the marine environment, ecological systems, or economic potentialities." Material includes, but is not limited to, dredged material; solid waste; incinerator residue; garbage; sewage; sewage sludge; munitions; chemical and biological warfare agents; radioactive materials; chemicals; biological and laboratory waste; wrecked or discarded equipment; rocks; sand; excavation debris; and industrial, municipal, agricultural, and other waste. The term does not include sewage from vessels or oil, unless the oil is transported via a vessel or aircraft for the purpose of dumping. Disposal by means of a pipe, regardless of how far at sea the discharge occurs, is regulated by the CWA through the NPDES permit process.

Title III of the MPRSA, later called the National Marine Sanctuaries Act, charged the Secretary of the Department of Commerce to identify, designate, and manage marine sites based on conservational, ecological, recreational, historical, aesthetic, scientific, or educational value within significant national ocean and Great Lake waters. The NOAA administers the National

Marine Sanctuary Program. Thirteen national marine sanctuaries and one national monument, representing a wide variety of ocean environments, have been designated.

C.1.14 The Merchant Marine Act of 1920 (Jones Act)

The Merchant Marine Act of 1920 (Jones Act) regulates coastal shipping between U.S. ports and inland waterways. The Jones Act provides that "no merchandise shall be transported by water, or by land and water . . . between points in the United States . . . in any other vessel than a vessel built in and documented under the laws of the United States and owned by persons who are citizens of the United States . . . ." Therefore, the Jones Act requires that all goods shipped between different ports in the United States or its territories must be:

- Carried on vessels built and documented (flagged) in the United States,
- Crewed by U.S. citizens or legal aliens licensed by the USCG, and
- Owned and operated by U.S. citizens.

The rationale behind the Jones Act and earlier sabotage laws was that the United States needed a merchant marine fleet to ensure that its domestic waterborne commerce remains under Government jurisdiction for regulatory, safety, and national defense considerations. The same general principles of safety regulations are applied to other modes of transportation in the United States. While other modes of transportation can operate foreign-built equipment, these units must comply with U.S. standards. However, many foreign-built ships do not meet the standards required of U.S.-built ships and, thus, are excluded from domestic shipping.

The U.S. Customs Service has determined that facilities fixed or attached to the OCS used for the purpose of oil exploration are considered points within the United States. The OCS oil facilities are considered U.S. sovereign territory and fall under the requirements of the Jones Act; so all shipping to and from these facilities related to OCS oil exploration can only be conducted by vessels meeting the requirements of the Jones Act. Shuttle tankering of oil that is produced at OCS facilities can only be legally provided by U.S.-registered vessels and aircraft that are properly endorsed for coastwise trade under the laws of the United States.

C.1.15 The National Fishing Enhancement Act

The National Fishing Enhancement Act of 1984, also known as the Artificial Reef Act, established broad artificial-reef development standards and a national policy to encourage the development of artificial reefs that will enhance fishery resources and commercial and recreational fishing. The national plan identifies oil and gas structures as acceptable material of opportunity for artificial-reef development. MMS, now BSEE, adopted a rigs-to-reefs policy in 1985 in response to this Act and to broaden interest in the use of petroleum platforms as artificial reefs.

C.1.16 The National Historic Preservation Act (NHPA)

The National Historic Preservation Act of 1966 (NHPA) requires the head of any Federal agency possessing licensing authority or having direct or indirect jurisdiction over a proposed Federal or federally assisted activity to consider the proposed activity's effect on any district, site, building, structure, or object that is included in or eligible for inclusion in the *National Register of Historic Places*. The historic properties (i.e., archaeological resources) on the OCS include historic shipwrecks, sunken aircraft, lighthouses, and prehistoric archaeological sites that have become inundated due to the 120-m (394-ft) rise in global sea level since the height of the last ice age (ca. 19,000 yr ago).

Because the OCS is not federally owned land and the Federal Government has not claimed direct ownership of historic properties on the OCS, BOEM and BSEE only have the authority to ensure that any agency-funded and permitted actions do not adversely affect significant historic properties. Beyond avoidance of adverse impacts, BOEM and BSEE do not possess the legal authority to manage the historic properties on the OCS. BOEM has conducted archaeological baseline studies of the OCS to determine where known historic properties may be located and to outline areas where presently unknown historic properties may be located. These baseline studies are used to identify "archaeologically sensitive" areas that may contain significant historic properties.

Prior to approving any OCS exploration or development activities within an archaeologically sensitive area, BOEM requires the lessee to conduct a marine remote sensing survey and to prepare an archaeological report. If the marine remote sensing survey indicates any evidence of a potential historic property, the lessee must do one of the following:

- Move the site of the proposed lease operations a sufficient distance to avoid the potential historic property, or

- Conduct further investigations to determine the nature and significance of the potential historic property.

If further investigation determines that there is a significant historic property within the area of proposed OCS operations, NHPA consultation procedures are followed.

C.1.17 The Oil Pollution Act (OPA 90)

The Oil Pollution Act (OPA 90) establishes a single uniform Federal system of liability and compensation for damages caused by oil spills in U.S. navigable waters. The OPA 90 requires removal of spilled oil and establishes a national system of planning for and responding to oil-spill incidents. In addition, OPA 90 includes provisions to do the following:

- Improve oil-spill prevention, preparedness, and response capability;

- Establish limitations on liability for damages resulting from oil pollution;

- Promote funding for natural resource damage assessment;
- Implement a fund for the payment of compensation for such damages; and
- Establish an oil pollution research and development program.

The USCG is responsible for enforcing vessel compliance with the OPA 90. The Secretary of the Interior is given authority over offshore facilities and associated pipelines (except deepwater ports) for all Federal and State waters, including responsibility for spill prevention, oil-spill contingency plans, oil-spill containment and cleanup equipment, financial responsibility certification, and civil penalties. The Secretary of the Interior delegated this authority to BOEM and BSEE.

BOEM regulations governing oil-spill financial responsibility (OSFR) for offshore facilities and related requirements for certain crude oil wells, production platforms, and pipelines located in the OCS and certain State waters became effective in October 1998. The regulations implement the OPA requirement for responsible parties to demonstrate they can pay for cleanup and damages caused by facility oil spills. Responsible parties can be required to demonstrate as much as $150 million in OSFR if BOEM determines that it is justified by the risks from potential oil spills from the covered offshore facilities. The minimum amount of OSFR that must be demonstrated is $35 million for covered offshore facilities located in the OCS, and $10 million for covered offshore facilities located in State waters. The regulation exempts persons responsible for facilities having a potential worst-case, oil-spill discharge of 1,000 bbl or less, unless the risks posed by a facility justify a lower threshold.

C.1.18 The Outer Continental Shelf Deep Water Royalty Relief Act

The Outer Continental Shelf Deep Water Royalty Relief Act of 1995 authorizes the Secretary of the Interior to offer OCS blocks for lease with suspension of royalties for a volume, value, or period of production. Deepwater royalty relief applies to blocks offered for lease in the western and central Gulf of Mexico in water depths exceeding 200 m (656 ft) through November 28, 2000. MMS, now the Office of Natural Resources Revenue (ONRR), developed procedures for suspension of royalty payment on production from eligible leases.

C.1.19 The Ports and Waterways Safety Act

The Ports and Waterways Safety Act authorizes the USCG to designate safety fairways, fairway anchorages, and traffic separation schemes to provide unobstructed approaches through oil fields for vessels using ports. The USCG regulations provide listings of these designated areas along with special conditions related to oil and gas production. In general, no fixed structures such as platforms are allowed in fairways. Temporary underwater obstacles such as anchors and attendant cables or chains attached to floating or semisubmersible drilling rigs may be placed in a fairway under certain conditions. Fixed structures may be placed in anchorages, but the number of structures is limited.

C.1.20 The Resource Conservation and Recovery Act (RCRA)

The Resource Conservation and Recovery Act (RCRA) provides a framework for the safe disposal and management of hazardous and solid wastes. Most oil-field wastes have been exempted from coverage under RCRA hazardous waste regulations. Any hazardous wastes generated on the OCS that are not exempt must be transported to shore for disposal at a hazardous waste facility.

C.1.21 The Rivers and Harbors Act (RHA)

Section 10 of the Rivers and Harbors Act (RHA) of 1899 (33 USC 403) prohibits the unauthorized obstruction or alteration of any navigable water of the United States. This section provides that the construction of any structure in or over any navigable water of the United States, or the accomplishment of any other work affecting the course, location, condition, or physical capacity of such waters, is unlawful unless the work has been recommended by the Chief of Engineers of the U.S. Army Corps of Engineers (USACE) and authorized by the Secretary of the Army. The Secretary's approval authority has since been delegated to the Chief of Engineers of the USACE. This legislative authority to prevent inappropriate obstructions to navigation was extended to installations and devices and the seabed to the seaward limit of the Outer Continental Shelf by Section 4(e) of the Outer Continental Shelf Lands Act of 1953, as amended.

Operators planning to install structures for the exploration, production, and transportation of oil, gas, and minerals on the OCS must apply for a Section 10 Permit. The USACE can authorize these activities by a standard individual permit, letter-of-permission, general permit, nationwide permit, or regional permit, and makes this determination at the time of application. Typically, the USACE authorizes the installation of these OCS structures under a nationwide permit, Nationwide Permit 8. Under a Nationwide Permit 8, such structures shall not be placed (1) within the limits of any designated shipping safety fairway or traffic separation scheme, except temporary anchors that comply with the fairway regulations in 33 CFR 322.5(l), (2) within established danger zones or restricted areas as designated in 33 CFR Part 334, or (3) within USEPA- or USACE-designated dredged material disposal areas.

C.2 EXECUTIVE ORDERS (EO)

C.2.1 Executive Order 12898: Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations (February 1994)

In the memorandum to heads of departments and agencies that accompanied the Executive Order (EO), the President specifically recognized the importance of procedures under the NEPA for identifying and addressing environmental justice concerns. The memorandum states that "each Federal agency shall analyze the environmental effects, including human health, economic and social effects, of Federal actions, including effects on minority communities and low-income communities, when such analysis is required by [NEPA]." In August 1994, the Secretary of the Interior directed its bureaus to include environmental justice (EJ) in NEPA documentation, and in February 1998, the CEQ issued guidance to assist Federal Agencies in addressing EJ.

The issue of disproportionate, OCS-related impacts on minority and low-income populations is addressed in all OCS regions when such analysis is required by the NEPA. This issue is a primary focus in Alaska OCS Region environmental assessments where Native Alaskan subsistence hunting, fishing, and gathering activities occur in coastal areas.

Executive Order No. 12898 provides the following:

Section 1-1. IMPLEMENTATION.

1-101. *Agency Responsibilities*. To the greatest extent practicable and permitted by law, and consistent with the principles set forth in the report on the National Performance Review, each Federal agency shall make achieving environmental justice part of its mission by identifying and addressing, as appropriate, disproportionately high and adverse human health or environmental effects of its programs, policies, and activities on minority populations and low-income populations in the United States and its territories and possessions, the District of Columbia, the Commonwealth of Puerto Rico, and the Commonwealth of the Marianas Islands.

1-102. *Creation of an Interagency Working Group on Environmental Justice*.

(a) Within 3 months of the date of this order, the Administrator of the Environmental Protection Agency ("Administrator") or the Administrator's designee shall convene an interagency Federal Working Group on Environmental Justice ("Working Group"). The Working Group shall comprise the heads of the following executive agencies and offices, or their designees: (a) Department of Defense; (b) Department of Health and Human Services; (c) Department of Housing and Urban Development; (d) Department of Labor; (e) Department of Agriculture; (f) Department of Transportation; (g) Department of Justice; (h) Department of the Interior; (i) Department of Commerce; (j) Department of Energy; (k) Environmental Protection Agency; (l) Office of Management and Budget; (m) Office of Science and Technology Policy; (n) Office of the Deputy Assistant to the President for Environmental Policy; (o) Office of the Assistant to the President for Domestic Policy; (p) National Economic Council; (q) Council of Economic Advisers; and (r) such other Government officials as the President may designate. The Working Group shall report to the President through the Deputy Assistant to the President for Environmental Policy and the Assistant to the President for Domestic Policy.

(b) The Working Group shall:

(1) provide guidance to Federal agencies on criteria for identifying disproportionately high and adverse human health or environmental effects on minority populations and low-income populations;

(2) coordinate with, provide guidance to, and serve as a clearinghouse for, each Federal agency as it develops an environmental justice strategy as required by section 1-103 of this order, in order to ensure that the administration, interpretation and enforcement of programs, activities and policies are undertaken in a consistent manner;

(3) assist in coordinating research by, and stimulating cooperation among, the Environmental Protection Agency, the Department of Health and Human Services, the Department of Housing and Urban Development, and other agencies conducting research or other activities in accordance with section 3-3 of this order;

(4) assist in coordinating data collection, required by this order;

(5) examine existing data and studies on environmental justice;

(6) hold public meetings as required in section 5-502(d) of this order; and

(7) develop interagency model projects on environmental justice that evidence cooperation among Federal agencies.

1-103. *Development of Agency Strategies*.

(a) Except as provided in section 6-605 of this order, each Federal agency shall develop an agency-wide environmental justice strategy, as set forth in subsections (b)–(e) of this section that identifies and addresses disproportionately high and adverse human health or environmental effects of its programs, policies, and activities on minority populations and low-income populations. The environmental justice strategy shall list programs, policies, planning and public participation processes, enforcement, and/or rulemakings related to human health or the environment that should be revised to, at a minimum: (1) promote enforcement of all health and environmental statutes in areas with minority populations and low-income populations; (2) ensure greater public participation; (3) improve research and data collection relating to the health of and environment of minority populations and low-income populations; and (4) identify differential patterns of consumption of natural resources among minority populations and low-income populations. In addition, the environmental justice strategy shall include, where appropriate, a timetable for undertaking identified revisions and consideration of economic and social implications of the revisions.

(b) Within 4 months of the date of this order, each Federal agency shall identify an internal administrative process for developing its environmental justice strategy, and shall inform this Working Group of the process.

(c) Within 6 months of the date of this order, each Federal agency shall provide the Working Group with an outline of its proposed environmental justice strategy.

(d) Within 10 months of the date of this order, each Federal agency shall provide the Working Group with its proposed environmental justice strategy.

(e) Within 12 months of the date of this order, each Federal agency shall finalize its environmental justice strategy and provide a copy and written description of its strategy to the Working Group. During the 12 month period from the date of this order, each Federal agency, as part of its environmental justice strategy, shall identify several specific projects that can be promptly undertaken to address particular concerns identified during the development of the proposed environmental justice strategy, and a schedule for implementing those projects.

(f) Within 24 months of the date of this order, each Federal agency shall report to the Working Group on its progress in implementing its agency-wide environmental justice strategy.

(g) Federal agencies shall provide additional periodic reports to the Working Group as requested by the Working Group.

1-104. *Reports to the President*. Within 14 months of the date of this order, the Working Group shall submit to the President, through the Office of the Deputy Assistant to the President for Environmental Policy and the Office of the Assistant to the President for Domestic Policy, a report that describes the implementation of this order, and includes the final environmental justice strategies described in section 1-103(e) of this order.

Sec. 2-2. FEDERAL AGENCY RESPONSIBILITIES FOR FEDERAL PROGRAMS.

Each Federal agency shall conduct its programs, policies, and activities that substantially affect human health or the environment, in a manner that ensures that such programs, policies, and activities do not have the effect of excluding persons (including populations) from participation in, denying persons (including populations) the benefits of, or subjecting persons (including populations) to discrimination under, such programs, policies, and activities, because of their race, color, or national origin.

Sec. 3-3. RESEARCH, DATA COLLECTION, AND ANALYSIS.

3-301. *Human Health and Environmental Research and Analysis*.

(a) Environmental human health research, whenever practicable and appropriate, shall include diverse segments of the population in epidemiological and clinical studies, including segments at high risk from environmental hazards, such as minority populations, low-income populations and workers who may be exposed to substantial environmental hazards.

(b) Environmental human health analyses, whenever practicable and appropriate, shall identify multiple and cumulative exposures.

(c) Federal agencies shall provide minority populations and low-income populations the opportunity to comment on the development and design of research strategies undertaken pursuant to this order.

3-302. *Human Health and Environmental Data Collection and Analysis*. To the extent permitted by existing law, including the Privacy Act, as amended (5 U.S.C. § 552a):

(a) Each Federal agency, whenever practicable and appropriate, shall collect, maintain, and analyze information assessing and comparing environmental and human health risks borne by populations identified by race, national origin, or income. To the extent practical and appropriate, Federal agencies shall use this information to determine whether their programs, policies, and activities have disproportionately high and adverse human health or environmental effects on minority populations and low-income populations;

(b) In connection with the development and implementation of agency strategies in section 1-103 of this order, each Federal agency, whenever practicable and appropriate, shall collect, maintain and analyze information on the race, national origin, income level, and other readily accessible and appropriate information for areas surrounding facilities or sites expected to have a substantial environmental, human health, or economic effect on the surrounding populations, when such facilities or sites become the subject of a substantial Federal environmental administrative of judicial action. Such information shall be made available to the public unless prohibited by law; and

(c) Each Federal agency, whenever practicable and appropriate, shall collect, maintain, and analyze information on the race, national origin, income level, and other readily accessible and appropriate information for areas surrounding Federal facilities that are: (1) subject to the reporting requirements under the Emergency Planning and Community Right-to-Know Act, 42 U.S.C. section 11001-11050 as mandated in Executive Order No. 12856; and (2) expected to have a substantial environmental, human health, or economic effect on surrounding populations. Such information shall be made available to the public, unless prohibited by law.

(d) In carrying out the responsibilities in this section, each Federal agency, whenever practicable and appropriate, shall share information and eliminate unnecessary duplication of efforts through the use of existing data systems and cooperative agreements among Federal agencies and with State, local, and tribal governments.

Sec. 4-4. SUBSISTENCE CONSUMPTION OF FISH AND WILDLIFE.

4-401. *Consumption Patterns*. In order to assist in identifying the need for ensuring protection of populations with differential patterns of subsistence consumption of fish and wildlife, Federal agencies, whenever practicable and appropriate, shall collect, maintain, and analyze information on the consumption patterns of populations who principally rely on fish and/or wildlife for subsistence. Federal agencies shall communicate to the public the risks of those consumption patterns.

4-402. *Guidance*. Federal agencies, whenever practicable and appropriate, shall work in a coordinated manner to publish guidance reflecting the latest scientific information available concerning methods for evaluating the human health risks associated with the consumption of pollutant-bearing fish or wildlife. Agencies shall consider such guidance in developing their policies and rules.

Sec. 5-5. PUBLIC PARTICIPATION AND ACCESS TO INFORMATION.

(a) The public may submit recommendations to Federal agencies relating to the incorporation of environmental justice principles into Federal agency programs or policies. Each Federal agency shall convey such recommendations to the Working Group.

(b) Each Federal agency may, whenever practicable and appropriate, translate crucial public documents, notices, and hearings relating to human health or the environment for limited English speaking populations.

(c) Each Federal agency shall work to ensure that public documents, notices, and hearings relating to human health or the environment are concise, understandable, and readily accessible to the public.

(d) The Working Group shall hold public meetings, as appropriate, for the purpose of fact-finding, receiving public comments, and conducting inquiries concerning environmental justice. The Working Group shall prepare for public review a summary of the comments and recommendations discussed at the public meetings.

Sec. 6-6. GENERAL PROVISIONS.

6-601. *Responsibility for Agency Implementation*. The head of each Federal agency shall be responsible for ensuring compliance with this order. Each Federal agency shall conduct internal reviews and take such other steps as may be necessary to monitor compliance with this order.

6-602. *Executive Order No. 12250*. This Executive order is intended to supplement but not supersede Executive Order No. 12250, which requires consistent and effective implementation of various laws prohibiting discriminatory practices in programs receiving Federal financial assistance. Nothing herein shall limit the effect or mandate of Executive Order No. 12250.

6-603. *Executive Order No. 12875*. This Executive order is not intended to limit the effect or mandate of Executive Order No. 12875.

6-604. *Scope*. For purposes of this order, Federal agency means any agency on the Working Group, and such other agencies as may be designated by the President, that conducts any Federal program or activity that substantially affects human health or the environment. Independent agencies are requested to comply with the provisions of this order.

6-605. *Petitions for Exemptions*. The head of a Federal agency may petition the President for an exemption from the requirements of this order on the grounds that all or some of the petitioning agency's programs or activities should not be subject to the requirements of this order.

6-606. *Native American Programs*. Each Federal agency responsibility set forth under this order shall apply equally to Native American programs. In addition, the Department of the Interior, in coordination with the Working Group, and, after consultation with tribal leaders, shall coordinate steps to be taken pursuant to this order that address Federally-recognized Indian Tribes.

6-607. *Costs*. Unless otherwise provided by law, Federal agencies shall assume the financial costs of complying with this order.

6-608. *General*. Federal agencies shall implement this order consistent with, and to the extent permitted by, existing law.

6-609. *Judicial Review*. This order is intended only to improve the internal management of the executive branch and is not intended to, nor does it create any right, benefit, or trust responsibility, substantive or procedural, enforceable at law or equity by a party against the United States, its agencies, its officers, or any person. This order shall not be construed to create any right to judicial review involving the compliance or noncompliance of the United States, its agencies, its officers, or any other person with this order.

C.2.2 Executive Order 13007: Indian Sacred Sites (May 1996)

The Indian Sacred Sites EO directs Federal land managing Agencies to accommodate access to, and ceremonial use of, Indian sacred sites by Indian religious practitioners, and to avoid adversely affecting the physical integrity of such sacred sites. It is BOEM's policy to consider the potential effects of all aspects of plans, projects, programs, and activities on Indian sacred sites, and to consult, to the greatest extent practicable and to the extent permitted by law, with tribal governments before taking actions that may affect Indian sacred sites located on Federal lands.

C.2.3 Executive Order 13089: Coral Reef Protection (June 1998)

This EO directs the U.S. Coral Reef Task Force, co-chaired by the Secretaries of Interior and Commerce, to develop and implement a comprehensive program of research and mapping to inventory, monitor, and "identify the major causes and consequences of degradation of coral reef ecosystems." In addition, the EO directs Federal agencies to protect coral reef ecosystems and, to the extent permitted by law, prohibits them from authorizing funding or carrying out any actions that will degrade these ecosystems. Relatedly, the USDOI works with domestic and international partners through the Coral Reef Initiative. This initiative focuses efforts to protect and monitor coral reefs around the world by building and sustaining partnerships, programs, and institutional capacities at the local, national, regional, and international levels.

C.2.4 Executive Order 12114: Environmental Effects Abroad (January 1979)

This EO requires that Federal officials be informed of environmental considerations, and take those considerations into account when making decisions on major Federal actions that could have environmental impacts anywhere beyond the borders of the United States, including Antarctica. Such Federal actions include the following:

- All major Federal actions significantly affecting the environment outside the jurisdiction of any nation (the oceans or Antarctica). This would apply to proposals that result in actions within the United States, which because of ocean currents, winds, stream flow, or other natural processes, may affect parts of the oceans not claimed by any nation (high seas). Included in this category would be an OCS project that, because of ocean currents, could result in effluents or spilled oil reaching fishing grounds or areas not claimed by another nation.

- All major Federal actions significantly affecting the environment of a foreign nation not involved in the action. This would apply to proposals that result in actions within U.S. territory or within the EEZ that, because of ocean currents, winds, stream flow, or other natural processes, may affect parts of another nation, or seas or oceans within the jurisdiction of other nations. This category would include an OCS project located up-current from the Mexican coastline that could affect Mexico's territory in the event of an oil spill. Also in this category are all major Federal actions in which a foreign nation is a participant and that would normally be covered by the EIS addressing the U.S. part of the proposal. An example would be an OCS right-of-way pipeline bringing Canadian energy resources to the northeast United States.

- All major Federal actions providing a foreign nation with a product, or involving a project that produces an emission or effluent prohibited or regulated by U.S. Federal law because of its effects on the environment or the creation of a serious public health risk.

Federal actions causing significant impacts on environments outside the United States are to be addressed in the following:

- EISs (generic), program (5-Year OCS Leasing Program) EISs, and project-specific (OCS lease sale) EISs;

- Documents prepared for decision makers containing reviews of environmental issues involved in Federal actions, or summaries of environmental analyses (e.g., OCS lease sale decision documents, Records of Decision); and

- Environmental studies or research prepared by the United States and one or more foreign nations, or by an international body in which the United States is a member or participant.

The United States, Canada, and Mexico are negotiating a Transboundary Environmental Impact Assessments (TEIA) Agreement through the North Atlantic Free Trade Agreement (NAFTA) Commission on Environmental Cooperation (CEC). The CEC deals with a wide range of environmental and natural resource protection issues common to Canada, the United States, and Mexico. Developing a TEIA process is one of the requirements of the 199l North American Agreement on Environmental Cooperation. Under this agreement, a transboundary environmental impact is any impact on the environment within the area under the jurisdiction of Canada, the United States, or Mexico caused by a proposed project, the physical origin of which is situated wholly or in part within the area under the jurisdiction of one of the three countries. For example, a proposed project on the United States OCS that, because of ocean currents, winds, or proximity to the Mexican coastline, could affect Mexican waters (fishing industry, fish resources, etc.) or the Mexican coastline (oil spill contacts, etc.) would be a project considered to have the potential to cause transboundary environmental impacts. The agreement recognizes that there is a significant bilateral nature to many transboundary issues and calls upon the three countries to develop an agreement to do the following:

- Assess the environmental impacts of proposed projects in any of the three countries party to the agreement (NAFTA) that would be likely to cause significant adverse transboundary impacts within the jurisdiction of any of the other parties;

- Develop a system of notification, consultation, and sharing of relevant information between countries with respect to such projects; and

- Give consideration to mitigating measures to address the potential adverse effects of such projects.

Negotiations are currently underway between the three parties to the agreement, but the final language has yet to be worked out. Because the requirements of the assessment portion of the agreement are somewhat similar to the requirements imposed by EO 12114 (i.e., impacts on foreign territory must be addressed in NEPA documents), BOEM requires that EISs prepared on major Federal OCS actions contain an assessment of potential significant impacts on foreign territory.

C.2.5 Executive Order 13158: Marine Protected Areas (MPAs) (May 2000)

The EO defines an MPA as "any area of the marine environment that has been reserved by Federal, State, territorial, tribal, or local laws or regulations to provide lasting protection for part or all of the natural and cultural resources therein." The EO directs Federal agencies to work closely with State, local, and nongovernmental partners to create a comprehensive system of MPAs "representing diverse U.S. marine ecosystems, and the Nation's natural and cultural resources." Ultimately, the MPA system will include new sites, as well as enhancements to the conservation of existing sites. Five principal components of the EO are the following:

- **National MPA List:** The USDOC and the USDOI will develop and maintain a national list of MPAs in U.S. waters. Candidate sites for the list are drawn from existing programs for Federal, tribal, State and local protected areas. When completed, the list and the companion data on each site will serve several purposes, such as ensuring that agencies "avoid harm" to MPAs, providing a foundation for the analysis of gaps in the existing system of protections, and helping improve the effectiveness of existing MPAs.

- **The MPA Web Site:** The USDOC and USDOI will develop and maintain a publicly accessible Web site to provide information on MPAs and Federal agency reports required by the EO. In addition, the Web site will be used to publish and maintain the National MPA List and other useful information, such as maps of MPAs; a virtual library of MPA reference materials, including links to other web sites; information on the MPA Advisory Committee; activities of the national MPA Center; MPA program summaries; and background materials such as MPA definitions, benefits, management challenges, and management tools.

- **The MPA Federal Advisory Committee:** Created to provide expert advice on, and recommendations for, a national system of MPAs, this advisory committee will include nonfederal representatives from science, resource management, environmental organizations, and industry.

- **The Mandate to Avoid Harmful Federal Actions:** This mandate directs Federal Agencies to avoid harm to MPAs or their resources through activities that they undertake, fund, or approve.

- **The Marine Protected Areas Center:** The EO directs NOAA to create a Marine Protected Areas Center (MPA Center). In cooperation with the USDOI and working closely with other organizations, the MPA Center will coordinate the effort to implement the EO and will do the following:
  - develop the framework for a national system of MPAs;
  - coordinate the development of information, tools, and strategies;
  - provide guidance that will encourage efforts to enhance and expand the protection of existing MPAs and to establish or recommend new ones;
  - coordinate the MPA Web site;
  - partner with Federal and nonfederal organizations to conduct research, analysis, and exploration;
  - help maintain the National MPA List; and
  - support the MPA Advisory Committee.

C.2.6 Executive Order 13112: Invasive Species (February 1999)

The EO defines an "invasive species" as a species that is nonnative (or alien) to the ecosystem under consideration and whose introduction causes or is likely to cause, economic or environmental harm or harm to human health. This EO requires all Federal agencies to do as follows:

- Identify any actions affecting the status of invasive species;

- Prevent invasive species introduction;

- Detect and respond to and control populations of invasive species in a cost-effective and environmentally sound manner;

- Monitor invasive species populations accurately and reliably;

- Provide for restoration of native species and habitat conditions in invaded ecosystems;

- Conduct research on invasive species and develop technologies to prevent introduction and provide for environmentally sound control of invasive species;

- Promote public education on invasive species and the means to address them; and

- Refrain from authorizing, funding, or carrying out actions that are likely to cause or promote invasive species introduction or spread, unless the agency has determined that the benefits of such actions clearly outweigh the potential harm caused by invasive species and that all feasible and prudent measures to minimize risk of harm will be taken.

In addition, the EO established the National Invasive Species Council (Council), co-chaired by the Secretaries of Agriculture, Commerce and the Interior, and comprised of the Secretaries of State, Treasury, Defense, and Transportation, and the Administrator of the USEPA. The Council does the following:

- Provides national leadership on invasive species;
- Sees that Federal efforts are coordinated and effective;
- Promotes action at local, State, tribal and ecosystem levels;
- Identifies recommendations for international cooperation;
- Facilitates a coordinated network to document and monitor invasive species;
- Develops a web-based information network;
- Provides guidance on invasive species for Federal Agencies to use in implementing the NEPA; and
- Prepares an Invasive Species Management Plan to serve as the blueprint for Federal action to prevent introduction; provide control; and minimize economic, environmental, and human health impacts of invasive species.

BOEM requires that EISs prepared on major Federal OCS actions (e.g., 5-Year OCS Leasing Program and OCS lease sales) contain an assessment of the proposed action's contribution to the invasive species problem.

C.2.7 Executive Order 11988, Floodplain Management (May 24, 1977), amended by EO 12148 (July 20, 1979)

EO 11988 requires Federal agencies to avoid to the extent possible the long- and short-term adverse impacts associated with the occupancy and modification of floodplains and to avoid direct and indirect support of floodplain development wherever there is a practicable alternative. In accomplishing this objective, "each agency shall provide leadership and shall take action to reduce the risk of flood loss, to minimize the impact of floods on human safety, health, and welfare, and to restore and preserve the natural and beneficial values served by flood plains in carrying out its responsibilities" for the following actions:

- Acquiring, managing, and disposing of Federal lands and facilities;
- Providing federally undertaken, financed, or assisted construction and improvements;

- Conducting Federal activities and programs affecting land use, including but not limited to water and related land resources planning, regulation, and licensing activities.

The EO outlines an eight-step process (summarized below) that Federal agencies should carry out as part of their decision-making on projects that may have potential impacts to or within a floodplain.

1. Determine if a proposed action is in the base floodplain (that area which has a one percent or greater chance of flooding in any given year).

2. Conduct early public review, including public notice.

3. Identify and evaluate practicable alternatives to locating in the base floodplain, including alterative sites outside of the floodplain.

4. Identify impacts of the proposed action.

5. If impacts cannot be avoided, develop measures to minimize the impacts and restore and preserve the floodplain, as appropriate.

6. Reevaluate alternatives.

7. Present the findings and a public explanation.

8. Implement the action.

C.2.8 Executive Order 11990: Wetlands Protection (May 24, 1977), amended by EO 12608 (September 9, 1987)

The purpose of EO 11990 is to "minimize the destruction, loss or degradation of wetlands and to preserve and enhance the natural and beneficial values of wetlands." To meet these objectives, the order requires Federal agencies, in planning their actions, to consider alternatives to wetland sites and limit potential damage if an activity affecting a wetland cannot be avoided. The order applies to the following Federal actions:

- Acquisition, management, and disposition of Federal lands and facilities;

- Federally undertaken, financed, or assisted construction and improvements;

- Improvement projects which are undertaken, financed, or assisted by Federal agencies;

- Federal activities and programs affecting land use, including but not limited to water and related land resources planning, regulation, and licensing activities.

The EO outlines a similar eight-step process as that required in EO 11988 for floodplain management that Federal agencies should carry out as part of their decision-making on projects that may have potential impacts to or within wetlands.

C.2.9 Executive Order 13175 – Consultation and Coordination with Indian Tribal Governments

Pursuant to EO 13175, executive departments and agencies are charged with engaging in consultation and collaboration with Indian tribal governments, strengthening the government-to-government relationship between the United States and Indian tribes, and reducing the imposition of unfunded mandates upon Indian tribes.

The EO applies to the formulation or implementation of rules, policies, and guidance with tribal implications. Agencies shall adhere, to the extent permitted by law, to the following criteria when formulating and implementing policies that have tribal implications:

- Agencies shall respect Indian tribal self-government and sovereignty, honor tribal treaty and other rights, and strive to meet the responsibilities that arise from the unique legal relationship between the Federal Government and Indian tribal governments.

- With respect to Federal statutes and regulations administered by Indian tribal governments, the Federal Government shall grant Indian tribal governments the maximum administrative discretion possible.

- When undertaking to formulate and implement policies that have tribal implications, agencies shall:
  - Encourage Indian tribes to develop their own policies to achieve program objectives;
  - Where possible, defer to Indian tribes to establish standards; and
  - In determining whether to establish Federal standards, consult with tribal officials as to the need for Federal standards and any alternatives that would limit the scope of Federal standards or otherwise preserve the prerogatives and authority of Indian tribes.

C.2.10 Executive Order 13186: Responsibilities of Federal Agencies To Protect Migratory Birds (January 10, 2001)

EO 13186 directs executive departments and Federal agencies to take certain actions to further implement the MBTA. Any executive department or Federal agency taking actions that have, or are likely to have, a measurable negative effect on migratory bird populations is directed to develop and implement a MOU with the USFWS that shall promote the conservation of migratory bird populations.
